This paper investigated the relation between human thermal comfort and indoor environment in two historical buildings in Italy during summer season. Results showed quite different results of occupants' evaluations from what it would have been expected in modern buildings with similar indoor conditions. Most occupants don't feel thermally comfortable in the two case studies. However, their thermal comfort seems not influencing their pleasure of working in a historical building. In conclusion, even if strategies to ameliorate indoor environmental conditions are necessary, it seems fundamental to educate users to adequately manage their working environment, especially when a cooling system is present.

## ACKNOWLEDGEMENTS

Authors would like to thank the two institutions presented as case studies for sharing their data, actively participating to the research and being partner of the project.

## **Towards human-centred intelligent envelopes: A framework for capturing the holistic effect of smart façades on occupant comfort and satisfaction**

### **ABSTRACT**

Intelligent buildings have the potential to simultaneously revolutionise the way humans live and reduce energy demand in buildings. In particular, the so-called, smart / dynamic / adaptive building envelope can selectively modulate the energy transfer between the building and its environment in response to transient outdoor conditions and indoor requirements, thereby providing a low-carbon means of achieving occupant satisfaction and well-being. However, the effect of smart façades on holistic occupant comfort and satisfaction with the environment is yet to be fully captured and quantified. This information is essential for evidence-based design and control of smart building envelopes. In this paper, the smart façade characteristics that underpin satisfactory environmental conditions are identified and metrics for their transient and holistic assessment are discussed. A methodology to capture the effect of smart façades on the holistic occupant comfort and satisfaction is then proposed together with its implementation into an early stage design tool. Finally, a ranking system is suggested to assess and compare alternative smart façade technologies according to their overall effect on user satisfaction and productivity for a UK climate.

occupant comfort, user satisfaction, intelligent, dynamic façades, human factors

### **INTRODUCTION**

Although human-centred design in architecture is not a new concept, occupants are often dissatisfied with their environment (Frontczak and Wargocki 2011), regardless of the large amount of energy consumed to condition them (IEA, 2017). Novel façade technologies are often able to minimise energy consumption but they are also often the strongest drivers of occupant discomfort or dissatisfaction (Huizenga et al., 2006). Façades are the multi-sensorial skin of buildings, a boundary between indoors and outdoors, which is responsible for filtering light, heat, air and water vapour to maximise the health, well-being and productivity of occupants. Hence, façades have the potential to holistically affect occupants on different sensorial and psychological levels, such as aesthetic or personal control satisfaction, and, thus, actual occupant satisfaction requires a unified balance between all environmental comfort features. For instance, a strong dissatisfaction or “dissonance” (Clements-Croome, 2013) in any of these single comfort features would imply overall discomfort, even if greater satisfaction levels are achieved in the remaining features (Humphreys, 2005). Among all the multi-objective requirements of façades (Favoino et al., 2014), façades primary objective should be to sustain healthy and satisfactory environmental condition for occupants. A human-centred façades should be able to provide and regulate daylight and heat transfer, protecting occupants from overheating and preventing large heat losses, maintaining healthy levels of air quality. Potentially, human-centred façades should be “dynamic”, able to change their performance and characteristics according to the changing indoor and outdoor demands. Beyond this, a human-centred façade should have an “artificial intelligence” (Clements-

Croome, 2013) to allow them to be adaptive, able to capture real-time actual occupant demands and learn from past experiences to adapt and sustain optimal environmental conditions. The combination of current façade technologies with accurate control strategies and artificial intelligence provides unprecedented opportunities to create optimal human-centred façades. However, there is a need for new simulative, experimental and theoretical methodologies to capture actual occupant demand and response, and trigger responsive behaviours of intelligent façades that maximise occupant satisfaction. A fundamental distinction is made in this paper between two forms of environmental comfort: satisfaction and preference. In this research, environmental satisfaction is considered as the condition of mind where occupants express satisfaction with overall environment (Figure 1), including satisfaction with view and personal control or interaction strategies. Satisfaction is considered as the condition whereby the occupant might not be in a neutral condition, but expresses the willingness of remaining in the same condition. Environmental preference is instead defined as the desired environmental condition thriven by the occupant. This paper adopts the unified framework of personal comfort model, as defined by Kim et al. (2018), where the individual comfort response is predicted or assessed instead of the average response of a large population, and applies it to the assessment and control of dynamic façade technologies.

This paper attempts to provide initial methodological results of ongoing research at the University of Cambridge on novel methods for capturing the transient and holistic effect of intelligent façades on occupant satisfaction. A framework to capture the transient and holistic effect on personal occupant satisfaction is proposed and its future implementation in early design stage tools or ranking is discussed.

## THEORETICAL BACKGROUND AND PROPOSED FRAMEWORK

The proposed framework endeavours to capture the overall holistic occupant response to and preferences for façade environmental effects. The façade effect on occupant holistic environmental satisfaction has been framed conceptually as shown in the diagram in **Error! Reference source not found.** Holistic satisfaction or preference considers the overall satisfaction with the visual, thermal, aesthetic, view, air quality, acoustic and interactive environment and their mutual interrelationships or conflicts (shown in Figure 1 as linking lines between each single comfort feature). In the diagram, the façade is considered as an interface that modulates the energy and mass flows (so called “primary inputs”) from outdoors and transfers them to indoors. Hence, alternative façades technologies have the potential to filter and modulate these flows in a different manner and according to their physical components or characteristics (such as type of glass, glass thickness, type of cavity, shading devices, coating characteristics, etc.), labelled in the framework as “Façade physical characteristics”. Consequently, the effect of a façade on occupants depends on the joint value in time of all façade properties, such as surface temperature or light transmitted, that directly affect the environment as result of the energy and mass flow across the façade. For the purposes of this framework, these façade properties will be named as “Façade comfort variables” and are considered to be the main drivers of the façade effect on occupant comfort. The façade comfort variables are directly related to “Façade physical characteristics”. However, alternative façade characteristics can result in the same comfort façade variables. For instance, different types for shading devices can produce the same value of light transmittance and different U-values could result in similar values of mean surface temperature. A literature review was conducted to identify the main façade comfort variables that affect occupant environmental satisfaction and the results are summarised in Table 1. The local environmental conditions in the vicinity of the occupant is affected by the transient value of the façade comfort properties and the non-façade input effect of environmental services or

other contextual conditions, such as space layout or furniture, that are identified in this framework as “Not-façade inputs”. The local environmental characteristics that affect occupant environmental satisfaction are labelled “Local comfort variables”. The final output of this process is the holistic response of the occupant to the local environmental conditions, and the façade comfort properties (which includes also the interaction strategies). This final output depends on the “human filter”, which is the ensemble

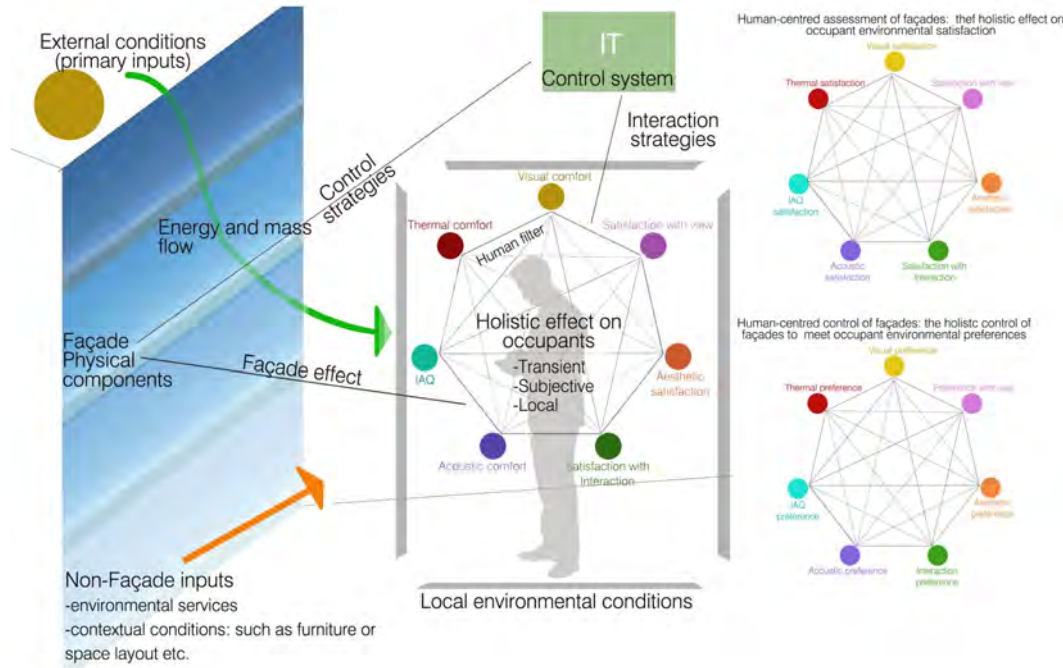

Figure 1 Diagram of the façade effect on occupants

of all individual and collective psychological features that affect human perception of the environment. Figure 2 illustrates the overall conceptual model described above. The variables and parameters of this framework are then grouped as follows: External conditions, Façade physical component, Façade comfort variables, Local comfort variables, Contextual variables, Human filter variables and Occupant response. The framework identifies all groups of variables involved in the problem of capturing the façade effect on occupant satisfaction. The research project endeavours to find a correlation between the façade comfort variables and occupant response through direct or indirect collection of occupant feedback. The correlations that will be investigated in the course of this research project are highlighted in green. As above mentioned, all these variables are time and location dependent. In order to identify a correlation between façade comfort variables and physical properties with occupant response (in terms of preferences or satisfaction) it is essential to monitor them locally and transiently, with particular attention to their rate, velocity and frequency of change and, simultaneously, gather high frequency feedback from occupants.

## DISCUSSION, EXPECTED RESULTS AND FUTURE WORK

The proposed framework offers a methodology to gather valuable information on occupant levels of dissatisfaction or satisfaction with alternative façades technologies or controls. This could be useful for two purposes (Figure 3): 1) Assessing the façade quality and performance in terms of personal occupant environmental satisfaction and its effect; 2) Informing intelligent façades control strategies on actual personal occupant preferences and on the correlation between façade physical properties and comfort variable with occupant. The post-process of the data through machine learning techniques could also help to predict occupant

preferences and create personalized comfort models to be used for controlling jointly intelligent façades and BMS.

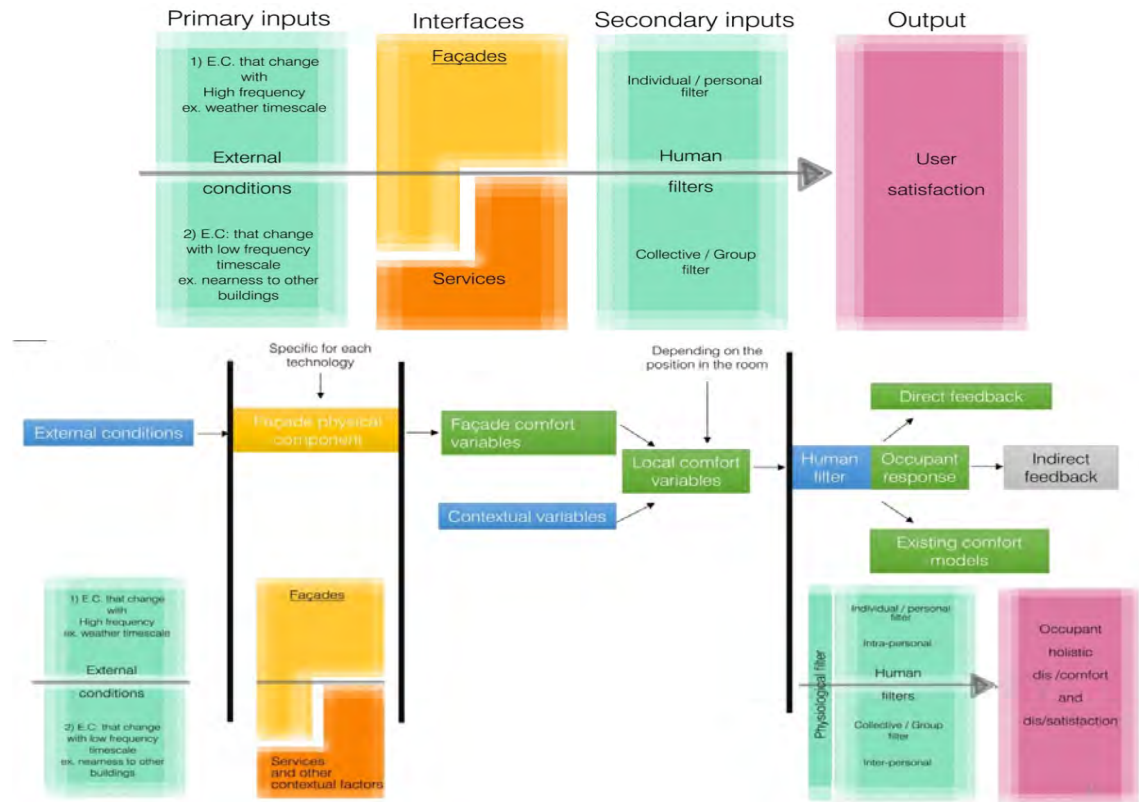

Figure 2 Concept map of the research problem: how to capture the façade effect on occupants

Table 1 Results from a literature review on the main façade comfort properties

Façade comfort variable	Unit of measure	Key reference
Surface temperature	°C	(Huizenga, 2006)
Draft: air velocity, air temperature, humidity	m/s, °C, gr/m <sup>3</sup>	(Huizenga, 2006)
Solar radiation transmitted (Irradiance and direction)	W / m <sup>2</sup> ; degree	(Huizenga, 2006)
Luminance	Cd/m <sup>2</sup>	(Wienold & Christoffersen, 2006)
Light transmitted (intensity, direction, colour)	Lux; degree, ζ	(Nabil & Mardaljevic, 2006);
View extension		(Carmody et al., 2004)
View clarity		(Ko & Schiavon, 2017) (Konstantzos et al., 2015)
Sound absorbed and transmitted	dB	(Carmody et al., 2004)
User friendliness OR Ease of use	-	To be defined by follow-up research

The comfort and satisfaction assessment of façades, particularly intelligent façades, is challenging since there is a lack of holistic and transient metrics to identify occupant response. This is even more challenging considering the strong influence of occupant location on the

perceptible effect of façades and the differences in the type of sensorial perception affected with distances from the façade. The data gathered from this framework could be used to identify the main triggers of occupant satisfaction with façades and, potentially, the thresholds of occupant dissatisfaction and discomfort. More importantly, the data from façade comfort properties and occupant response would allow to assess the human-centred performance of alternative intelligent façade technologies. This would also provide the platform to compare façades and understand which façade and control strategy is more appropriate in different contexts, space layouts and building typology.

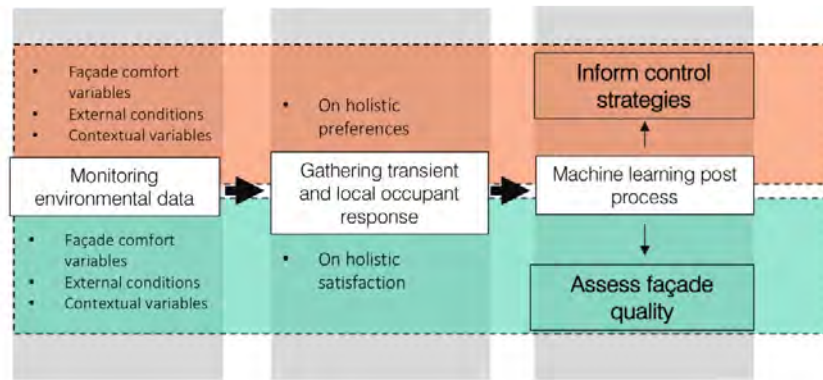

Figure 2 Diagram of the potential applications of the framework

### Implementation of the new metrics in early design stage tools

A potential façade comfort scale is then proposed in Figure 3 to assess and measure the level of environmental personal comfort or, conversely, discomfort that a façade and its control strategy is associated with. Since façades need to be assessed transiently and locally, the scale in Figure 3 provides a holistic, local and transient assessment of occupant response for each category of holistic occupant satisfaction. Firstly, each category is assessed holistically considering the potential conflicts and inter-effects with other satisfaction categories, since occupants response is gathered experimentally and exposing them to the overall holistic effect of façades. Secondly, the scale indicates a value of occupant satisfaction regarding three different occupant positions with respect to the façades (1, 3 and 5 metres from the facade) in order to show the different effect of façades with distance on non-uniformity tendency. Lastly, façades are assessed according to 5 classes of occupant response and satisfaction. Each category is an indication of the percentage of time in a year when an occupant is satisfied with the dynamic performances of façades or, in other words, the proportion of time in which a façade has successfully interpreted occupant preferences and personal satisfaction criteria and has adapted with an appropriate frequency and velocity. This comfort assessment tool could average occupant response in time or weight a group of occupant responses according to specific design criteria or motivations (such as importance of task to be performed or health sensitivity). This draft comfort scale tool is highly dependent of the type of building, space layout and all the variables that affect environmental occupant responses, such as cultural and geographic context. Eventually, the scale has the potential to be implemented in an early-design stage tool to rank alternative façade technologies and inform early-design decision on façade physical components and control strategies.

### CONCLUSIONS

This paper was conceived to frame the transient changes in façade properties, including frequency, level and velocity of change, to occupant holistic levels of comfort and satisfaction. The short-term experimental work will aim to validate the framework and

provide quantitative data to inform the draft comfort scale and gain a better understanding of how to implement the transient and holistic effect of façades in early-design stage tools.

### ABSTRACT

With the growing application of renewable energy, the stability of power systems can be seriously affected due to the fluctuations in the instantaneous generated power. As one of the potential solutions for this upcoming challenge, energy flexibility of buildings has received attention for research and technology development. Demand response and energy flexibility should be implemented at a large scale to have the accumulated energy flexibility to a magnitude, which can be meaningful for energy sectors. Studies have shown that the energy flexibility of a building is greatly influenced by both building physical characteristics and occupancy pattern of residents. To the best knowledge of authors, occupancy has not been considered in the study of building cluster. The aim of this paper is to present the modelling process of occupancy/vacancy of Danish households based on Danish Time Use Survey (DTUS) 2008/09 data. In this paper, we present a data-driven approach to generate occupancy/vacancy models for different types of household and for building cluster of different scales. As the result, vacancy profile and vacancy duration models are developed. The stochasticity of occupancy is also unveiled. The next step is to apply these models to quantify energy flexibility of building cluster and the uncertainty of energy flexibility due to the stochastic occupancy.

### KEYWORDS

Occupancy; Stochastic; Building cluster; Energy demand flexibility

### INTRODUCTION

The penetration of renewable energy resources is increasing rapidly. In EU countries, at least 20% of total energy demand must come from renewables by 2020 (EU, 2009). Denmark plans to be fossil-fuel free by 2050 (The Danish Government, 2013). High penetration of intermittent renewables will affect the stability of energy grid and energy flexibility in the grid will be more crucial. Buildings account for one third of total energy consumption in Denmark and most other developed countries, which amounts to considerable potential for activating flexible energy demand in buildings. In future smart cities, demand response and energy (demand) flexibility of buildings are likely to play a significant role.

Demand response and energy flexibility should be implemented at a large scale to have the accumulated energy flexibility to a magnitude, which can be meaningful for energy sectors. To the best knowledge of the authors, there are only a few publications about demand response or energy flexibility at building cluster level. Vigna et al. (2018) presented an overview of the concept of building cluster and its relevant concepts. A definition to Building Cluster was defined from the perspective of building and energy grid interaction. In this definition, the building cluster is an aggregation of buildings which can be managed by a common agent such as a utility company to exploit the energy flexibility of the building cluster.

Studies have shown that the energy flexibility of a building is greatly influenced by both building physical characteristics and occupancy pattern of residents (Masy et al., 2015), (Li et al., 2017). A review of large scale demand response estimation (Goy and Finn 2015) conducted in 2015 concluded that studies by then commonly oversimplified building models without considering different building types nor various building characteristics such as thermal characteristics and occupants behavior. There are only a few studies done after 2015 (Li et al., 2016), (Ma et al., 2016), (Georges et al., 2017), but none of the studies included the influence from occupancy and occupant behavior. The lack of data support and multidisciplinary knowledge together with the requirement on computational efficiency are among the main reasons for achieving better investigations.

In this study, we aim to model the stochastic occupancy to quantify its influence on energy flexibility of building cluster with different scales of occupants and quantify the uncertainty of flexibility. The value of the uncertainty quantification is in the planning of energy services.

## **METHODS**

Occupancy models are developed based on data from Danish Time Use Survey (DTUS) 2008/09 (Bonke and Fallesen, 2010). The data consists of 9640 individuals and 4679 households. Individuals' daily activities were logged in two diaries, one for a weekday and another for a weekend day with 10 min time interval starting at 4:00 and ending at 3:50 the next day (Bonke and Fallesen, 2010), (Barthelmes et al., 2018). In this study, only weekday is considered, as on weekend vacancy time is much shorter for residential buildings and the pressure on the energy grids could be less in comparison with weekdays.

Based on the Statistics Denmark (2017), 84% of the households living in apartment buildings consist of no more than three members. The data of household with one to three persons from the DTUS are used in this study. The data consists of 1641 one-person households, 1980 two-person households and 448 three-person households, which is generated from the same data source presented in (Barthelmes et al., 2018).

Occupancy modelling includes three steps: 1) data resampling, 2) occupancy/vacancy profiling and 3) occupancy/vacancy duration estimation.

### **1) Occupancy data resampling**

We resampled the data by randomly divide N households into X samples with each sample contains Y (**n, 2n, 3n ...**) households using Bootstrapping method. Limited by the total number of each type of household, we predefined  $n=100$  for one-person household,  $n=50$  for two-person household and  $n=33$  for three-person household. For example, in the case of 1641 one-person households, the data processing steps are as follows.

- a) Sample size: 100 households.
- b) Randomly divide 1641 households into 16 groups with each group contains 100 households.
- c) Repeat the above process for several times (In this study, 10 times).
- d) Obtain 160 samples.
- e) Change sample size to 200, 300, 400 ...

### **2) Vacancy profiling based on Normal Distribution Probability**

Each data sample is a 3D matrix as shown in Equation (1) with 1 indicates occupancy and 0 indicates vacancy.

$$OccupancyData(household\ serial\ number, timeline, sample\ serial\ number) = \begin{pmatrix} timeline \\ house_1 \begin{bmatrix} s_1^1 & \dots & s_1^{144} \\ \vdots & \ddots & \vdots \\ house_n \begin{bmatrix} s_n^1 & \dots & s_n^{144} \end{bmatrix} \end{pmatrix} (s_i^t = 1 \text{ or } 0), sample\ serial\ number \end{pmatrix} \quad (1)$$

Taking the case of the 160 samples of 100 one-person households as an example to explain the processing in detail. The size of the 3D matrix is  $100 \times 144 \times 160$  (households: 100, the length of timeline: 144, samples: 160). As the time interval is 10 min, there are thus 144 states for one day. For every state, vacancy percentage of 100 households are calculated. As for every state, there are 160 different samples; there are thus 160 vacancy percentages. A Normality Test (95% confidence) is carried out on these 160 vacancy percentages. The result can be expressed in equation (2).

$$VacancyPercentage_t \sim N(\mu, \sigma^2) \quad (2)$$

Where  $\mu$ : mean, also the mathematical expectation;  $\mu + 1.96\sigma$ : upper limit of 95% confidence interval,  $\mu - 1.96\sigma$ : lower limit of 95% confidence interval.

The result of probability distribution of vacancy is a  $3 \times 144$  matrix as shown in Equation (3).

$$Probability\ distribution\ of\ vacancy = \begin{matrix} \mu \\ \mu + 1.96\sigma \\ \mu - 1.96\sigma \end{matrix} \begin{matrix} timeline \\ \begin{bmatrix} \mu_1 & \dots & \mu_{144} \\ \vdots & \ddots & \vdots \\ (\mu - 1.96\sigma)_1 & \dots & (\mu - 1.96\sigma)_{144} \end{bmatrix} \end{matrix} \quad (3)$$

The above data processing is applied to all three household types. This results with probability distribution of vacancy matrices for every sample size and every type of household.

To assign the above probability distribution of vacancy to Danish households, we used the data from Statistics Denmark (2017). Among the households living in apartment buildings, 38% are one-person household, 33.7% are two-person household and 11.9% are three-person household. Only 16% of Danish households living in apartment buildings consist of more than three residents. Therefore, households of four people and above are not included in this study. Taking these three household sizes as a whole, one-person household accounts for 45.5%, two-person household accounts for 40.3% and three-person household accounts for 14.2%. Vacancy matrices for every sample size and every type of household are aggregated according to these three percentages as shown in Equation (4).

$$Probability\ distribution\ of\ vacancy_{aggregated} = \begin{bmatrix} 45.5\% & 40.3\% & 14.2\% \end{bmatrix} \begin{bmatrix} Probability\ distribution\ of\ vacancy_{1\ person} \\ Probability\ distribution\ of\ vacancy_{2\ persons} \\ Probability\ distribution\ of\ vacancy_{3\ persons} \end{bmatrix} \quad (4)$$

### 3) Vacancy duration based on Kaplan-Meier estimator

Survival analysis (Kaplan-Meier estimator) is applied to estimate vacancy duration, which is the time duration occupants are away from home. The Kaplan-Meier estimator, also known as the product limit estimator, is a non-parametric statistic to compute probabilities of occurrence of an event from a certain moment (Goel et al. 2010). The estimator is given by:

$$S(t) = \prod_{i:t_i} \left( \frac{n_i - d_i}{n_i} \right) \quad (5)$$

Where  $n_i$  is the number of activates on-going at time  $t_i$  and  $d_i$  is the number of actions ended. The followings are the steps of survival analysis.

- a) The initial matrix (InitialOccupancyData) shown in Equation (6) is used for survival analysis.

$$\begin{aligned}
 & \text{InitialOccupancyData}(\text{household serial number}, \text{timeline}) \\
 &= \begin{matrix} \text{house}_1 \\ \vdots \\ \text{house}_n \end{matrix} \begin{matrix} \text{timeline} \\ \begin{bmatrix} s_1^1 & \cdots & s_1^{144} \\ \vdots & \ddots & \vdots \\ s_n^1 & \cdots & s_n^{144} \end{bmatrix} \end{matrix} (s_i^t = 1 \text{ or } 0)
 \end{aligned} \quad (6)$$

- b) There are 144 observation states in the timeline. For each state, all the vacant households is identified and then the vacancy duration of these households is calculate from this moment to the future. Then the matrix of SurvivalTimeLength is generated as shown in Equation (7).

$$\text{SurvivalTimeLength} = \begin{matrix} \text{house}_1 \\ \vdots \\ \text{house}_n \end{matrix} \begin{matrix} \text{timeline} \\ \begin{bmatrix} d_1^1 & \cdots & d_1^{144} \\ \vdots & \ddots & \vdots \\ d_n^1 & \cdots & d_n^{144} \end{bmatrix} \end{matrix} \quad (7)$$

Where  $d_i^t$  is the vacancy duration at time  $t$  of  $\text{house}_i$ ,  $d = 0$  means occupancy.

- c) For every state (1~144), Kaplan-Meier Estimator is used to estimate the probability of vacancy duration as shown in Equation (8).

$$(\text{timelen}_t, P_t) = \text{Kaplan} - \text{Meier} \left( \begin{matrix} \text{house}_1 \\ \vdots \\ \text{house}_n \end{matrix} \begin{bmatrix} d_1^t \\ \vdots \\ d_n^t \end{bmatrix} \right) \quad (8)$$

## RESULTS

With the aggregation of the probability distribution of vacancy of different types of household, vacancy matrix becomes a 3D matrix where the first two dimensions are shown in Equation (3) and the third dimension is the sample size. This vacancy matrix is generated for cluster of households consisting of one person, two persons and three persons. Fig. 1 shows three different sample sizes of the matrix. With number of residents and number of households specified, sample size of occupancy model is determined and thus the occupancy model can be chosen. In the timeline of one day, there are 144 states with 10-minute interval between each state. For each state, the mathematical expectation,  $\mu + 1.96\sigma$  and  $\mu - 1.96\sigma$  of vacancy percentage are determined as it is shown in Fig. 1. For example, for a building cluster with 1000 residents and 643 households, the right diagram in Fig. 1 is the vacancy profile can be used.

Fig. 1 Vacancy profile of clusters with different number of people and households

As it is shown in Fig.1, expected value of vacancy percentage does not change with the number of residents. However,  $\sigma$  becomes smaller with more residents aggregated. In other words, uncertainty of vacant percentage decreases with the size of residents increases.

Fig. 2 Survival analysis of vacancy for all 144 states.

The probability of vacancy duration is shown in Fig. 2. It is the aggregation of results from all 144 states. This figure shows the probability a house is vacant from any states onwards. For example, if a house is unoccupied at 8:00 (see x-axis), the probability it is still unoccupied after two hours (see y-axis) is around 80% (color bar) and after six hours is around 60%.

## DISCUSSIONS

In this study, using a data-driving approach, statistical occupancy models were developed for the investigation of the uncertainty of energy flexibility due to the stochastic nature of occupancy using TUS data. Some existing studies showed that TUS data was a valuable resource by validating their TUS-based approaches against field measurements. Fischer et al. (2015) modelled household electricity load profiles based on German TUS. The models were validated against measurement data from 430 households with good accuracy. Widén et al. (2009) modelled household electricity load profile based on Swedish TUS data. The profile was validated with electricity measurements in a few households. It revealed that the models captured important features of the measured data. Although there is no measured data from Danish households available for the authors now, model validation is planned for further work. Nevertheless, the models developed in our study can be a tool for the simulation of energy flexibility of buildings for district energy planning under the background of mass application of renewable energy in the future. In addition, this method can be used in other geographical areas if TUS data of these areas are available. The vacancy percentage, vacancy duration, household size, etc. might be different due to different geographical and demographical conditions. This method can also be used to capture seasonal differences in vacancy using TUS data collected during specific seasons, such as heating/winter season.

## CONCLUSIONS

In this paper, we presented a data-driven approach to generate occupancy/vacancy models for different types of household and for different scales of building cluster using Danish Time User Survey 2008/09 data. Using this approach, vacancy profile and vacancy duration of any building cluster can be generated. The stochasticity of occupancy is also unveiled. The next step is to apply these models in the quantification of energy flexibility of building cluster and the uncertainty of the quantification due to the stochastic occupancy. The value of the uncertainty

quantification is in the planning of energy services. A typical case is that a grid operator will have information on the reliability of deploying a certain amount of households and buildings for using demand flexibility to balance the grid.

## ACKNOWLEDGEMENT

This study was made possible with the financial support of two Danish pilot projects: EnergyLab Nordhavn: New Urban Energy Infrastructures and CITIES: Centre for IT-Intelligent Energy Systems in cities. This work partially receives the support from Tsinghua University Initiative Scientific Research Program. The authors would also like to acknowledge IEA EBC Annex67 – Energy Flexible Buildings for providing excellent research networking.

## **HOUSE: Building energy efficiency understanding through an enabled boundary object**

Deborah Adkins<sup>1,\*</sup> and Peter R.N. Childs<sup>1</sup>

### **ABSTRACT**

We report the results of an empirical study on an enabled application's ability to act as a boundary object and build understanding of energy efficiency solutions. Combining digital and tangible technology with radio-frequency identification (RFID) tags, we have created an interactive, digitally enabled device and application called HOUSE (Home User and Stakeholder Environment). The HOUSE tool and application have been designed and developed to support interaction and collaboration in the exploration of domestic energy efficiency solutions.

HOUSE allows users to associate information with physical representations, and to explore this information through manipulation of enabled objects. The interactive application consists of a 24:1 scale representation of an archetypal UK home and thirteen model energy efficiency interventions integrated with a digital application. Each energy efficiency intervention is enabled with RFID tagging and detection, to allow participants to physically interact with the HOUSE application. The app detects when a model energy efficiency intervention is placed in the model HOUSE. Participants then receive real-time feedback on their energy efficiency selection and the implication of their retrofit decisions.

We explore the role of HOUSE acting as a boundary object, in facilitating the transfer of knowledge across domains. The application was evaluated in academic non-expert and industry (expert) stakeholder workshops. Results showed there is a self-reported increase in collaboration and consensus amongst non-experts (Group A) using the HOUSE interactive application. There is also a self-reported difference in the decision-making process surrounding retrofit selection for experts (Group D) using the HOUSE interactive application. Moreover, there is evidence from experts to conclude that the HOUSE can assist in transmitting findings in meaningful ways to non-experts in the field.

**KEYWORDS** Boundary Object, Energy Efficiency, Exploratory Study, Tangible User Interface.

### **INTRODUCTION**

The decision-making process surrounding domestic energy use and retrofit is complex, dynamic, multidimensional and involves multiple stakeholders and information asymmetry. However how to enable the transfer of knowledge between stakeholders has received little attention. As a society, we are facing complex challenges such as climate change, energy transition and adaption that require large numbers of multidisciplinary stakeholders to interact and quickly navigate elaborate data sets. Stakeholders need to rapidly access a wide range of scenarios, build understanding and decide on an appropriate set of actions.

New technologies have made it possible to create new ways for stakeholders to interact. Innovations allow us to enable objects with digital information and allow us to interact with this information through tactile interaction with radio-frequency identification (RFID) enabled

(tangible) media. Enabled media can be combined with technologies to provide instantaneous feedback on a wide range of different scenarios.

Despite wide-ranging policies for encouraging and supporting energy efficiency, there remains a persistent gap between the technological and economic potential and actual market behaviour (Jaffe & Stavins 1994). Two of the most crucial retrofit decision-making barriers identified are firstly the 'cognitive burden' regarding the difficulty of taking complex and permanent decisions (Phillips 2012) and secondly the 'hassle factor', i.e. the anticipation of the inconvenience provided by the retrofit operations (Roy et al. 2007). It is widely accepted that interventions to reduce the energy efficiency gap need to address these and other behavioural factors (Whitmarsh 2009). This article introduces a combined physical and digital application to assist stakeholders' decision-making process in selecting retrofit technologies. To do this, we have developed the HOUSE (HOMe User and Stakeholder Environment) tool which provides a tangible representation of an average UK home and allows stakeholders to interact with energy efficiency interventions.

### TANGIBLE BOUNDARY OBJECTS

The exchanges of knowledge between organisations and stakeholders throughout the retrofit process take place along multidisciplinary boundaries between specialist and non-specialist, as shown in Figure 1a. A boundary object can link retrofit stakeholders together via 'collaboration on a common task' (Star & Griesemer 1989).

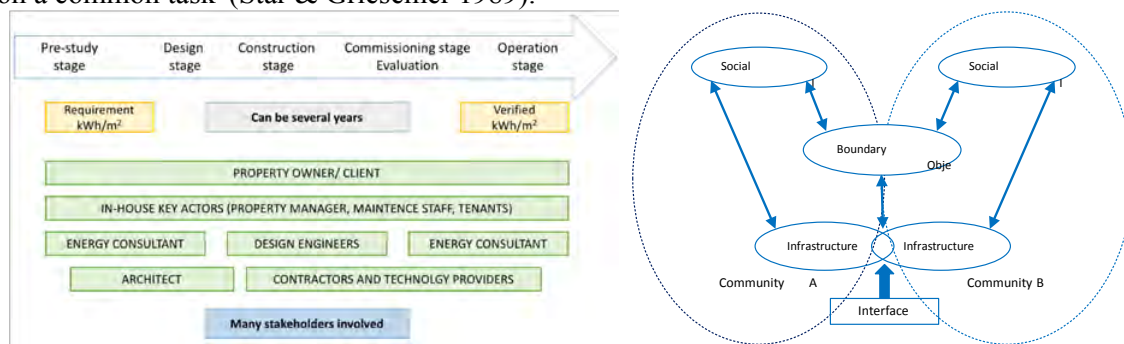

Figure 1a. (Left) Some of the stakeholders throughout the retrofit process adapted from Moseley (2016) Figure 1b. (Right) Representation of a boundary object.

Boundary objects (Figure 1b) are mediating artefacts that have interpretive flexibility and can be a means of achieving collaboration and promoting the sharing of knowledge among diverse groups (Sapsed & Salter 2004). The practice of reducing and managing domestic energy consumption, as well as upgrading or retrofitting a house, incorporates numerous objects (interventions) including requirements (specifications) and user behaviour methodologies. By combining elements with an architectural model, we seek to bridge and overcome knowledge boundaries between those with technical knowledge (e.g. an engineer) and others with domainspecific knowledge (e.g. home users with knowledge of their individual needs and requirements) (Tiwana & Mclean 2005).

Ishii & Ullmer (1997) define a tangible user interface (TUI), as a device that "augments the real physical world by coupling digital information to everyday physical objects and environments." Fishkin's (2004) taxonomy for tangible interfaces defined them as a device which allows "the user to use their hands to manipulate some physical object(s) via physical gestures, and a computer detects this and alters its state and gives feedback accordingly." Some researchers have demonstrated the advantages of TUIs, regarding a more natural, intuitive, user-friendly experience with the potential to promote stronger and long-lasting engagement with

stakeholders. In this paper, we define an enabled Boundary Object (BO) as a TUI realised as a boundary object.

### HOUSE: A NEW MEDIUM TO EXPLORE ENERGY EFFICIENCY

One of the most common UK residential typologies is the semi-detached house built in the 1930's. There are currently 1,731,000 semi-detached dwellings in England built between 1919 and 1944, equating to approximately 1 in 6 UK homes. Because of its prevalence, the 1930's semi-detached house can be defined as “the average UK dwelling” (Beizaee et al. 2015). We used a plan of a 1930's house situated in London as a reference for the development of the scale model. The floor plan of the house and the elements relevant to energy efficiency interventions such as suspended floor and cavity walls were integrated into the scale model. The final model of the case study dwelling is shown in Figure 3. Table 1 provides a list of the interventions considered in the study. The interventions were exemplified as physical objects that could be manipulated by users and added and removed from the model to represent the process of retrofitting.

Table 1. Energy efficiency interventions

1	Internal wall insulation	7	Draught stripping
2	Cavity wall insulation	8	Low energy lights
3	External wall insulation	9	Replacement gas boiler
4	Floor Insulation	10	Upgrading heating controls
5	Loft insulation	11	1 kW Solar Photovoltaic Panels
6	Replacement windows and doors	12	3 kW Solar Photovoltaic Panels
		13	Solar hot water heating

A digital application, developed in Objective-C in Xcode 8.2 and displayed on an iPad, was designed to provide a visualisation of the model HOUSE status. When an intervention was applied to the model (input), the digital application senses this input event and alters its state. The digital application provides feedback (output event) to show the impact of the addition or removal of an intervention. The digital application displays a series of properties such as total installation cost, annual savings on bills and annual CO<sub>2</sub> savings based on the interventions currently added to the property. The costs and savings were calculated based on straightforward calculations and were therefore provided instantaneously on the iPad. The final HOUSE tool, as shown in Figure 3 was an interactive tool of enabled interventions allowing customers to ‘play’ with a representation of their home.

Figure 3 The Model of the case study dwelling

## METHOD

This exploratory study aimed to understand the contribution of the HOUSE application. To design the HOUSE tool a mix of literature review and stakeholder input through interviews and discussions were used to develop the initial HOUSE prototype. In the descriptive study, firstly, a non-expert (academic) workshop was held to provide an evaluation of the tool and the workshop design. Secondly, an expert (industrial) workshop was held to provide an assessment of the prototype and to gather suggestions for improvements. An identical design exercise took place in each workshop; participants were split into three groups and using three different tool sets (c.f. Table 2) were asked to address the same design brief. The design exercise was designed to compare the effect of the various tool sets on the behaviour (e.g. interactions, collaboration, discussions, manipulations, solutions and intervention selections) of participants.

Table 2. Schematic setup of the tool sets provided to each workshop group

Group	HOUSE model	Digital Application	Pens and Paper
A non-expert	Yes	Yes	Yes
B non-expert	No	Yes	Yes
C non-expert	No	No	Yes
D expert	Yes	Yes	Yes
E expert	No	Yes	Yes
F expert	No	No	Yes

## RESULTS

The initial academic (non-expert) workshop was conducted with 12 non-specialists, during a one-hour session, to evaluate the functionality of the device and its impact on the group. The non-specialists were split into three groups A, B & C with four participants in each group. The groups were asked on a Likert scale if they felt the tool set provided (Table 2) increased collaboration and improved consensus. To compare participants' subjective experience while using the three different tool sets, we conducted several two-way analyses of variance (ANOVA) with the format of presenting tool sets as independent variables. The ANOVA (Table 3) was significant for collaboration (question 1):  $F(2, 9) = 13.286$ ,  $p < .05$  ( $p = .002$ ) and consensus (question 2):  $F(2, 9) = 6.643$ ,  $p < .05$  ( $p = .017$ ). Thus, there is evidence to reject the null hypothesis and conclude there is a self-reported increase in the collaboration and consensus for Group A conducting the same task using the HOUSE interactive application tool set. Table 3. Academic workshop one-way between groups ANOVA for each domain and group

ANOVA		Sum of squares	df	Mean Square	F	Sig.
1) Do you feel HOUSE provided increased collaboration amongst your group?	Between Groups	5.167	2	2.583	13.286 <sup>a</sup>	.002 <sup>b</sup>
	Within Groups	1.750	9	.194		
	Total	6.917	11			
2) Do you feel HOUSE provided improved consensus?	Between Groups	5.167	2	2.583	6.643 <sup>a</sup>	.017 <sup>b</sup>
	Within Groups	3.500	9	.389		
	Total	8.667	11			

<sup>a</sup>Critical Value 4.26, <sup>b</sup>Statistical significance testing ( $p > .05$ ).

The industry (expert) workshop was conducted with 18 specialists, during a longer three-hour session, to further evaluate the functionality of the device and its impact on decision making. The specialists were split into three groups D, E & F with six participants in each group. During this workshop participants were given a longer questionnaire and were asked additional questions on a Likert scale to investigate if they felt the tool set provided improved the decisionmaking process and if they thought the tool set provided could assist in transmitting findings.

The ANOVA (Table 4) was significant for decision-making (question 3):  $F(2, 15) = 4.239$   $p = .035$  and transmitting findings to non-experts in the field (question 4):  $F(2, 15) = 5.648$   $p = .015$ . Thus, there is evidence to reject the null hypothesis for question 3 and conclude there is a self-reported difference in the decision-making process surrounding retrofit selection for Group A using the HOUSE. There is also evidence to reject the null hypothesis for question 4 and conclude there is self-reported evidence that the HOUSE can assist in transmitting findings in meaningful ways to those (non-experts in the field). However, the actual difference in mean score between groups was quite small based on Cohen's (1992) conventions for interpreting effect size.

Table 4. Industry workshop one-way between groups ANOVA for each domain and group

ANOVA		Sum of squares	df	Mean Square	F	Sig.
1) Do you feel HOUSE provided increased collaboration amongst your group?	Between Groups	.778	2	.389	.530	.599
	Within Groups	11.00	15	.733		
	Total	11.778	17			
2) Do you feel HOUSE provided improved consensus?	Between Groups	2.778	2	1.389	3.378	.061
	Within Groups	6.167	15	.411		
	Total	8.944	17			
3) I feel HOUSE improved the decisionmaking process surrounding retrofit selection.	Between Groups	4.333	2	2.167	4.239 <sup>a</sup>	.035 <sup>b</sup>
	Within Groups	7.667	15	.511		
	Total	12.000	17			
4) I feel HOUSE could assist in transmitting findings in meaningful ways to non-experts in the field.	Between Groups	6.778	2	3.389	5.648 <sup>a</sup>	.015 <sup>b</sup>
	Within Groups	9.000	15	.600		
	Total	15.778	17			

<sup>a</sup>Critical Value 3.68, <sup>b</sup> Statistical significance testing ( $p > 0.05$ ).

## DISCUSSION

As boundaries pose difficulties in knowledge flows, we aimed to reduce the influence of boundaries on multi-stakeholder and multi-domain collaboration by finding a way to communicate across them. There is a need for a comprehensive but easy to use tool to allow interaction amongst stakeholders during retrofit selection. Current retrofit selection tools are complex methodologies and software tools, requiring extensive training and guidance. These tools do not utilise tangible representations or allow for stakeholder interaction.

The evidence from the non-expert workshop suggests that participants felt that the HOUSE tool provided increased collaboration amongst the group of participants and improved consensus. The evidence from the industry workshop suggests that the participants perceived that the HOUSE tool improved the decision-making process surrounding retrofit selection and that the HOUSE tool could assist in transmitting findings in meaningful ways to non-experts in the field. The HOUSE concept was found to have the potential to act as a transdisciplinary boundary object, engaging non-scientists in shaping and achieving societal goals.

It is interesting to note there was no significant self-reported increase in the collaboration and consensus amongst the experts (Group D) conducting the same task using the HOUSE interactive application tool set. This lack of significance may be as a result of the group's dynamic and requires further exploration. It would have been ideal to have asked the first workshop groups the longer questionnaire, to investigate if they felt the tool set provided improved the decision-making process surrounding retrofit selection and if they thought it could be used to assist in transmitting findings in meaningful ways to non-experts in the field.

## CONCLUSION

This article has introduced the HOUSE tangible application. Although this presents a preliminary study, the workshops yielded important insights and show that a tool such as HOUSE can support collaboration, consensus, improve decision making and transmit findings in meaningful ways. The results of the stakeholder workshops also demonstrate that the HOUSE tool has the potential for further development and implementation as part of a user-centred engagement process. Because participants were taking part in a theoretical design exercise rather than real-world selection and implementation – there are some limitations to this study although the initial results are promising. The tool should adapt to answer the questions and priorities that emerged from stakeholder engagement. The authors agree with the proposition given by Underkoffler & Ishii (1999) when outlining areas for future work “the proposition of giving additional meaning and animate life to ordinary inert objects is a cognitively powerful and intriguing one.”

## ACKNOWLEDGEMENT

We gratefully acknowledge funding from the Engineering and Physical Sciences Research Council (EPSRC) for the Design the Future ‘HOUSE’ Grant no EP/N009835/1. We would like to thank Dr Shayan Sharifi and Dr Weston Baxter for acting as workshop facilitators. We are also grateful to all the workshop participants for their input and insight.

### **ABSTRACT**

Building simulations rely on fixed assumptions and mathematical models to describe a specific building scenario, overlooking the building occupants' component. Almost 40% of in-home energy use is due occupants interacts with the building systems. The goal of this paper is to understand the magnitude of the performance gap when applied to two case studies in a Mediterranean climate. A set of scenarios are simulated assuming both a typical building usage and possible variations given by the users' interactions with shading, ventilation and cooling systems. Results show that the magnitude of the effects with a negative impact is bigger if compared to actions that might have a positive influence, this means that simulated results with standard usage assumptions are not an average of the possible effects but they reflect an optimistic outcome given by the optimal equipment usage.

### **KEYWORDS**

Users interactions, energy efficiency, occupants behaviour, building simulation.

### **INTRODUCTION**

Buildings sustainability standards usually focus on passive strategies to reduce the energy consumption by improving the envelope and system performances ( Rodriguez-Ubinas et al., 2014). Considering the operational phase, several studies (Fabi et al., 2013; Shuqin et al., 2015; Martinaitis et al., 2015) attest a deep performance gap between simulated/predicted and real data, quantifiable towards, e.g.: the 56% offices' electrical request for lighting during non-working hours (Masoso and Grobler, 2010); the 200% increase in energy bills (Fabi et al., 2012). This gap clearly relates buildings' performances to the occupants' misuse of buildings systems that often does not follow the designed assumptions (Hale, 2018). Actually, virtual simulations take into account standard conditions of use, neglecting the big influence of users and reducing their interactions to a fixed system of defined schedules. Whereas some software integrate users-related variables, often their predictions fail because the working hypotheses do not properly reflect real conditions. The real human action drivers can contribute to model a reliable algorithm of interaction between users and buildings. A driver is anything that pushes an occupant to perform either an action or an interaction with the building system, affecting also the energy consumptions. The interactions between occupants and the construction system could be related to a combination of several drivers, both external and internal (Schweiker and Shukuya, 2009; Boerstra et. Al, 2013, Hellwig, 2015; Lou et al., 2016). The main objective of the study is to assess the magnitude of the users' impact on buildings behaviour in relation to outstanding examples of sustainable architecture. The analysis is performed on certified case studies of Mediterranean Active House, in order to exclude any possible bias of non-optimised design. Active House (AH) is a holistic approach

to building design aimed at promoting sustainability. AH is supported by a network of research centres and construction companies (namely AH Alliance), among which Politecnico di Milano is delegated to adapt the vision to Mediterranean climate. This analysis is part of the preliminary research done in this field. The analysis concerns the cooling season, since a hot-warm climate characterises the weather clusters of the Mediterranean region (Peel et al., 2007). Here, winter is a mild season, while summer offers a large daily range of temperature (Causone et. Al, 2014), requiring a dynamic approach and proving to be more relevant to the definition of the design resilience in Mediterranean region.

## METHOD

The proposed analysis performs several sets of dynamic simulation scenarios in the software tool TRNSYS17 (<http://www.trnsys.com/>), starting from the typical usage assumptions, and implementing possible interactions with (i) cooling, (ii) shading and (iii) ventilation systems.

## Case studies

The dynamic simulations are performed on two outstanding examples of sustainable and high energy-efficient buildings, designed and validated according the AH principles ([www.activehouse.info](http://www.activehouse.info)): SVEVAH and VELUXlab<sup>1</sup>. While SVEVAH virtual model represent an example of applied design strategies for a Mediterranean building project, VELUXlab is a real building prototype, whose virtual model has been set and calibrated according to the real use and measured energy consumption (Imperadori et al., 2013).

Table 1. Main features and technical characteristics of the two case studies.

		VELUXlab	SVEVAH
Project data	Location	Milan	Rome
Roof	Transmittance (W/m <sup>2</sup> K)	0,133	0,117
	Damp effect (h)	10,5	10
Envelope	Transmittance (W/m <sup>2</sup> K)	0,124	0,137
	Average FLD (%)	5,7	5
Transparency	Transmittance (W/m <sup>2</sup> K)	1,1	1,1

## Baseline scenario

The buildings are equipped with a fully automated system that controls heating and cooling, as well as natural ventilation and shading systems. It operates as follows: i) cooling is switched on only when the indoor temperature  $T_i$  is above the AH overheating thresholds<sup>2</sup>; ii) natural ventilation is allowed when outdoor temperature  $T_e$  is above 22°C and  $T_i > T_e$ ; iii) windows facing north are never shaded; iv) windows are shaded when outdoor temperature is above 24°C,  $T_i > T_e$ , and the irradiance on the glass overcomes 140W/m<sup>2</sup> (Reinhart, 2001); v) East and West facing windows are shaded only if the condition in iv) is met during morning/afternoon time. Following the performance rating method of ASHRAE 90.1 §G1.2, these assumptions have been used to create a baseline scenario, within which the simulated performances represent the baseline for further results from different user-driven scenarios.

<sup>1</sup> Designed as the demo-house ATIKA, by ACXT/IDOM studio for VELUX, in 2011; retrofitted by Atelier2 – Valentina Gallotti and Prof. Marco Imperadori – Politecnico di Milano

<sup>2</sup> According to the AH Specifications, 2<sup>nd</sup> edition (2013) ([www.activehouse.info](http://www.activehouse.info)), the maximum operative temperature limits follow the AH ranking: 1.  $T_{i,o} < 25.5^\circ\text{C}$ ; 2.  $T_{i,o} < 26^\circ\text{C}$ ; 3.  $T_{i,o} < 27^\circ\text{C}$ ; 4.  $T_{i,o} < 28^\circ\text{C}$ , with an outside  $T_m \geq 12^\circ\text{C}$ . Beyond the set threshold of 26°C, the automated control system activates the floor cooling system.

### Cooling set point variation scenarios

The set of simulation scenarios (Table 2) compares the several static set point (a) with a complex modulation (b, c) that reflects the real conditions of use, and an adaptive setup (d), which assures the lowest adaptive category of comfort (UNI EN 15251:2008). Only for this analysis, the reference scenario adopted is the one with cooling system set at 26°C, as it reflects the standard cooling set point temperature in Mediterranean climate.

Table 2. Set of scenarios defining the users' action of changing the cooling set point

SCENARIO	TIME	SET POINT (°C)
Sp_(set point) (a) Static set point	0-24	from 24 to 28 with 1°C step
sp_night (b) Night set back	8-20 (20-8)	26 (28)
sp_c (c) Daily combination	8-20 (20-23) 23-6.30 (6.30-8)	26 (28) off (28)
sp_a (d) Adaptive opportunity	8-23 (23-8)	$0,33T_{rm}^3 + 20,8^{\circ}\text{C}$ (off)

### Shading system variation scenarios

Buildings users interact with the shading system as a reaction to sun position and solar radiation intensity and depth (Reinhart, 2001), even if indoor daylight supply is lower than the comfort threshold. In order to represent the effect of different drivers, several scenarios are scheduled (Table 3), differing in duration (all day, AM, PM) and interaction between users and MAS (Multi Agent Systems).

Table 3. Set of actions scenarios for the interactions with the shading system.

SCENARIO	MAS ON	MAS OFF (time) control modification
Base_s	-	(0-24) 80% shading (no ref. on external conditions)
Base_n	-	(0-24) Not shaded

### Ventilation scenarios

Ventilation interactions are set according to different time schedule of natural ventilation. (Herkel et al., 2009). Scenarios are shown in Table 4. Ceiling fans are not considered, since the prime design strategies of the buildings did not account them.

Table 4. Actions scenarios for the interactions with the ventilation system.

## RESULTS

Figure 1. Variation of cooling demand in the different scenarios compared to the baseline, expressed as percentage.

Figure 1 shows that some scenarios improve the final energy performance up to 90% less; others instead increase it up to almost 230%. The first important observation concerns the asymmetry of the variations: this is particularly clear in the cooling set up scenarios, where a 1°C variation in the setpoint temperature causes different effects on energy consumption. In fact, a 1°C reduction in setpoint temperature increases the cooling demand by approximately 60% above the baseline, while a 1°C increase in setpoint temperature reduces cooling demand of 20% below baseline. This tendency is even clearer when a 2°C variation is taken into account. This means that the cooling demand variation and the set point variation are not proportional and, therefore, the energy efficiency can drastically change if lower setpoint temperatures are considered (SP 24°C 150% more in cooling demand if compared to SP 26°C). Generally, it is possible to notice that the set of scenarios with shading interactions has less influence on the energy demand. This is due to the resilient design of the case studies, which integrate architectural features to prevent summer overheating, such as enclosed shape and internal shaded patio (VELUXlab) and smaller openings to South (SVEVAH). Another interesting consideration involves the influence of different outside scenarios, between the two case studies: although the observed tendency is the same, VELUXlab prove to be more sensible to setpoint changes, while it is more resilient to variations in the ventilation management system. The background reason stands in the different climate: Rome is a warmer city if compared to Milan, meaning that natural ventilation and external air infiltration are more critical. On the opposite side, when cooling is relying only on mechanical air conditioning, the relative influence is lower, due to the already higher cooling demand.

Figure 2. Variation of overheating hours in percentage, calculated according to AH Specifications, 2<sup>nd</sup> edition (2013) ([www.activehouse.info](http://www.activehouse.info)) and compared to baseline scenario.

Figure 2 shows the overheating hours for the scenarios with interaction on the shading and ventilation systems. Similar ventilation and shading scenarios have comparable effects on the comfort point of view -in contrast with previous results. The highest number of overheating hours is detected when no ventilation is allowed, this means that the buildings are unable to dissipate the internal heat gains and the overheating is mainly internally driven. These results confirm that modern efficient buildings are less sensitive to external stress, due to their engineered envelope with optimized performance, but also less resilient to indoor increasing heat gains.

## DISCUSSIONS

The results clearly attest the outcomes of experimental and monitored experiences in literature (Fabi et al., 2013; Shuqin et al., 2015; Martinaitis et al., 2015): the users interaction with the building systems could create a significant gap between predicted and real performance.

The presented case studies are supposed to be at the forefront of a sustainability. However, final performances change completely when the simulation assumptions and parameters are modified. This result indicates that the actual energy efficiency standard should account for the criticism related to users' interactions, allowing a better calibration of the design strategies. At last, the simplified scenarios could represent a limitation of the study, which does not account for more complex interactions. However, this simplified approach, based on the one-at-a-time method, helps to separate possible correlations and to quantify the criticisms of each system in the Mediterranean climate. According to this approach, users' influence represents a big source of uncertainty in the final energy performance of Mediterranean sustainable buildings. Sometimes also positive: shading scenarios are controlled by irradiance (Reinhart, 2001) and decrease the energy consumption of the building: less irradiance would mean less solar gain, and thus, a reduction of overheating effect and cooling demand. These outcomes represent a first step towards a proposal for modification of the thresholds on efficiency in regulations and standards, which should clearly account for usage behavior.

## CONCLUSIONS

The analysis is a preliminary step into the investigation of the interaction between users and building automation systems. According to the achieved results, the actual sustainability certification scheme can lead to biased conclusion on buildings final energy performance. The analysis in this paper is an additional contribution to the research on this issue and the case studies analysed show that the criticisms is not related only to low-performing buildings, but it is extended also to ambitious projects that claim outstanding performances.

Future

investigations of the presented project aim at defining a threshold acceptance boundary to account for misuse and interaction between MAS and users to be integrated into the future generation of sustainability standards.

### **ABSTRACT**

In this paper, we discuss the presence of habits in the window opening behaviour of social housing tenants in a nearly zero-energy development in Belgium. A window opening habit can be defined as an action with a window that is repeated daily around the same time independently of the prevailing weather conditions. A carbon neutral social housing estate (106 apartments and 90 single family dwellings) was used as a test case. Questionnaires, window opening logging with a building monitoring system and cross-sectional surveys were used to collect window opening data. A method to identify window opening habits is determined. Up to 45% of the occupants act on some sort of habit in wintertime, predominantly in the bedrooms and in the morning. In summer these habits dissipate due to very long window openings. Weather variables and indoor climate parameters, traditionally used as the basis for window opening behaviour models, are rather poor predictors of opening behaviour in winter. The incorporation of habits in window opening models can lead to more reliable predictions of window opening behaviour.

### **KEYWORDS**

Habits, Windows, Occupant behaviour, Residential energy use, NZEB

### **INTRODUCTION**

The occupants' window opening behaviour can have a substantial influence on the indoor climate and the energy use in a dwelling. In order to implement this behaviour in energy simulation tools, window opening models have been developed. In literature, most window opening models are based on outdoor and/or indoor climate variables (Brundrett and Poultney, 1982; Conan, 1982; Erhorn, 1988; Fabi et al. 2013; Lyberg, 1983; Maeyens and Janssens, 2000; Rijal et al. 2007). However, the study of Verbruggen et al. (2017) on the window opening behaviour of social housing tenants in a Belgian case study revealed that weather variables cannot accurately predict the window opening behaviour in winter time. The weather variables have a significant influence on the window opening behaviour when yearly data are considered, nevertheless the influence is not significant when only winter data are analysed. It was revealed that most occupants who opened their windows in wintertime either could not define an explanation for their actions or linked it to the need to 'air' the dwelling. A recent study (Clarysse, 2018) did not reveal any performance issues with the heat recovery ventilation system. The lack of (accurate) motivation to perform these window openings leads to the hypothesis that the occupants interact with the windows out of habit.

A habit can be defined as an automatic action carried out without conscious effort that is the consequence of frequently repeating this action in a stable context (Ouellette and Wood, 1998). Consequently, a window opening habit is an action with a window that is repeated daily around the same time independently of the prevailing weather conditions. Habits have been elaborately researched in the field of sociology and psychology (Ajzen, 2002; Ouellette and Wood, 1998; Verplanken et al. 1998); however, little research has been carried out in the building sciences.

In several window opening studies, occupant characteristics have been reviewed, such as age, income, sex and household size, but the habits of the occupants have not been considered. Habits are very personal and vary greatly among the different occupants. It is consequently difficult to incorporate them into a window opening model. Nonetheless, it is interesting to investigate these habits, since window opening actions can considerably influence the ventilation rate and accompanying energy losses.

This paper first explains how the presence of window opening habits is determined in a case study. Subsequently, the observed habits are discussed and their influence on the energy use is assessed.

## **METHODS**

### **Case study**

The research is based on data collected in a nearly zero-energy social housing development in Belgium (Himpe et al. 2015). The housing project is equipped with a building monitoring system which is directly linked to a university server. The project, built between 2010 and 2015, consists of 106 apartments and 90 single family houses. All apartments and 39 houses are fitted with a balanced mechanical ventilation system with heat recovery, while the other dwellings have demand controlled exhaust ventilation with trickle vents.

### **Data-acquisition**

In 14 apartments and 16 houses, window sensors were installed which provided direct measurements on the window opening actions. The time and state of the windows were registered when a window is opened or closed. Only one sensor was installed on each window; therefore, it was not possible to differentiate between turning and tilting actions. In the apartments, the signals of the sensors were combined into one signal per apartment. Consequently, the individual actions with a single window were not registered. The window sensor data were analysed for the years 2015 and 2016 for the apartments, but only for the year 2016 for the houses since they were inhabited later. In four apartments, the data was corrupted so these were discarded from the analysis. To broaden the window opening data, a logbook study was carried out between 20 January and 27 February 2017. The occupants were asked to write down when the windows were opened and closed, and to mention whether those were opened completely or tilted. A total of 47 occupants filled in a logbook. However, the motivation of occupants to participate dropped considerably after a few weeks. The validity of the logbooks was checked by visual observations carried out during the same period, and compared with window sensor data if available. In total, 62% (20 apartments, 9 houses) of the logbooks were evaluated as correct. Additionally, the occupants were queried on the reasons for opening and closing the windows, the family composition, the presence in the house and the occupants' satisfaction with the ventilation system. In Himpe et al. (2015) and Verbruggen et al. (2017) respectively, the case study is discussed in more detail and a summary is provided of the observed window opening behaviour.

### **Determining Habits**

The data of the logbook study was used to determine which occupants perform habitual actions. Indications of a habit can be observed when examining the opening percentage per hour, this is the fraction of the hour that the window is opened. When the opening percentage approximates a value of 1 (100%), it indicates that the window is always opened at that time (independently of e.g. indoor and/or outdoor climate); consequently, the presence of an opening habit is very likely. This was visually checked by plotting the average opening percentages per hour over the measuring period (Jan-Feb 2017) for every hour of the day (Figure 1). When a clear peak in

opening percentages was observed, but the 100% mark was not reached, an opening habit could still be present. This can indicate an opening habit that occurred a limited number of times per week (e.g. only on weekdays), a habit that has slightly shifted in time throughout the days or a habit with a duration shorter than one hour. For example, clear habits could be observed in apartments 6 and 21 (Figure 1), while the opening percentages of apartments 20 and 22 merely suggest a habit. Additionally, indications of habits were derived from conversations with the occupants.

Next, these habits were more precisely determined by examining the exact data of the logbook papers. In all dwellings with an indication of a habit, it was checked if the windows were actually opened every day at that time. First, an average starting-time of the habit was determined, as well as an average end-time. Subsequently, it was checked if this habit is present every day during the measuring period. A deviation of the starting- and end-time of one hour was allowed to compensate for incorrect clock-setting and the lack of accuracy in time notation. Generally, the habit will not be present every single day at the exact time-slot; therefore, it was also determined on how many days the habit was present. This value was corrected when a habit was only performed on specific days of the week (e.g. only on Mondays), for the number of these specific days present in the measuring period. The analysis was repeated for the data of the window sensors, considering the same winter period as the logbook study (Jan-Feb 2017).

Figure 1. Average opening percentages per hour – Dwellings with a window opening habit.

## RESULTS & DISCUSSION

### Habits in winter

In 17 of the 47 dwellings (36 %) that participated in the logbook study, at least one opening habit was registered. This percentage rose to 45% when not all logbooks were considered, but only those that were assumed to be correct. When assessing the window sensor data, only in 5 of the 26 dwellings (19 %) a habit could be observed. This habit presence is lower than observed from the logbook data. However, 4 from the 5 dwellings where habits were observed are apartments which leads to a habit presence of 40% in the apartments, while in merely 1 out of 16 houses (6%) a habit is present. In Table 1, the dwellings that exhibited a window opening habit are presented with the corresponding percentage of the day that the habit occurred. The table also shows in which rooms and on which days of the week the habit was carried out. Even if no habits were found in certain dwellings, they may still be present. The presence of a habit can be missed by the determination method when the habit is performed on varying times during the day or is repeated on only a few days in the week/month. The difference in the number of detected habits between the logbook-data and sensor-data may be attributed to the occupants' participation in the survey. Most participants of the logbook-study partook in the survey, wherein some mentioned specific habits that could have been missed by the determination

method (e.g. cleaning every Thursday). Of the dwellings with window sensors, only a few occupants participated in the survey consequently lowering the probability of detecting habits. Accordingly the substantial difference between apartments and houses may be attributed as well to the limitations of the determination method or the small data sample. However, it may also be due to a better understanding of the working of the ventilation system by the inhabitants of the houses. Further research is needed on the occupants' knowledge of the ventilation system and the corresponding relationship with the presence of habits.

Most habits occurred in the bedrooms in the morning (Table 1). This observation corresponds to the findings of Fabi et al. (2013) that the probability of opening a window is the highest in the morning. However, they attribute the opening actions to the presence of high CO<sub>2</sub>-levels, while it is more likely that occupants open their windows when they wake up, as a habit. The windows will not necessarily be opened due to high CO<sub>2</sub>-levels, rather due to the fact that occupants are only able to interact with the windows when they are awake and because the CO<sub>2</sub>-levels will only decrease as a result of the opening of the windows. In merely four dwellings a living room opening habit was observed. Other habits were present when a recurring activity took place every week that demanded the opening of windows or doors. For example, cleaning personnel may clean the dwelling every week at the exact same time and open the windows while doing so. On average, the habits were present during more than 80% of the measuring period, so on more than 80% of the days the habits were executed. Some dwellings showed just a 50% presence of habits; in these dwellings the hours at which the opening actions occurred were shifted. This may indicate that the habits are linked to a certain activity rather than to a certain time-slot. For example, the opening of the bedroom windows in the morning will be closely linked to the waking-up event, which may not happen every day at exact the same time. Other dwellings revealed a 100% habit-presence; in these dwellings the habit was punctually repeated every day.

### Habits in summer

The discussed habits are the results of a winter study; additionally, it was checked if these habits were similarly present in summer. No logbook study has been performed in summer,

consequently solely the window sensor data could be used. The month August in 2016 was selected since in June and July the monitoring system was not working properly and in previous years the sensors in the houses were not yet operational. It was observed that the winter-habits were not present anymore in summer, as visualised in Figure 2. The majority of the windows were continuously opened in summer, which leads to the dissipation of the winter-habits. This may evidently be a habit as well. It is necessary to do more research on the 'survival time' of these habits, this is the time that the context is stable and habits are executed (Ouellette and Wood, 1998), in order to examine in which period the winter-habits and summer-habits are present and to develop a window opening model accordingly. There may be spring- and autumn-habits as well, but this needs to be analysed further.

Figure 2. Average opening percentages per hour in winter and summer

### Influence of window opening habits on opening percentages and energy use

The average window opening percentages per day in winter were higher for dwellings where a habit was present, compared to dwellings without a habit. In the master bedrooms the average opening percentages for dwellings with a habit was 19%, while for dwellings without habits it was 9%. In the living room the opening percentages were lower, but the difference was still present with respectively 3% and 1% for dwellings with and without habits. Consequently, a large part of the opening actions happened independently of any weather variables. This demonstrates why the window opening models based on weather variables were not able to correctly predict the opening behaviour in winter. There is a potential large effect on the energy use when the opening percentages increase. Nevertheless, no significant correlation was found between the monitored energy use and the presence of a habit, which could be caused by the limited number of cases or the multitude of other factors that simultaneously influence the energy use.

### CONCLUSION

Using logbook and window sensor data the presence of habits in winter was determined for the residents of a nearly zero-energy social housing neighbourhood. In 45% of the dwellings a habit was performed with an average presence of 80% during the measuring period. A 100% habit-presence could not be observed in all dwellings since the habitual opening actions could differ slightly in time. Consequently, it is assumed that the window openings are rather linked to an activity which is performed consistently every day than to an exact time-slot. Most habits occurred in the morning in the bedrooms, this may be closely linked to the waking-up event. Other habits were present due to repeated activities during the week such as cleaning. In summertime these winter-habits dissipated due to the extended duration of the window openings. Further research is needed to determine the presence of summer-habits and the 'survival time' of these habits. The winter-habits have an important influence on the opening percentage of the windows. With the window opening models based on weather variables

lacking accuracy in winter time, developing a model that includes these habits may lead to more precise predictions of the window opening behaviour.

## ACKNOWLEDGEMENT

We gratefully acknowledge the financial support received for this work from the Fund for Scientific Research (FWO) in the frame of the strategic basic research (SBO) project “NEPBC: Next generation building energy assessment methods towards a carbon neutral building stock” (S009617N). The authors would also like to thank the social housing company ‘Goedkope Woning’ and the occupants who willingly participated in this project.

### **ABSTRACT**

In new houses in Europe the share of mechanical ventilation with heat recovery is increasing as a result of more severe energy performance requirements and of energy labelling for residential ventilation units. The methods used to assess the influence of heat recovery ventilation on the heating energy use in energy labelling and certification are typically based on single zone energy balance equations, although heating behaviour and set-points differ in different rooms of a dwelling. As a result of this the energy savings of heat recovery ventilation as assessed with single zone methods may be larger than when the spatial variations in dwellings are taken into account. This is related to the fact that the recovered heat supplied to the dwelling through the ventilation system is not ‘useful’ to reduce space heating and cooling demand at all time and in every room.

A two-zone steady-state heat loss analysis was conducted to investigate the relation between spatial variations in a dwelling and the utilization of heat recovery. One zone represents the rooms in a house which are regularly heated and are typically equipped with heat emitters and local controls. The other zone represents the rooms which are rarely heated or have no individual heat emitters or controls.

The results show the differences between a single zone and two-zone approach in terms of the effects of heat recovery ventilation on building heat loss, and define the main influencing parameters for the utilization of heat recovery in residential ventilation systems.

The analysis is supported by results of a field study where energy use in 114 low-energy houses was monitored. Half of the houses had mechanical ventilation systems with heat recovery, while the other half had demand-controlled mechanical extract ventilation. Apart from the differences in ventilation systems, the houses were largely identical.

Heat recovery ventilation, Building heat loss, Temperature zoning, Energy performance

### **INTRODUCTION**

The European market for residential ventilation is highly driven by energy performance regulations. In new buildings the share of mechanical ventilation with heat recovery (MVHR) is increasing as a result of more severe energy performance requirements. For instance in Belgium the share of MVHR in new single family houses has increased in 10 years’ time from 25% to almost 50% since the introduction of the energy performance regulation in 2006 (VEA, 2015). The energy labelling for residential ventilation units and the ecodesign requirements for ventilation units may further contribute to the wide-spread application of MVHR in new buildings (EC, 2014).

However, at the same time research reveals a performance gap between the rated energy performance of residential buildings and the actual energy use. The effect of energy saving

measures is typically overrated compared to reality. Majcen et al. (2016) found that in 280 houses where mechanical exhaust ventilation was replaced by MVHR the actual reduction in gas use was less than a quarter than what was expected based on the EPC-rating. One possible cause of the discrepancy is a poor installation quality of the ventilation unit, resulting in shortcuts and leakage that may decrease dramatically the efficiency of heat recovery (Roulet et al. 2001). Another cause of the discrepancy is the simple model used in rating methods to calculate the ventilation heat loss, perhaps not sufficiently accurate to reflect the actual influence of the heat recovery system (HRS).

Indeed, the methods used to assess the influence of heat recovery ventilation on the energy use of buildings in energy labelling and certification are typically based on single zone steady-state energy balance equations, using the thermal efficiency or heat exchange effectiveness of the HRS as an input. The single zone approach assumes that all rooms are heated to the same set-point temperature and that the extract air temperature equals room temperature. Intermittency and multi-zoning is not considered although heating behaviour and set-points may differ in different rooms of a dwelling. In a typical lay-out of MVHR air is extracted from wet rooms with lower set-point temperatures than the main living areas and recovered heat is also supplied to unheated habitable rooms (eg bed rooms), unnecessarily increasing the indoor temperature and heat loss in the latter rooms. As a result of this the energy savings of heat recovery ventilation as assessed with single zone methods may be larger than when the spatial variations in dwellings are taken into account.

Faes et al. (2017) assessed the influence of MVHR on the space heating demand of a detached dwelling using dynamic simulations with a 10-zone-model and defined different ‘use factors’ to take temporal and spatial variations in temperature into account. Their results show that less than 50% of the heat recovered from the extraction air is actually supplied usefully to the rooms of the dwelling, in the sense that the recovered heat contributes to the reduction of yearly heating demand. Furthermore the relative influence of MVHR on the heating demand increases with higher thermal resistance and airtightness of the building envelope. A high performance building envelope causes the temperature throughout the dwelling to be more constant over time and uniform with respect to the different spaces. As a result the single zone assumption is valid and the thermal efficiency of the HRS better reflects the energy savings of MVHR. However, as Berge et al. (2016) observed in field studies in Norway, inhabitants of highly insulated dwellings with heat recovery tend to apply extensive window ventilation in bedrooms to compensate for the undesired oversupply of heat to these rooms. This leads to an increased space-heating demand, and again reduces the potential energy savings of MVHR, and the validity of the single zone assumption.

In this work, a two-zone steady-state heat loss analysis is conducted to investigate the relation between spatial variations in a dwelling and the utilization of heat recovery to reduce the building heat loss. A definition of the ‘useful’ efficiency of MVHR is proposed and compared to the thermal efficiency of the HRS. The results show the differences between a single zone and two-zone approach in terms of the effects of heat recovery ventilation on building heat loss, and define the main influencing parameters for the utilization of heat recovery in residential ventilation systems. The analysis is supported by results of a field study where energy use in 114 low-energy houses in a carbon neutral social housing district was monitored (Janssens et al. 2017). Half of the houses had mechanical ventilation systems with heat recovery, while the other half had demand-controlled mechanical extract ventilation. Apart from the differences in ventilation systems, the houses were largely identical.

## METHODS

### Heat loss analysis

In order to take spatial temperature variations within a dwelling into account different methodologies exist, ranging from correction factors introduced in a single zone model to a coupled multi-zone representation of a house (Delghust et al. 2015). Here a two-zone approach is chosen as a first order improvement of the single zone assumption. One zone represents the rooms in a house which are regularly heated and are typically equipped with heat emitters and local controls, such as living room and kitchen. The other zone represents the rooms which are rarely heated or have no individual heat emitters or controls, for instance bedrooms, bath rooms and hallway. Figure 1 shows the model parameters in a single-zone and two-zone representation of a dwelling with MVHR.

Figure 1. Single-zone model (left) and two-zone model (right) of a dwelling with MVHR, with indication of model parameters:  $\eta_t$ , thermal efficiency of HRS (-);  $V$ , building volume ( $\text{m}^3$ );  $n_v$ , ventilation air change rate ( $\text{h}^{-1}$ );  $\theta_e$ , exterior temperature ( $^{\circ}\text{C}$ );  $\theta_i$ , set-point temperature in heated zone ( $^{\circ}\text{C}$ );  $\theta_{sup}$ , supply air temperature ( $^{\circ}\text{C}$ );  $\theta_{ex}$ , extraction air temperature ( $^{\circ}\text{C}$ );  $\theta_u$ , balance temperature in unheated zone ( $^{\circ}\text{C}$ );  $H$ , heat loss coefficient of building envelope ( $\text{W/K}$ );  $H_{iu}$ , heat loss coefficient of partition walls between heated and unheated zone ( $\text{W/K}$ );  $f_h$ , fraction of building envelope heat loss related to heated zone (-);  $f_{sup}$ , fraction of supply air supplied to heated zone (-);  $f_{ex}$ , fraction of extraction air extracted from heated zone (-).

The overall steady-state heat loss  $\Phi_L$  (W) of the heated zone is defined by Eq. 1 and Eq. 2 in the single-zone and two-zone model, respectively:

$$\Phi_{L,1z} = [H + 0.34n_vV(1 - \eta_t)](\theta_i - \theta_e) \quad (1)$$

$$\Phi_{L,2z} = f_hH(\theta_i - \theta_e) + H_{iu}(\theta_i - \theta_u) + 0.34f_{sup}n_vV(\theta_i - \theta_{sup}) \quad (2)$$

The heat loss equation of the two-zone model may be solved using the heat balance equation of the unheated zone to find  $\theta_u$  (Eq. 3) and the heat transfer and mixing equation of the supply and extraction air to find  $\theta_{sup}$  (Eq. 4).

$$[H_{iu} + 0.34(f_{sup} - f_{ex})n_vV](\theta_i - \theta_u) = (1 - f_h)H(\theta_u - \theta_e) + 0.34(1 - f_{sup})n_vV(\theta_u - \theta_{sup}) \quad (3)$$

$$\theta_{sup} = (1 - \eta_t)\theta_e + \eta_t[f_{ex}\theta_i + (1 - f_{ex})\theta_u] \quad (4)$$

### Expression of results

The heat loss calculation is applied for different values of the heat loss coefficient  $H$  of the building envelope, using typical values for the other model parameters (Laverge et al. 2013):  $V = 500 \text{ m}^3$ ,  $n_v = 0.5 \text{ h}^{-1}$ ,  $H_{iu} = 200 \text{ W/K}$ ,  $f_h = 0.5$ ,  $f_{sup} = 0.45$ ,  $f_{ex} = 0.30$  and  $\eta_t = 0.80$ .

The overall heat loss of the heated zone of the dwelling with MHRV is compared to the heat loss of the dwelling with a ventilation system without HRS, eg mechanical exhaust ventilation (MEV) or mechanical ventilation with  $\eta_t = 0$ . The difference between both defines to what extent the overall heat loss is reduced by the application of MVHR. The ratio between this difference and the extra heat loss incurred by adding ventilation defines the specific heat loss reduction or 'useful' efficiency of the HRS in Eq. 5 (called 'use factor' by Faes et al. 2017) :

$$\eta' = \frac{\Phi_{L,MEV} - \Phi_{L,MVHR}}{0.34 n_v V (\theta_i - \theta_e)} \quad (5)$$

When applying the single-zone model, the useful efficiency  $\eta'$  is equal to the temperature efficiency  $\eta_t$  of the HRS, independent of other parameters.

## RESULTS

### Calculated useful efficiency

Figure 2 shows the results of the two-zone heat loss analysis for the parameter values given in the previous paragraph. The dimensionless temperature in the unheated zone and the useful efficiency are depicted as a function of the volumetric heat loss coefficient of the building envelope  $H/V$ . The right hand side of the x-axis corresponds to poorly insulated envelopes, the left hand side to highly insulated envelopes. The temperature in the unheated zone decreases with higher values of heat loss coefficient. In the dwelling with MVHR the unheated zone is slightly warmer than with MEV since air preheated by the HRS is supplied to the unheated zone. Since the supply air temperature of MVHR depends on the temperature of the extraction air and a large share of the extraction is taken from the unheated zone, the supply air temperature also decreases with higher values of heat loss coefficient, thus diminishing the heat loss reduction provided by MVHR. This effect is reflected in the calculated useful efficiency, which remains substantially lower than the value of the thermal efficiency of the HRS (equal to the useful efficiency in the single-zone approach). With better insulation of the building envelope and lower ventilation rates, the useful efficiency predicted by the two-zone model increases towards the result of the single-zone model.

Figure 2: Results of two-zone heat loss analysis: dimensionless temperature in unheated zone with MEV and MVHR and supply air temperature with MVHR (left) and useful efficiency  $\eta'$  following from two-zone model compared to single zone model (right).

### Field study

The heat loss analysis shows that the energy performance of MVHR largely depends on modelling assumptions. Still, both the 1-zone and 2-zone model remain simplifications; in reality the spatial variations in temperature in dwellings are in between both modelling extremes. To put the results of the theoretical analysis into perspective monitoring results of a field study are now discussed, where the total metered heat use (space heating and sanitary hot water) in the dwellings of a carbon neutral housing district was compared to the heat use rated in the energy performance certificates. In Belgium the energy performance of new and renovated buildings needs to be assessed at the moment of completion of the works by an EPB-assessor, who collects the as-built information, creates the input in the EPB-software, and evaluates whether the building meets the requirements. Half of the houses had MVHR with a rotary HRS ( $\eta_t = 80\%$ ), while the other half had demand-controlled MEV. The volumetric heat loss coefficient of the building envelope was about  $0.15 \text{ W}/(\text{m}^3\text{K})$ . In total 90 houses (41 MVHR, 49 MEV) had complete metering data to perform the comparison. More information about the district and the monitoring method is given by Janssens et al. (2017).

As Figure 3 shows, the rated heat use in houses with MEV was significantly higher than that in houses with MVHR, on average 32%. However, this is not reflected in the results of the monitoring where the metered heat use shows no significant difference between both types of houses. Apart from the ventilation system the houses were largely identical. Also the user behaviour in both groups of houses was similar according to the monitored living room temperatures, with average values in winter months  $23.0 \pm 1.5^\circ\text{C}$  for MEV and  $22.7 \pm 1.5^\circ\text{C}$  for MVHR. Temperatures in bedrooms were on average 3 to  $4^\circ\text{C}$  lower in both types of houses. Therefore differences in heating behaviour are no explanation for the deviation between rated and metered performance of the houses with MVHR.

An analysis based on the EPB input-files of the rated houses shows that the heat use in the houses with MVHR strongly depends on the input value of the thermal efficiency of the HRS (Figure 3, right). So the reduced useful efficiency of MVHR as a result of temperature differences between rooms may partly explain the underperformance of MVHR in terms of metered heat use. Furthermore large differences were measured between day zone temperatures and extract air temperatures in some houses, possibly related to window opening in wet rooms. This still needs to be investigated in more detail.

Figure 3: Comparison between the rated and metered (1/5/2015-30/4/2016) heat use of low-energy dwellings with MVHR and MEV (left) and relation between rated heat use of houses with MVHR and thermal efficiency of HRS, with specified thermal efficiency of 80% (right).

## CONCLUSIONS

A two-zone steady-state heat loss analysis was conducted to investigate the relation between spatial variations in a dwelling and the utilization of heat recovery in mechanical ventilation. The results show that the building heat loss reduction of MVHR assessed by single zone methods typically used in energy labelling and certification is optimistic compared to the assessment of a two-zone model. When temperature differences between heated and unheated rooms are taken into account, the building heat loss reduction of MVHR is influenced not only by the thermal efficiency of the HRS but also by building envelope heat loss, flow rates and lay-out of the ventilation system, and size of day and night zone. Field studies show evidence that the positive influence of MVHR on heating energy use as predicted by single zone rating methods, is not confirmed by the metered heat use. A definition of the 'useful' efficiency of MVHR is proposed as a metric to take heat recovery ventilation into account in a more correct way in energy performance rating methods. With better insulation of the building envelope and lower ventilation rates, the useful efficiency predicted by the two-zone model increases towards the result of the single-zone model.

### ABSTRACT

Considering the quality of the classroom light-environment will directly affect students' eye health and learning efficiency, it is a problem to be solved that how to evaluate the visual comfort levels of the classroom light-environment and save lighting energy on the premise of necessary visual comfort. Aiming at these problems above, this study restored the classroom scene through adjustable full-size light-environment simulation laboratory, in which 135 subjects participated in the visual comfort evaluation experiment of the indoor light-environment. After features (illuminance and correlated color temperature) and labels (comfort levels) preprocessed, we trained and visualized the visual comfort classification models of desktop reading and blackboard reading using the algorithms of C-Support Vector Machine (C-SVM). Through the contour map and the scatter diagram, we get the classification boundary of different comfort levels and the relationship between visual comfort and lighting parameters, which has guiding significance to classroom lighting design and evaluation.

**KEYWORDS:** Classroom lighting; Visual comfort; Lighting energy efficiency; Subjective evaluation experiment; C-SVM

### INTRODUCTION

The quality of indoor artificial light-environment has important influence on the indoor space user's psychological feeling, visual effect, visual fatigue, physiological rhythm and so on. Classrooms are the main venues for students to study in, the pros and cons of the light-environment will directly affect not only the students' eyesight health, but also the student's psychological feeling and learning efficiency (Gao, 2013). Considering the variable classroom usage patterns, it is necessary to verify the comfort range of light parameter of desktop reading, blackboard reading and PPT reading. Only in this way can we guide the light-environment design of classrooms according to the actual usage patterns.

The A.A.Kruithof's lighting comfort curve, which is considered the classic research on spatial light-environment visual comfort, roughly shows the corresponding relationship among the visual comfort, color temperature and illuminance (Kruithof, 1941). After that, visual comfort of light-environment research mainly divided into two directions: one is to further explore the relationship among the visual comfort, illuminance and correlated color temperature (CCT) under different space types based on Kruithof's curve; The other one is to use the methods of fuzzy comprehensive evaluation, linear regression or some other mathematical methods to find the mathematical relationship among the visual comfort, illuminance, CCT and other explanatory variables.

However, most research results are controversial or difficult to apply to practical applications. As an important algorithms in the fields of pattern recognition and machine learning, support

vector machine (SVM) which is based on the theory of VC (Vapnik-Chervonenkis) dimension theory and structural risk minimization principle performs well on the nonlinear and small sample classification or regression problems, which causes scholars' continuous exploration on the optimization of this model and the practical application in recent years (Ben et al, 2012; Kaya et al, 2012; Huo and Duan, 2011). This research tries to develop a classification model using the algorithm of C-support vector machine (C-SVM) with features of illuminant parameters and labels of subjects' visual comfort level. The results can be visualized on 2d contour plots which can estimate the quality of light-environment easily and guide the lighting design of the same space type.

## METHODS

### *Experiment Platform*

The experiment was carried out in the experimental module of variable building space designed and constructed independently by Tianjin university. The length and width of the experimental module are both 24 m, which can be divided into any space by partitions. The ceiling is composed by the 16 pieces of 6 m \* 6 m lift alone LED lighting modules with individual lift range of 3 m to 9 m. Each lighting module deploys 12 LED tube lights which can be adjusted within a certain range of luminous flux and CCT. Therefore, it can stimulate real light-environment of any regular space with proper scene decoration. The experiment cabin exterior and interior view are shown in Figure 1.

Figure 1. Exterior and interior view of the experiment cabin.

### *Working Condition*

This experiment was carried out in a 12 m \* 6 m \* 9 m stimulated classroom through space adjusting device. As shown in Figure 2, The outer windows were covered with opaque grey curtain and 18 sets of desks (size: 1.2 m \* 0.6 m) and chairs and a blackboard (size: 2 m \* 1 m) were put properly.

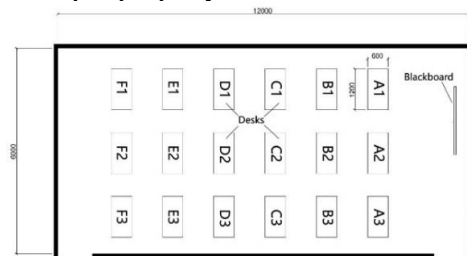

Figure 2. Stimulated classroom setting.

Figure 3. Measuring points on blackboard.

In this experiment, the visual comfort of desktop reading and blackboard reading was taken as the evaluation object. The experiment set up 74 working conditions with only general lighting, making sure that the illuminance parameters of the two lighting modules were consistent. With adjustment of lighting parameters under different working conditions, the 0.75 m horizontal illuminance and CCT covered 20-1100 lx and 2670-6700 K respectively, and

making sure the color rendering index was above 80 in any case. The illuminance and CCT of each measuring point in each working condition was measured by the spectrophotometer (KONICA MINOLTA CL-500A). The layout of measuring points on the blackboard is shown in Figure 3, and the measuring points on desktops were the subjects' visual center of reading. The average value of two-time measurement of each point was taken as the final measured value. The measuring time was chosen after 20 o'clock to minimize the effect of natural light.

For the blackboard surface, the arithmetic mean value of all measurement points was taken as the average illuminance of current working condition. The formula is as follows:

$$E_{av} = \frac{1}{M \cdot N} \sum E_i \quad (1)$$

In this formula:  $E_{av}$  is the average illuminance and the unit is lux (lx);  $E_i$  is the illuminance of the  $i$ th measure point, and the unit is lux (lx);  $M$  and  $N$  are respectively the longitudinal and transverse measurement points. The measurement results are shown in Table 1 and Table 2:

Table 1. Measurement values of light-environment parameters on desktop.

Condition No.	Percentage of maximum power of white light	Percentage of maximum power of yellow light	Measuring point	Average illuminance (lx)	CCT (K)
1	0%	80%	A1	582.60	2729
			...	...	...

...	...	...	...	...
74	20%	80%	436.18	3054

*Subjective evaluation experiment of visual comfort in light-environment.*

As shown in Fig. 4, 8 group experiments were carried out in which 16 to 18 undergraduates or postgraduates aged 20 to 26 evaluated the visual comfort of desktop reading and blackboard reading under 74 sets of lighting conditions. The whole subjects were consists of 135 students with a roughly equivalent sex ratio.

Figure 4. Subjective evaluation experiment of visual comfort in classroom light-environment.

After taking 1-minute rest with eye masks on between adjacent sets of working conditions, the subjects can minimize the influence of the former light-environment. Each question on the subjective evaluation questionnaire, with an evaluation standard of "If it is conducive to learning or not", must be chosen one number among 0 to 10 as the visual comfort score of the current conditions. The questionnaire is as Table 3:

Table 3. Subjective evaluation questionnaire

Condition No.										
1. Which do you think is the visual comfort score of current desktop reading?										
0	1	2	3	4	5	6	7	8	9	10
2. Which do you think is the visual comfort score of current blackboard reading?										
0	1	2	3	4	5	6	7	8	9	10

## RESULTS

### *Data preprocessing*

We removed the outliers of visual comfort evaluation scores according to the quartile of 8 group experiments. Then we get mean value of the visual comfort evaluation scores of the same seat position, and discretized the average of normal values into 4 range:  $0 < \text{comfort average} \leq 2.5$ ,  $2.5 < \text{comfort average} \leq 5$ ,  $5 < \text{comfort average} \leq 7.5$  and  $7.5 < \text{comfort average} \leq 10$ , representing "awful", "uncomfortable", "good" and "excellent". For visual comfort of blackboard reading, we still need to take arithmetic mean value of 18 subjects in the same group of experiment as the overall comfort value of each condition. Finally, the label of each lighting condition is expressed as integer 0~3, which corresponding to "awful", "uncomfortable", "good" and "excellent" visual comfort level. The data prepared for modeling are shown in table 4 and table 5.

Table 4. Desktop reading data.

### *Light-environment evaluation modeling based on C-SVM*

Support vector machine (SVM) is a machine learning algorithm based on VC dimension theory and the principle of structural risk minimization (Brereton and Lloyd, 2010), and can improve the generalization ability of the models as far as possible, even to the limited training set. So the SVM model has a good performance on small sample data. By using Python3.6 and its extension packages, we built C-SVM light-environment quality evaluation models of desktop reading and blackboard reading with the kernel of radial basis function (RBF). The specific modeling process is shown as follows:

(1) Divide training set and test set: in this study the blackboard reading visual comfort experiment has 74 groups of data samples, while desktop reading comfort experiment 1332

ones. They were divided into training set and test set randomly according to the proportion of 4:1 respectively, which prepared to train and test the C-SVM model.

(2) Parameter adjustment and model training: C-SVM models were trained for desktop reading and blackboard reading respectively with features of average illuminance and CCT and labels of visual comfort level pre-processed; Through adjusting the parameter by grid search and K-fold cross-validation, we get the optimal C and gamma value (the penalty factor C for error, gamma for parameter of RBF kernel function), and prevent model overfitting by observing the training set prediction accuracy.

(3) Then we got the C-SVM light-environment evaluation model by training on the whole training set with the optimal combination of C and gamma obtained in the previous step.

(4) At last we can evaluate the performance of the trained C-SVM model by predicting accuracy on test sets.

Eventually we got the C-SVM model for desktop reading and blackboard reading as shown in Figure 4, and “x” means “awful”, “●” means “uncomfortable”, “▲” means “good”, “■” means “excellent”:

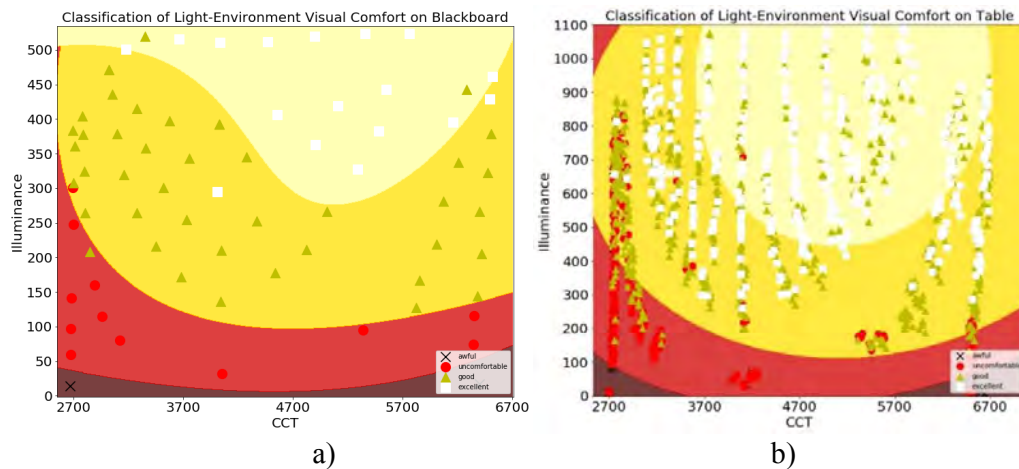

Figure 4. Visual comfort C-SVM model. a) For blackboard reading (accuracy on test set and training set are 0.933 and 0.898), b) For desktop reading (accuracy on test set and training set are 0.667 and 0.663).

## DISCUSSIONS

As shown in Fig.4, the horizontal axis represents CCT, the vertical axis represents the illuminance, yellow and white areas are for good and excellent combinations of illuminance and CCT, red and dark red area are for uncomfortable and awful ones. The following conclusions can be drawn from the two graphs:

For blackboard reading:

a) The light yellow area is the best for blackboard reading visual comfort and should be as a priority for teaching mode. The lowest vertical illuminance of blackboard is required to be 290 lx in the goal of achieving “excellent” visual comfort with a CCT of 5000 K at the same time. When the CCT is adjusted lower or higher than 5000 K, we must increase the illuminance to maintain the same level of visual comfort at the price of higher lighting power density (LPD). Even if there are special requests for the CCT of light source, try not to make CCT lower than 4000 K or higher than 6000 K, or we need above 400 lx of illuminance to achieve the same visual comfort level, which is not conducive to energy saving.

b) The yellow area is recommended as a good or acceptable area for non-teaching mode. In this area, the lowest vertical illuminance of blackboard should be limited to 100 lx with a CCT

of 4000-5500 K at the same time. Similarly, CCT lower than 4000 K is not recommended.

c) Red and dark red area are uncomfortable and awful area respectively. If the vertical illuminance of blackboard is lower than 100 lx, no matter what CCT can meet the requirement of visual comfort. Therefore, the vertical illuminance of blackboard should be higher than 100lx.

For desktop reading:

a) The light yellow area is the best for desktop reading visual comfort and should be as a priority for self-study or reading mode. Similarly, the lowest vertical illuminance of desktop is required to be 450 lx in the goal of achieving “excellent” visual comfort with a CCT of 5000 K at the same time, but we cannot achieve “excellent” area if the CCT is lower than 3700 K or higher than 6500 K. Even if there are special requests for the CCT of light source, try not to make CCT lower than 4200 K or higher than 6000 K for the sake of energy saving.

b) The yellow area is recommended as a good or acceptable area when there is less use of desktop. In this area, the lowest vertical illuminance of desktop should be limited to 140 lx with a CCT of 5200 K at the same time. Similarly, CCT lower than 3700 K or higher than 6500 K is not recommended for energy efficiency.

c) Red and dark red area are uncomfortable and awful area respectively. If the vertical illuminance of blackboard is lower than 140 lx, no matter what CCT can meet the requirement of visual comfort. Therefore, the vertical illuminance of desktop should be higher than 140 lx.

## CONCLUSIONS

The quality of indoor light-environment is often difficult to evaluate directly. The research results of lighting-environment visual comfort experiment show that the light-environment quality evaluation model based on C-SVM has good interpretability, strong generalization capacity and low risk of wrong classification in the limited sample space. It can effectively identify the visual comfort level of classroom light-environment, which is also a guide to other research of light-environment quality in different space types.

### ABSTRACT

The dense redevelopment of inner cities (intensification) has been accompanied by a dramatic surge in the development of multi-unit residential buildings (MURBs) within ever shrinking proximities to one another. Modern multi-unit residential building design often embodies conflicting desires for daylighting and visual privacy, or designers simply do not consider collective occupant discomfort factors. Thus, the focus of this project was to develop and validate conceptual and quantitative variables influencing visual privacy, such that future and existing residential designs can be analyzed from a visual privacy perspective. This paper formulates an approach that combines building physics (visual angles and relative brightness) with social and psychological factors to avoid conflicts between competing aspirations for sustainable and resilient buildings that promote occupant wellbeing.

### KEYWORDS

Visual privacy, occupant discomfort, visual angles, relative brightness, occupant wellbeing.

### INTRODUCTION

Visual privacy is a common perception that is influenced by different cultural, psychological and physiological experiences (Kennedy and Buys, 2015). It is a perceptual progression that occurs between an individual and 'others'. Studies show that visual privacy can be a major influence on a building inhabitant's awareness of comfort (Kang and Kim, Lee et al Lee, 2014). Practically speaking, this means that perceptions of privacy differ among cultures, age groups and sexes, and all variables should be considered in the design-appropriate levels of privacy. Globalization, urban intensification and the trend to larger glass areas in residential buildings are making visual privacy an increasingly critical consideration. Canada is a suitable "living laboratory" for examining visual privacy because it has among the highest percentage of foreign-born citizens who hold diverse perceptions of privacy due to their various religious, cultural and psychological backgrounds (Roy, 2013). Combined with a growing trend toward the use of large windows and glazed facades around the world, visual privacy is being recognized as a major problem in dense urban environments, such as the large cities in Canada where multi-unit residential buildings predominate. Architects and developers put little to no attention towards visual privacy when designing these residential buildings because the metrics of visual privacy are not part of their design vocabulary.

Theoretical approaches to privacy consider the human psychology, culture, and behaviour. Privacy has been split into different categories by theorists, where each defines the comfort level of a person with regards to being observed or touched. Since most individuals seek more privacy at home than anywhere else, the meaning of "solitude" (being free from the observation of others), defines a major need for visual privacy metrics in residential designs (Lang, 1987). When the achieved privacy is less than the desired privacy, a situation known as crowding, adaptive solutions are implemented to counteract the discomfort (Lang, 1987).

The optimum privacy can be difficult to achieve as the desired privacy from one individual to another may differ, causing the achieved privacy to result in social isolation or crowding (Altman and Grove, 1978). Meanwhile, prioritizing privacy through architectural design (e.g., small or translucent windows and moveable shading systems) may compromise views, daylight, and sense of spaciousness. The theoretical privacy mechanism mentioned by Altman is the nonverbal privacy mechanism (1978, pp.34). It suggests that body language reflects upon the level of comfort from non-verbal intrusion to one's privacy (through seeing or touching). The delinquency for someone's ability to visually step into another's private space can have no limitations. People may look into others' houses intentionally or unintentionally; but to the occupant, intention is irrelevant and still results in discomfort for the occupant. An essential factor of living in a multi-story apartment is the amount to which everyday routines are affected by "proxemics and sharing" (Kennedy and Buys, at el Miller, 2015). The connection between proxemics and privacy in housing raises the concern for personal space and the longing for a place that is acknowledged as one's own (Deasy and Lasswell, 1985). People often seek privacy and connection to the community, which creates a challenge for designers, as limits differ from one person to another. However, the connecting base-line to privacy for the occupants is usually their ability to control the privacy.

This research takes a conceptual and quantitative approach to visual privacy in multi-unit residential buildings and analyses the perception of privacy through a series of survey questions of real-life privacy related situations.

## METHODS

This research is focused heavily on peoples' perceptions of privacy which is influenced by their lifestyle and background. Therefore, this research focused exclusively on field data, and initiated the process by conducting a survey to facilitate the quantification of visual privacy comfort levels. The survey consisted of 32 questions where respondents evaluated real-life visual privacy-related scenarios. The aim of the survey was to produce a realistic setting (based on photographs and renderings) where responders were able to rate the privacy feeling with a scale value. Some of these images were taken of existing residential units in downtown Toronto. These images were then used as part of the questions in the survey to guide the responses to a personal level. Each question from the survey was defined by two visual privacy metrics that were identified to affect the visual privacy rating. These metrics are the visual angle and the brightness level. Visual angle is the viewpoint at which an object spans at the eye of an observer (COSMOS, 2003). It is the angle at which our eyes perceive the size of an object in real life, by incorporating the size of the object and its distance from the observer (see Figure 1 below). Using the equation below considers a small angle approximation.

$$\text{Visual Angle} \approx \frac{\text{Object size}}{\text{Distance}}$$

Figure 1: Visual Angle

The farther away a human is, the more private that human/occupant feels. Thus, distance is a variable that is considered in this calculation. Visual angles were chosen as the initial metric used to determine the equation for optimum visual privacy level, since it is dependent on the distance and the angle at which it is viewed. Multiple visual angles can be determined for

each window in a unit, but in this research the highest visual angle value has been utilized and ascribed to each scenario.

The brightness level is another crucial metric that defines the visibility of inside and outside. Figure 2 consists of two pictures of the same condominium, in Vancouver, in the morning and at night. In the morning, views into the condominium are very limited, whereas at night one can clearly see well into the condominium.

Figure 2: Appearance of condominium in Vancouver in the morning and at night (Gigapixel)

A brightness factor defines the light conditions that affect the privacy rating of housing design. This brightness factor is determined from a range of 1 to 5 which is applied to both the inside and outside conditions simultaneously to obtain a brightness ratio (see Figure 3). The brightness level outside and inside is dependent. For example, the sight conditions when it is bright inside and outside differ greatly compared to bright inside and dark outside. Hence, both conditions were applied as a factor, and then the ratio of what is observed inside to outside was identified.

Figure 3: Brightness factor rating from 1 to 5 and brightness ratio calculation.

When the brightness ratio approaches a value of 1/5 (very bright inside and dark outside) the occupied space is considered less private, and when the ratio approaches 5 (dark inside and very bright outside) the occupied space is considered more private. This method for estimating the brightness ratio has been created in support of this research and there are no known prior studies that calculate such factors.

The survey has been created upon the consideration of both the visual angles and brightness levels. Various scenarios were created in SketchUp and from images taken of the field study in Toronto, for the different views at which people would feel comfortable or uncomfortable in. Observers were placed in a hypothetical real-life setting (pedestrian walking, neighbour's balcony, etc.) at different distances away from occupants for visual angles to be calculated at diverse configurations. Figure 4 shows one observer looking at an occupant's window from two different horizontal distances.

Figure 4: SketchUp model. “A” from observer 5m away and “B” from observer 15 m away.

Most of the questions are scalar, meaning that pictures (like those in Figures 2 and 4) were presented and participants were asked to rate the situation by a scale of 1 (not very private) to 10 (very private). A sample question can be seen in Figure 5.

Q25) On a scale of 1 (not private) to 10 (very private), how private would you feel if you lived in this condominium at this time of day?  
Mark only one oval.

	1	2	3	4	5	6	7	8	9	10	
Not Very Private	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	<input type="radio"/>	Very Private

Figure 5. Sample question from online survey.

Overall, the survey consisted of 32 questions of this type. It was presented to a variety of age groups, genders and persons from different cultures to enhance the understanding of visual privacy in relation to identity and background. A relationship between visual privacy rating (dependent variable) and visual angles and brightness levels (independent variables) can then be established from survey answers, by graphing the results of the three variables together.

## RESULTS

Numerous relationships have been interrogated through the 32 survey questions to examine the relationships between the visual privacy metrics and age, gender, and culture. The survey was completed by 214 people varying in age, gender, background. The results were processed and modelled, using MATLAB and Excel, aiming to create an equation for visual privacy rating. To confirm the affiliation and viability of the privacy metrics, a graph was created for both the brightness levels and visual angles against privacy ratings.

Figure 6 below shows the relationship between brightness ratio levels and participant-rated privacy ratings. As seen in the graph, the hypothesis based in Figure 3 earlier is confirmed: perceived privacy decreases as the brightness ratio decreases (it is brighter indoors than out) – particularly below 1. The most critical values lie where the brightness ratios are lower than 0.5. This is where it is bright inside and dark outside, which is considered the high stakes of visual privacy issues as so much detail can be seen inside. Brightness ratio is primarily dependent on weather conditions and indoor electric lighting intensity.

Unlike brightness ratios, visual angles are influenced by geometric factors such as window size, orientation, balcony size, etc. Nonetheless, the affiliation of the visual angles with privacy ratings, from the conducted survey, shows a relatively linear relationship (see right side of Figure 6) – beyond certain angles privacy is not affected.

Figure 6. Comparison of relationship between Brightness Ratios and Privacy Ratings versus Visual Angles and Privacy Ratings.

The first and third quartiles in the graphs above lie within reasonable distance to the mean, meaning that generally the privacy is favoured under most circumstances. The quantity at which the amount of visibility (visual angle) is considered acceptable from one person to another is mutable. Cultural influence, for example, plays a key role in the value of privacy and explains the divergence between the data from one person to another, which is discussed later. Thus, the distribution of data in Figure 6 implies a combination of two observations. The first is that people feel differently about privacy and hence answer differently, while the second is that people interpreted the survey questions inconsistently. Further analysis is required understand the variability of responses.

Through MATLAB, the linear relationship between Visual Angle, Relative Brightness, and Privacy Rating was obtained (see Figure 7). Visual angles and relative brightness values can be used to estimate the privacy ratings for any room or unit in residential buildings.

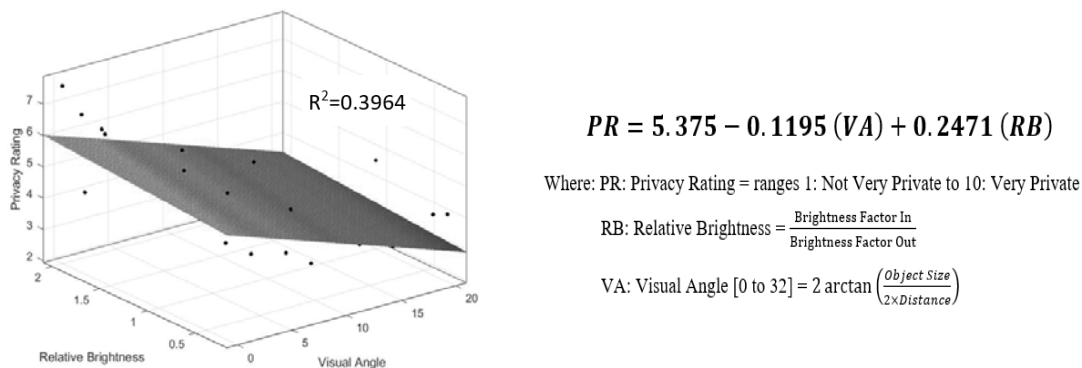

Figure 7. Graph and equation for visual privacy rating as a function of visual angle and relative brightness.

## DISCUSSIONS

One of the aims of this research was to compare the visual privacy rankings between the different genders, age groups, and cultural standards. The limited length of this paper does not permit presenting the statistics, however several relationships were found. First, culture plays a significant part in privacy ratings, hence in multi-cultural and densely developed urban regions designers should address the full range of cultural values. Second, age was

also found to be a determining factor for visual privacy standards. In this research, perceptions of privacy were more closely correlated for two age cohorts, ages 18-29 and 50+, while a difference in response was reported for the age group of 30-50 years. Young people, and especially females, demand higher levels of visual privacy to feel comfortable. The relationship between room types (e.g., bedroom/bathroom versus living room and clothing levels (e.g., fully dressed versus sleep wear) was not surveyed, but it is reasonable to assume different expectations of privacy based on these parameters. The multi-unit residential building design challenge is to recognize the importance of daylighting and views for occupant wellbeing (Veitch and Galasiu, 2012), while still providing acceptable visual privacy.

## CONCLUSIONS

Visual privacy in residential design has been an issue in various countries for many years (Kennedy, Buys and Miller, 2015). However, there has been very minimal research to develop practical design metrics for visual privacy. This paper indicates that both relative brightness and visual angle are important predictors for visual privacy. However, the large spread in the data indicate two possibilities: 1) that there are many other predictors for privacy (as preliminary examination on demographics has revealed); or 2) that there were multiple interpretations of survey questions. Field studies are needed to confirm the visual privacy metrics advanced in this paper are effective in predicting the need for mitigating measures such as plantings, screens or blinds, frosted glass, etc., and to help determine the potential tradeoffs between daylighting, views and visual privacy. In the future, a visual privacy metric could be incorporated into architectural design software tools as well as building standards (e.g., WELL™ Building Standard).

### **ABSTRACT**

Living labs offer a powerful, new way to measure human-building interactions. In addition to having the advantages of a traditional controlled laboratory setting, living labs facilitate the study of how combinations of environmental factors directly affect human health and satisfaction in a real-world setting. The aim of this experimental study was to characterize the relationship between individual-level exposure to environmental conditions and reported satisfaction with environmental quality in a simulated open-office workspace created in a living lab. Eight office workers were exposed to six different week-long combinations of light (natural and electric), sound, and thermal conditions over 18 weeks in a living lab. We assigned exposure to temperature, relative humidity, and light, specifically illuminance, to each participant using measurements from the environmental sensor in closest proximity to the participant. Sound measurements were collected by only one device, so all participants were assigned the same sound exposure. Participants also completed daily questionnaires in which they rated their level of satisfaction with the overall quality of the workplace and with specific environmental parameters in the simulated workspace. Using ordinal response mixed effects models, we found that temperature, noise, and light — individually and in combination — were significant predictors of self-reported occupant satisfaction. Our results contribute to a better understanding of the relative importance of environmental parameters to employee satisfaction in a real-world context, which may be useful for guiding and optimizing building design and management decisions to best serve its occupants.

### **KEYWORDS**

Controlled-study, IEQ, Living lab, Satisfaction, Workplace

### **INTRODUCTION**

An active area of research at the intersection of building sciences, health sciences, and behavioural sciences is understanding the relative impact of different environmental conditions on satisfaction with the indoor environment. This is important because environmental conditions are key determinants of occupant comfort and satisfaction, as well as health, well-being, and performance (Wargocki et al. 2000; Veitch et al. 2008; Lan et al. 2012; Al Horr et al. 2016; MacNaughton et al. 2017; Tanabe et al. 2014; Geng et al. 2017; Küller et al. 2006). Living labs, defined as research settings in which study participants occupy a simulated environment for an extended period of time, are well-positioned to collect this information. Living labs enable the delivery of combinations of environmental conditions, while providing the scientific rigor of an experimental study and the real-world applicability of an observational study.

The aim of this study was to examine the association between exposure to environmental conditions and reported satisfaction with environmental quality in a simulated open-office workspace created in a living lab. This study is also an extension of a proof-of-concept study previously reported by Jamrozik (2018) that found that changes in environmental office conditions affected occupants' experiences inside and outside of the space. In contrast to Jamrozik et al.'s scale of analysis at the level of weeklong "scenes" – combinations of acoustic, lighting, and thermal conditions, this study examined the daily-level relationship between individual exposure to these combinations of environmental conditions and reported satisfaction with office environmental quality. This approach was undertaken for two reasons: 1) doing so enabled an analysis at increased temporal granularity (i.e., from the average response over multiple weeks to the daily scale), and 2) actual exposure values may differ day-to-day and between weeks despite having identical scene conditions and setpoints.

## **METHODS**

### **Study design**

The Well Living Lab is a research facility consisting of six experimental modules that can be configured to simulate real-world indoor environments (Jamrozik et al. 2018). In this study, three of the fabric modules (Modules D, E, and F) were combined to form a 124 m<sup>2</sup> open office (Figure 1), which served as the experimental setting for six environmental "scenes" made up of combinations of acoustic, lighting, and thermal conditions. A baseline condition (scene 1) was designed based on existing research and the participants' previous office in order to simulate environmental conditions commonly found in an average office setting.

Figure 1 shows the layout of the modules where eight office workers sat at desks 1-4 and 6-9 and worked in the simulated office, where they were exposed to week-long combinations of natural light (three levels), electric light (four levels), sound (five levels), and temperature (three levels) (Table 1). A nine-week sequence of scenes (order: 1, 2, 3, 4, 1, 2, 5, 6, 2) was repeated twice over a period of eighteen weeks, from May 31, 2016 to September 30, 2016.

### **Acoustic, lighting, and thermal conditions**

Using the Center for the Built Environment Thermal Comfort tool, assuming a mean radiant temperature of 26.0°C, a wind speed of 0.1 m/s, relative humidity (RH) of 45%, a metabolic rate of 1.1 met, and a clothing level of 0.7 clo (Hoyt et al. 2017), three temperature setpoints were chosen for this experimental study: 21.7°C (cool-neutral temperature), 23.9°C (neutral-warm), and 19.4°C (uncomfortably cold). Additionally, study participants were exposed to five acoustic conditions including sound masking via white noise (two conditions), sound masking via simulated speech (two conditions), and no sound masking.

To vary participant exposure to natural light, windows were equipped with electrochromic (EC) glass (VIEW Dynamic Glass, Inc.) which provided controllable window tinting. Sheer shades (Phifer SheerWeave 4100, 10%, Alabaster – motorized by Lutron) provided occupants a means of controlling natural light via wall switches next to windows, and blackout shades (Mermet Blackout-White – motorized by Lutron) were used to simulate a windowless office. The EC glass tint varied between clear (visible transmittance 58%), dark (visible transmittance 1%), and intelligence mode, in which tint level is automated and varied over four levels throughout the day to limit glare and reduce solar heating. For electrical lighting (S30, Ketra), the following color correlated temperature (CCT) setpoints were used: 2700°K (warm colour), 3500°K (warm-neutral white), 4200°K (cool-neutral white), and 6500°K (cool white).

## Participants

The eight participants recruited for this study were employees of the Mayo Clinic in Rochester, Minnesota, all of whom were adults between the ages of 18 and 65 years, able to conduct current work duties from a remote location (i.e., the living lab), and able to work 20-40 hours per week. Full inclusion and exclusion criteria for study participants have been previously described in detail by Jamrozik (2018). One participant (located at desk 4) was removed from the data set due to sensor connection issues, leaving a total of seven participants for inclusion in the data analysis (mean age = 46.9 years, standard deviation (SD) = 13.1). The study was approved by the Mayo Clinic Institutional Review Board.

Figure 1. Layout of the experiment space and locations of a) temperature, relative humidity (RH), and illuminance sensors, b) thermostats, sound level meter, and ventilation diffusers, and c) electrochromic (EC) tint glass, sheer shades, and blackout shades. Participants were located at desks 1-4 and 6-9.

## Survey design

At the start of the study, participants completed a baseline survey asking about demographics, work, and health behaviors. At the end of each day, participants completed questionnaires asking about satisfaction with environmental conditions and their overall work experience for the day, as well as their mood and health behaviors. In this study, we focused our analysis on daily ratings of overall workplace quality (How much did your work environment make it easy for you to get your work done? 1-5 scale; 1: Not at all, 5: Very much) and satisfaction with the noise level, lighting, and temperature (Today, how satisfied are you with the \_\_\_ in the work environment? 1-5 scale; 1: Very dissatisfied; 5: Very satisfied).

## Data collection, processing and analysis

At desk-level, wireless temperature and humidity sensors (Wireless Humidity Sensor, Monnit Corp.) collected data at five-minute intervals, and wireless horizontal illuminance sensors (Lux1000 Light Level Sensor, Wovyn LLC) collected data at ten-minute intervals. Sound level was measured every ten seconds by a single sound level meter (XL2 Audio and Acoustic Analyzer with M2211 Microphone, NTi Audio Inc.) located at desk 5. Because of connection issues for the temperature and RH sensor located at desk 4, which resulted in missing data, all information collected from the participant located at desk 4 was excluded from the analysis.

The calculation of average daily exposure was restricted to measurements collected between 7:00 and 17:00 CDT because participants' usual working hours were 6:30 to 17:30 CDT. We performed ordinal mixed effects regression analyses using the 'ordinal' package in R (Version 3.4.0). Day of the week, calendar date, and study week were assessed for confounding and not included in the final models. Final models included sound level, illuminance, temperature, and RH (all as continuous variables), an indicator for study scene, and a random intercept for study participant. The number of quadrature points in the adaptive Gauss-Hermite approximation was set to 10 to improve the accuracy of maximum likelihood estimates. To facilitate direct comparison across environmental conditions, odds ratios (ORs) and 95% confidence intervals (CIs) are reported for a normalized unit of exposure, i.e., a one standard deviation (SD) change in estimated exposure, assuming a linear exposure-response function.

## RESULTS

Overall (across the six experimental scenes), mean ( $\pm$  SD) desk-level temperature and RH was 24.1°C ( $\pm$  1.7) and 42.9% ( $\pm$  5.8), respectively, and mean illuminance was 778.2 lx ( $\pm$  692.8). Measured desk-level temperatures were, on average, higher than setpoints by 1.2 to 3.1°C. Mean RH across different scenes ranged from 37.6% ( $\pm$  3.0) to 48.6% ( $\pm$  4.5). Substantial variation was observed in mean illuminance between and within scenes, with estimates ranging from 413.1 lx ( $\pm$  495.0) to 1001.8 lx ( $\pm$  622.5). The mean sound level was 47.1 dBA ( $\pm$  1.0) and showed little variation between scenes, although measured sound levels were loudest for the two scenes in which sound masking was white noise (Table 1).

### Workplace quality satisfaction

Using ordinal response mixed effects models, we found that lower measured illuminance was significantly associated with greater workplace quality satisfaction and greater satisfaction with sound levels (Table 2). Additionally, greater measured overall volume was significantly predictive of increased satisfaction with overall workplace quality, sound levels, and temperature. Higher measured temperature was also significantly associated with increased satisfaction with temperature. We did not observe any significant associations for reported satisfaction with lighting. Although convergence criteria for all models were met, the condition number of the Hessian exceeded  $10^7$ , which indicates that models were not well-defined and should be interpreted with caution. The large variability in illuminance in this study likely contributed to the observed lack of empirical identifiability (e.g., scaling issues).

## DISCUSSION

Utilizing a living lab designed to simulate an open office workspace, we found that measured illuminance and sound were significantly predictive of satisfaction with overall workplace quality, and that this pattern was also true for satisfaction with sound levels. However, in contrast to these results, none of the four examined environmental parameters were associated with reported satisfaction with lighting. Additionally, we found that measured temperature and sound were significantly associated with satisfaction with temperature.

As reported previously by Jamrozik (2018), when participants were asked whether they were more sensitive to certain environmental conditions than to others, they most frequently reported that cold temperatures were the most noticeable and unpleasant conditions, followed by noise, and then lack of daylight. This analysis complements the previous qualitative findings, by quantifying the link between individual-level exposure to environmental conditions and reported satisfaction with environmental quality. However, based on model performance metrics, the magnitude and direction of our results should not be interpreted as indicative of the relative importance of environmental conditions nor of the direction of the

† P-value &lt; 0.05; ‡ P-value &lt; 0.01

relationships. Accordingly, although we observed interesting associations between environmental parameters and satisfaction with other parameters (e.g., light was predictive of satisfaction with acoustics; sound was predictive of satisfaction with temperature), these findings may be due to multi-collinearity since exposure was experimentally delivered in scene combinations. Nonetheless, our results support a link between temperature, noise, and light and satisfaction with workplace quality and/or indoor environmental conditions.

## CONCLUSIONS

In this study we demonstrate that living labs can be used to identify the environmental conditions predictive of higher self-reported satisfaction with overall workplace quality, and with specific workplace ambient conditions. We found that temperature, noise, and light are important, predictive factors of occupant satisfaction, consistent with prior studies. Future studies should examine more combinations of environmental parameters in a real-world setting, in order to generate evidence that may guide and optimize building design and management decisions to best serve occupants.

## ACKNOWLEDGEMENT

We sincerely thank the participants for their time and participation in this study. We especially thank the staff of the Well Living Lab who kept everything running, and the staff and leadership teams of Delos Living LLC, Mayo Clinic, the Well Living Lab (WLL), and the WLL's Joint Steering Committee, Scientific Advisory Council, and Alliance members.

### ABSTRACT

Despite the benefits of occupant behavior (OB) models in simulating the effect of design factors on OB, there are challenges associated with their use in the building simulation industry due to extensive time and computational requirements. To this end, we present a novel method to incorporate these models in building performance simulations (BPS) as design-sensitive schedules. Over 2,900 design alternatives of an office were generated by varying orientation, window to wall ratio (WWR), the optical characteristics of windows and blinds, as well as indoor surfaces' reflectance. By using daylight simulations and stochastic OB modeling, unique light use schedules were generated for each design alternative. A decision tree was then developed to be used by building designers to select light use schedules based on design parameters. These findings are relevant for building energy codes as they provide an approach to incorporate design-sensitive operational schedules for use as BPS inputs by practitioners. These design-sensitive schedules are expected to be superior to default ones currently specified in codes and standards, which ignore the effect of design factors on OB, and ultimately on energy consumption.

### KEYWORDS

occupant behavior modeling; light use schedules; building performance simulation; decision trees; office buildings

### INTRODUCTION

Occupant behavior (OB) is recognized as one of the sources of uncertainty in building performance simulations (BPS) (Delzendeh et al., 2017; Haldi and Robinson, 2010; Parys et al., 2011). It is often represented in BPS based on default assumptions rather than measured observations or predictive models (Virote and Neves-Silva, 2012), which could lead to a performance gap between estimated and measured energy consumption (Menezes et al., 2012). Default schedules, specified in building energy codes and standards, do not necessarily reflect the way buildings are occupied and used today, given new societal and technological trends (O'Brien et al., 2017). For example, default schedules assume 90 – 95% occupancy for office buildings during regular business hours. However, previous studies showed that peak occupancy rarely exceeds 50% in private offices (Duarte et al., 2015). The current schedule-based occupant modeling approach also assumes occupants are passive recipients of indoor environmental conditions and do not react to discomfort (Hong et al., 2015). However, the relationship between occupants and buildings is a two-way process, in which occupants' actions that influence energy consumption, are in turn influenced by building design and indoor environmental conditions (Gaetani et al., 2016; Haldi and Robinson, 2010; Yan et al., 2015). Therefore, default schedules that are currently prescribed in building energy codes and standards do not incentivize designers to explore the effect of design decisions on OB.

To partially address this issue, previous studies introduced stochastic models to represent OB more accurately in BPS based on monitoring of existing buildings (e.g. Haldi and Robinson,

2010; Page et al., 2008; Reinhart, 2004). These models can simulate occupants' presence or actions when triggered by environmental or situational conditions (Hong et al., 2016; Parys et al., 2011). Actions may include the use of lights, blinds, windows, thermostats or other building systems. Despite the advances in OB modeling research in the past decade, several issues remain unresolved such as these models' transferability and validation on a wider scale (Lindner et al., 2017). Similarly, the significant computation time required to run these models in BPS hinders their use in the building simulation industry, which is the main issue we address in this paper.

Quantifying the effect of OB on buildings' energy consumption requires integrating OB models in BPS tools. Several approaches can be used to achieve this, depending on the specific tool being used, its capabilities, and the available information about the model (Hong et al., 2017). Regardless of which approach to follow, one of the main challenges facing OB models' implementation in the building simulation industry is the extensive time and computational requirements for integrating them in BPS tools (Yan et al., 2015). As an alternative approach, we present a workflow to generate design-sensitive schedules that can be readily used as BPS inputs. Generating these design-sensitive schedules is based on parametric simulations of building design alternatives and using data-mining techniques to establish the relationship between design parameters and operational schedules. The process of generating these schedules which entails modeling OB needs to be performed only once, while its results can be used by building simulation practitioners to select design-sensitive schedules for their proposed designs.

The main goal of this paper is to provide a proof of concept application of the proposed workflow. However, undertaking this workflow on a larger scale to include other design factors, end-uses, and locations is a necessary step before results can be used by building simulation practitioners. Specific objectives of this study focused on generating light use schedules for 2,916 unique design alternatives of an office in Ottawa, ON. For each design alternative, parameters that influence workplane illuminance, and consequently the way occupants use lights were changed. These design parameters included, building orientation, WWR, windows and blinds' visible transmittance, wall, floor, and ceiling materials' reflectance. The second objective focused on developing a decision tree classification model to help in selecting light use schedules based on design parameters.

## METHOD

The RADIANCE-based simulation program DAYSIM was used to calculate workplane illuminance in an office room during the whole year. The shoe-box office model, shown in Figure 1, had a floor area of 15 m<sup>2</sup> and height of 3 m<sup>2</sup>, and was simulated in Ottawa, ON.

Figure 1 Three-dimensional diagram of the modeled shoe-box office

All possible combinations of the design parameters shown in Table 1 were modeled, resulting in 2,916 design alternatives. A window was modeled on one façade, whose dimensions were calculated to correspond to the proposed WWR for each design alternative. Since workplane illuminance, which triggers the use of lights is also influenced by blinds' position, five whole-year simulations were performed with the blind position in five equal increments: fully open, 1/4, 1/2, 3/4, and fully closed, resulting in a total of 14,580 simulations.

Table 1 Design parameters used to model different design alternatives of the shoe-box office model

Design parameters	Variations			
Building Orientation	South - 0°	West - 90°	North - 180°	East - 270°
WWR	20%	40%	60%	
Glazing Visible Transmittance	0.5	0.6	0.7	
Blinds Visible Transmittance	0.05	0.1	0.15	
Ceiling Reflectance	0.6	0.7	0.8	
Floor Reflectance	0.2	0.3	0.4	
Wall Reflectance	0.4	0.5	0.6	

The next step entailed generating light use schedules for each design alternative based on modeling OB. An occupancy model developed by Page et al. (2008), a blind use model developed by Haldi and Robinson (2010), and a light use model developed by Reinhart (2004) were implemented in MATLAB for each design alternative. Details about these models' parameters and their implementation process can be found in Gunay et al. (2016), and Lindner et al. (2017). Results were used to calculate an average daily light use schedule for each design alternative, based on their annual light use profile.

A decision tree classification model, developed using the Classification and Regression Trees (CART) algorithm by Breiman et al. (1984), was then implemented in MATLAB to predict daily light use based on design parameters. This algorithm generates a flowchart tree structure to categorize data into various subsets and is applicable for predicting categorical responses. Therefore, the average daily light use schedules which represent the target response were first transformed into a categorical variable. For each design alternative, the duration of light use per day was calculated from its daily light use schedule generated earlier. The duration of light use was then categorized as High, Medium, or Low by splitting the dataset equally over these three categories. Results of this equal split indicated that light use durations below 5.7 hours/day were classified as low, durations between 5.7 and 6.7 hours/day were classified as medium, and durations above 6.7 hours/day were classified as high. Therefore, three categories of light use schedules were used to build the decision tree classification model, by assigning each of the 2,916 design alternatives to one of these categories.

To provide a practical application for the developed decision tree classification model, three distinct light use schedules were specified that correspond to the three categories of light use durations. These schedules can be used as inputs in BPS tools, and have the same shape profile as the average light use schedule calculated from the entire dataset for all design alternatives. They were generated by normalizing the average light use schedule for all design alternatives, and multiplying it by the average light use duration of each category (5.15, 6.2, 7.4 hours/day for low, medium and high categories, respectively).

Developing the decision tree was a two-step process, where the dataset was split into two subsets; a training subset randomly populated using 80% of the data, and a validation subset populated using the remaining 20%. Readers can refer to (Breiman et al., 1984) for more

details on the methodology of developing decision tree classification models. The training subset was then used to generate the model, while its accuracy was evaluated by making predictions against the validation subset. Accuracy was measured by comparing the predicted categorical response from the model to the original category of each data-point in the validation subset. Furthermore, the relationship between original values of light use duration in the validation subset (prior to categorization), and the average light use duration of its predicted category was assessed using the coefficient of determination  $R^2$ .

## RESULTS

Using the CART algorithm, a classification decision tree, shown in Figure 2, was developed. Post-pruning the decision tree with a confidence factor of 0.01 resulted in a total of seven decision tree nodes, of which eight were leaf nodes, representing low, medium, or high light use durations. The confusion matrix, shown in Table 2, evaluated the decision tree's classification accuracy. It indicated that 61% of the validation dataset, were correctly classified. However, only 1.9% of the dataset was incorrectly classified by more than one profile away from the correct one (e.g. High light use duration being classified as low). As shown in Table 2, the number of correctly classified records is given in the main diagonal, i.e. upper-left to lower-right diagonal; while others were incorrectly classified. Using the 584 records in the validation subset, and comparing their daily light use durations to the average light use duration of their predicted classes,  $R^2$  was 0.66.

Despite the relatively low accuracy of this decision tree, one of its main advantages is the ease of use for practical applications by following the path from the root node to any of the leaf nodes. For example, if WWR is less than 0.3, building orientation is higher than  $225^\circ$ , and glazing visible transmittance is higher than 0.5, then medium light use duration and its corresponding schedule should be used in BPS. Changes to the parameters of the decision tree algorithm, the cross-validation method or the classification method used to split target variables can improve its accuracy. However, the main goal of this paper is demonstrating the workflow to generate design-sensitive schedules, and not improving the accuracy of the specific data-mining techniques used.

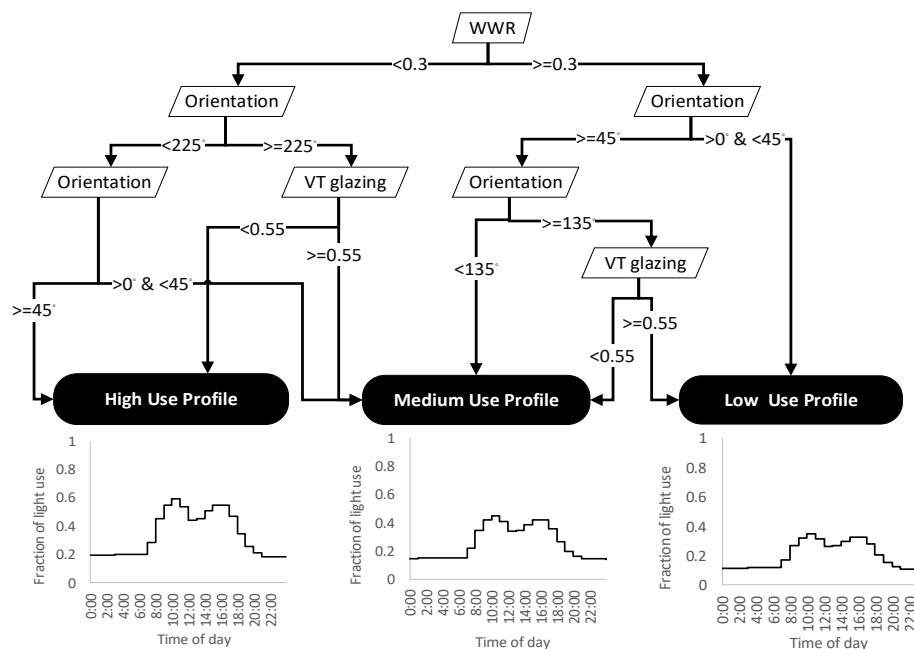

Figure 2 Decision tree diagram for selecting light use profiles

Table 2 Decision tree confusion matrix

Classified as →	Low light use profile	Medium light use profile	High light use profile
Low light use profile	137	49	4
Medium light use profile	78	116	50
High light use profile	7	39	103

## DISCUSSION

Decision trees can help designers and building simulation practitioners select approximate light use schedules based on their design. Instead of using one default light use schedule that does not consider the effect of design parameters on OB, the proposed method provides three potential schedules that correspond to different building designs. Given the modeled office location in Ottawa, ON, future research should include other locations which can be treated as an additional parameter in the decision tree to select location-specific light use schedules.

It is important to note that the specific daily light use durations and schedules reported in this study were a function of the OB models used, and the design parameters investigated. However, more robust OB models and other parameters that influence OB such as clothing, and the decision to sit or stand at modern workstations should be investigated in future research. The presented workflow only focused on showing a methodology to eliminate the extensive time requirements for running OB models by providing design-sensitive schedules, but it did not address these models' transferability or validation in other buildings.

## CONCLUSION

This paper demonstrated a novel method for generating design-sensitive schedules that can be used in BPS. For proof of concept, a decision tree was developed for selecting light use schedules based on design parameters. These design-sensitive schedules represent an improvement over the default schedules provided in current codes and standards, which do not match actual building operations. One approach to improve the accuracy of default schedules could be updating them based on data from a statistically representative sample of existing buildings, taking their design parameters into consideration. However, given the extensive logistical requirements for data collection at such large scale, the method presented in this paper relies on data-mining and parametric building simulations to account for the effect of building design on OB. This method only addresses the time and computational barriers to OB modeling, by providing ready-to-use design-sensitive schedules that can be used as BPS inputs. It does not address other issues related to OB modeling such as models' validation, which was outside the scope of this paper. Incorporating these schedules in building codes and standards would require extending the workflow on a larger scale for different locations and building archetypes.

## ACKNOWLEDGEMENT

The generous financial support of Natural Resources Canada through the Clean Energy Innovation Program is acknowledged. The authors have greatly benefited from discussion with project partners RWDI, Autodesk, and National Research Council Canada, and would like to acknowledge their generous support for this research.

### **ABSTRACT**

In Brazil, there has been an increase in the use of certifications designed to assess and improve building performance. Despite these advances, there is still little knowledge concerning the buildings' post-occupancy. Thus, the present work aimed to evaluate the occupants' behaviour regarding the use of lighting and internal shading devices. Classrooms and laboratories at UFMG Architecture and Design School were used as case study. The main objective was to analyse how a cycle of influences works: how occupants influence energy consumption and act in relation to the buildings systems, as well as how the building and the internal systems influence the occupants' behaviour. Firstly, daylighting and artificial lighting conditions of the rooms were diagnosed. As for the occupants' behaviour analysis in loco, observations were made to evaluate barriers and potentials in the systems use. Afterwards, changes were made in the lighting circuits division, in the curtain types and informative posters were installed in the studied rooms. The results showed that there is a hierarchy in the use of classroom systems, in which professors are the main controllers and that in laboratories the systems use is well distributed among occupants. It was considered that the original evaluated systems did not meet the occupants' expectations in general, so changes were proposed. The changes proved to be efficient once the interaction of users to the systems improved in quality and in number. This research allowed to infer that a more occupant-centered design leads to a more efficient use of spaces.

### **KEYWORDS**

Occupants' behaviour, Energy Efficiency, Buildings performance, School Building.

### **INTRODUCTION**

Buildings account for approximately 40% of the world energy consumption (IEA, 2013) and for 50.8% of all the electricity consumed in Brazil (EPE, 2016). According to PROCEL (2005), lighting represents 22% of this consumption to commercial buildings and 23% to public buildings. The emergence of building certifications and the effort that has been observed nowadays regarding this issue, in Brazil and in the world, points to visible advances for more efficient buildings. However, little is known about the operation of a cycle of influences that is essential for the buildings energy efficiency: how occupants influence the efficiency and comfort of buildings and how buildings as proposed influence the occupants' behaviour.

Lindelof and Morel (2006) described the results of an analysis carried out in Switzerland. They concluded that after the occupants' arrival and departure periods in the office the lighting system was only turned on again in cases of extreme discomfort. The authors believe that this behaviour was a consequence of the position of the light switches, which were located near the offices entrance door and not near the workers' tables. Mahdavi et al (2008) described a empirical study of occupant's operation of lighting and shading systems in Austria office

buildings. They concluded that patterns of user control behaviour depends on indoor and outdoor environmental parameters, as the illuminance and the solar radiation incidence. They also realized that there is a relationship between occupancy and lighting operation. Based on a literature survey on drivers and models, Fabi, Andersen and Corgnati (2015) reinforced that the probability of light-switching is highly related to people's arrival or departure in the offices. They also concluded that it is essential to consider the occupants' individuality in order to understand different behaviours, as some individuals consider daylighting when switching on the lights, whereas other occupants switch on the lights independently of daylighting. Reinhart and Voss (2003), while conducting a survey at an office building where one or two people worked, in Germany, concluded that groups of individuals follow a very similar behaviour, whereas isolated individuals follow more diverse patterns. The authors verified that all building occupants considered daylight, which could confirm the influence of architectural conception and lighting system proposed for the building on the differentiated occupants' behaviour.

Jennings et al (1999), after testing different lighting control technologies in an office building in San Francisco, concluded that the lighting requirements of occupants depend on their type of work. Daylight dimming, as an example, showed to be more adequate for workers who stay at their desks all day. Moore, Carter and Slater (2003) also concluded, after a long-term study which monitored the switching behaviour in offices where occupants could vary the level of illuminance on their working areas, that user controlled lighting systems could save energy, keeping the occupant's comfort. LEED Reference Guide for Green Building Design and Construction (USGREEN BUILDING COUNCIL, 2009) indicates that independent lighting controls should ensure occupants' autonomy in changing them in order to promote comfort, productivity and well-being. It also indicates that windows must be treated in order to allow appropriate levels of illumination without disrupting projections.

Gyberg and Palm (2009), in a study carried out on residential buildings, concluded that to change people's behaviour, it is necessary to ensure that the choices can be made by the individual, by the provision of design alternatives that do not affect their lifestyle. On the other hand, after analysing the use of curtains, windows and lamps in offices in Austria, Mahdavi and Proglhof (2009) verified how difficult it is to estimate a single individual's behaviour. Norman (2010) argues that bad projects, created for people the way designers would like them to be and not as they really are, constitute the real causes of design inefficiency. On the other hand, ISO 50.001 (2011) presents a methodology based on a continuous improvement model - "Plan-Do-Check-Act" - which points out the need for constant checks on installed systems to guarantee their quality, efficiency and understanding by their users.

Therefore, the present research aimed to verify the occupants' behaviour regarding artificial and daylighting systems, by identifying the barriers and potentialities of installed systems and proposing changes to enhance lighting and daylighting systems use.

## **METHODS**

### **Case Study: Architecture and Design School - UFMG**

For the present research, three classrooms and three laboratory rooms of the Environmental Comfort and Energy Efficiency in the Built Environment Laboratory (LABCON) of the Architecture and Design School of the Federal University of Minas Gerais (EAD-UFMG) were investigated. The rooms presented windows faced to different orientations and solar control elements. Classroom A has windows facing the North and South façade, translucent curtains in all windows and external shading devices to the North (Belo Horizonte is in the South hemisphere). Classroom B has windows oriented East façade and presented blackout curtains.

Classroom C windows faced West and besides blackout curtains presented the windows painted in white which indicated extreme user discomfort. The three rooms of the Laboratory face West and presented white metallic horizontal venetian blinds (Figure 1). All studied rooms presented internal controls for the artificial lighting switching, located next to the doors.

Figure1 – Classrooms A, B e C and laboratory rooms 01, 02 e 03, respectively.

### **In loco Observation and daylighting analysis**

The occupants' behaviour was investigated by a group of 3 *shadow observers* (an observer was always present in each of the studied rooms but not identified) during a total period of 161 days divided according to the classes schedule and the Laboratory occupation hours in the mornings and afternoons. Classroom A was observed in 31 classes (totalizing 136 hours); Classroom B in 34 classes (totalizing 111 hours); Classroom C in 21 classes (totalizing 56 hours); Room 1 was observed for 24 periods (totalizing 129 hours); Room 2 for 27 periods (totalizing 145 hours); Room 3 for 24 periods (totalizing 136 hours). For the data collection, checklists were fulfilled by each observer, that covered six aspects: General Characteristics of the room; Visual activities; Occupation; Lighting system status; Solar Incidence in the work plane; control systems and Use of windows. The observations were divided into four parts: a) rooms as originally configured, b) after changes were made in the lighting circuits, c) after the substitution of the solar shading devices and d) after the insertion of informative posters.

The daylight autonomy (DA) was analysed through simulations in Daysim software to help analyse the potential use of daylighting in the studied rooms.

### **Changes carried out in the lighting control systems and in the window shading devices**

The observations allowed the researches to point out barriers and potentialities of the existing systems. After that, changes were made in three stages: 1) Lighting system: circuit division modifications to allow the integrated use of daylighting and artificial lighting and light switches reorganization to better express the spatial distribution of the luminaires. 2) Solar shading devices: replacement of the blackout curtains for venetian blinds. The purpose of this change was to allow greater availability of daylight and to broaden the possibilities of user interaction with the system by changing the fins position. 3) Insertion of informative posters: this step was intended to fill up the lack of readability of the existing systems and to test the effectiveness of graphic representations of the ambient systems in informing users how to better use the venetian blinds and lighting switches. At each change, a new diagnosis was made to verify the effectiveness of the changes and the need for further modifications in the systems.

## **RESULTS**

In the first stage, when rooms were observed as originally configured, Classroom A and the laboratory rooms presented solar shading devices considered to be effective in controlling the

sun incidence indoors and the artificial lighting was adequately integrated with daylighting. On the other hand, classrooms B and C presented no integration with daylighting; besides that, the blackout curtains obstructed from 30 to 50% the window area. Daylight simulations showed that in classroom A the luminaires located near the windows could be turned off during the whole morning and part of the afternoon. Computer simulations also showed that if the blackout curtains were substituted by internal venetian blinds, in Classrooms B and C, the Daylight Autonomy near the window would be superior to 80% in all classrooms when there was no sunlight incidence in the façade.

For the laboratory offices, the use of integrated daylighting and artificial lighting systems showed greater potential in the morning during the first stage of the observations. In the afternoon, the venetian blinds tended to remain closed or partially closed in order to control sunlight radiation incidence once their windows face West. The observations pointed out that the professors were the main controllers of the lighting systems in the classrooms and that changes occurred mainly upon arriving and leaving the rooms. Changes during classes occurred only when the lack of lighting was noticed or when a change in the visual task was necessary (mainly for data-show use). In the laboratory rooms, there was no pre-defined controller and more changes were noticed in the lighting systems associated with the arrival of new occupants.

In the second stage of observations, after the changes to enhance the systems operation in classrooms B and C were made, it was found that the use of integrated daylighting and artificial lighting became more significant in both classrooms. The luminaires located near the windows remained turned off in 50% and in 67% of the observed classes in classrooms B and C.

Finally, after informative posters were fixed, luminaires association with daylighting enhanced and luminaires located near the windows remained turned off in 87% and in 67% of the observations in classrooms B and C, respectively. As for the LABCON rooms, luminaires located near the window were turned off in 34% of the observed days and the position of venetian blinds was modified in more than 50% of all observations. For classroom A considered to be the better daylit room in the study, on the other hand, the occupant behaviour was not significantly altered.

Regarding the use of solar shading devices, a tendency to preferably open the venetian blinds or curtains positioned on the movable parts of the windows was observed. This was mainly due to ventilation needs than to the intention of enhancing daylighting. After the substitution of blackout curtains to venetian blinds, an increase of difficulties in using this system was noticed. There was also an increase in the number of changes made in the venetian blinds especially during the classes where the data-show was used. The difficulties in the use of the blinds were reduced after the informative posters installation.

## **DISCUSSIONS**

The observations made reinforced the conclusions drawn by Lindelof and Morel (2006), who claimed that occupants tend to act in lighting systems upon arriving and leaving the rooms and that during this interval they only act on these systems when they feel disturbed or when there are changes in the visual task.

The lack of a user behaviour pattern in LABCON rooms confirmed the findings of Reinhart and Voss (2003), who observed that behaviours of groups of individuals are standardized, whereas isolated individuals follow a more diverse pattern of behaviour. While in the classrooms the use of the lighting system was mostly associated with the type of class that took

place and data-show use, in the laboratory rooms the use of the lighting systems was more related to the room occupation.

It was verified that, accordingly to the LEED Reference Guide, when the room presents different control options for the lighting systems, usage is enhanced. This finding also confirms the conclusions by Gyberg and Palm (2009) that individuals should have choices. The alterations made in the original systems enhanced occupants' behaviour, reinforcing Norman's (2010) conclusion that the inefficient use is a consequence of project failures. The significant increase in the number of observed cases in which the occupants had difficulty in using the venetian blinds, after they substituted blackout curtains, showed that the installed system was not intuitive enough to its users, confirming once again Norman's (2010) conclusions.

Lindelof and Morel (2006) statement in that users of rooms act on systems when they are disturbed was confirmed in all analysed rooms, once curtains and venetian blinds were closed when there was incidence of direct solar radiation in the work planes or desks. In this way, it was verified that in favourable orientations or when external shading devices were present, there were fewer actions in the solar incidence control system.

Observations also reinforced the validity of the model of continuous improvement proposed in ISO 50.001 (2011), as it was verified that each system change was correspondent to a change in user behaviour.

The study also showed the importance of detailing systems. The use of venetian blinds was an interesting alternative to encourage the use of daylight integrated with artificial lighting. As observed, the modifications in the curtains were made only to enable the opening of the windows for ventilation and not to improve daylighting. So, testing venetian blinds divided in 2 parts and not in 4 parts, as the original venetian blinds, could be a great alternative, as when they were opened for ventilation purposes, daylighting would automatically enhanced as the fixed parts of the windows would also be uncovered. This new system would probably work well in rooms with lower problems of direct sun incidence in the work planes.

## CONCLUSIONS

The present study showed that the usage efficiency of the buildings depends greatly in the architectural and interior systems design. If users tend to act on existing systems either when arriving or leaving internal spaces or when they are disturbed, it is concluded that the best designs are those which demand the minimum number of changes by users, especially when entering the rooms. Therefore, designers should be aware of the many factors that may influence the user behaviour and pay special attention to the first occupancy hours as they may determine if lighting systems will need to be turned on. The correct choice of room orientation and proposition of an adequate solar control system, consistent with the activities that will be carried out, is a point that must be observed. External elements that guarantee visual and thermal comfort showed to be preferable than internal shading devices that require special handling by the occupants.

In the study case, LEED recommendations contributed to the improvement of the use of the lighting system, confirming that not only the occupants influence the efficiency of the proposed system, but the way the system is proposed also influences the behaviour of the occupants.

It was observed, from the methodology applied in this work – which consisted in performing changes and re-evaluating the space use after the changes – that the process of working in a

cycle of continuous improvement is fundamental to improve the quality of existing systems. Working in a cycle of continuous improvement is also essential to understand the relations between systems' use and user behaviour.

Finally, it is recognized that projects are not static, as the needs change and since users of each space are different. When retrofitting a space, the decisions made must contemplate the resulting quality of the space and especially the users' well-being. It is only by observing the occupants' behaviour that patterns can be understood and it is only after understanding them that good projects can be designed. The way the design is thought influences greatly how users act in a particular building.

### ABSTRACT

It is challenging to design buildings that simultaneously consider both the dynamic nature of daylight and specific occupant preferences. The authors have investigated this problem by studying the performance of four specific shading strategies using quantitative measurements of occupants visual comfort: discomfort glare and daylight availability. This paper specifically evaluates the performance of four shading strategies, two types of electrochromic (EC) glass, an automated fabric roller shade, and a venetian blind in a building located in the Southeastern United States. This paper examines how these technologies impact occupant visual comfort and it also examines how the buildings perform relative to the two metrics outlined in IES LM-83-12. Horizontal illuminance and high dynamic range images were recorded to assess the existing luminous environment in order to better understand the potential of various shading strategies. Calibrated daylighting models were also constructed in DIVA. Our results suggest that perimeter-zone occupants benefits from EC glass as it can reduce more than 40% of glare annually in this zone. Findings from the interior zones are shown that all four shading strategies perform quite similarly in regards to reducing the glare. This study suggest that by providing a designer at early-design-stage with direct information related to the level of daylight availability and glare condition within a space will lead to improve occupant's visual comfort.

### KEYWORDS

Visual comfort; Shading strategies; Office building; Daylight Glare Probability (DGP)

### INTRODUCTION

Designing a well-daylit space requires to satisfy both qualitative and quantitative aspects of daylight by balancing daylight provision with occupant visual comfort in both core and perimeter zones of the work environment. Over the past two decades, much of the available literature on visual comfort deals with glare and the amount of light as the two most reliable metrics. Similarly, Carlucci (2015) reviewed the literature of several studies and highlighted that over 75% of metrics employed glare and amount of light to assess the visual comfort. Daylight Autonomy (DA) is one of the most common used approach to assess the annual amount of daylight in a space (Reinhart and Wienold, 2011). Results of various studies showed while DGP performs better than the other metrics in predicting discomfort glare when the direct sun is present, the DGP isn't effective at predicting contrast-based discomfort glare (Van Den Wymelenberg et al., 2010; Pierson et al., 2018; Jakubiec and Reinhart, 2012; Kleindienst and Andersen, 2009). This view is supported by Konis (2014) who found that simple contrast ratios predicted discomfort best in 'core' zones of buildings further than 6m from the facade. Together, in all the studies

reviewed here, DGP is recognized as the most robust glare metric as it is least likely to produce inaccurate glare prediction and also has a stronger correlation with vertical illuminance on the eye when bright, direct sunlight is generally associated with glare such as perimeter zone. In modern office spaces with large glazing facades, natural light coming in through the window can increase the visual comfort of occupants by providing the access to views, treating sleep disorder, and improving concentration and productivity of the working environment (Andersen, 2015; Keis et al., 2014). However, direct sunlight can cause visual discomfort in the form of glare. Therefore, the goal of shading technologies is to control the direct entry of sunlight from the windows in order to prevent severe glare. In order to avoid glare related problem which is the main cause of visual discomfort within office spaces, the direct sunlight should be blocked by using advanced glazings and innovative shading systems (Tzempelikos and Athienitis, 2007). Unlike the conventional shading strategies, the dynamic shading strategies, such as electrochromic glass, prevent severe glare, while also maintaining access to daylight and outdoor views. Electrochromic glass as an active device respond to various sensors (illumination and temperature) and the voltage causing the change in transmission. Following those works, this paper aim to investigate the visual comfort using the simulation-based visual comfort to evaluate the performance of various shading strategies in an open-office space. The objective of this paper is to assess the ability of four different shading strategies to reduce excessive glare while maintaining sufficient daylight through the space.

## METHODOLOGY

This study was conducted on the southwest side at the upper floor of a side-lit open office located in Charlotte, NC. The Southwest side of the office is chosen due to extreme condition related to sun exposure. The building form is square shape with a 22m deep floor plate. It is important to note that the core of the building (length 26.5m and width 22m) including stairs, elevators, and bathrooms, is excluded from the analysis. To analyse daylight sufficiency of the space, annual illuminance is used to quantify Spatial Daylight Autonomy (sDA) and Annual Sun Exposure (ASE) on horizontal surface for window without shading.  $sDA_{300lux50\%}$  expressing the percentage of analysed floor area that meet or exceed a threshold of 300 lx for more than 50% of occupied hours. Then, DA is used to compare the daylight availability for four shading strategies. 1534 sensors are distributed with 0.5m spacing on a horizontal measurement grid 76cm above the floor to assess daylight availability for different scenarios. In addition, annual glare and point-in-time glare were investigated to analyse the appearance of discomfort glare across two locations (Loc a and Loc b), positioned 1.2m above the floor to represent occupant's seated eye-height. For analysing point-in-time glare, the CIE clear sky was selected as direct sunlight reported the most important cause of discomfort for building occupants in modern spaces with large windows (Jakubiec and Reinhart, 2012) and simulation can predict discomfort glare of real lighting environments more accurately on sunny days than overcast sky (Kong et al., 2015). The method of this study consists of two steps. In the first step, an office without shading device is assessed using HDR image technique and compared with Radiance model to determine the accuracy of the model as a substitution tool. In this step, two HDR cameras are placed at Loc b, one towards southwest window and the other one facing southeast side, at the seated eye height level of 1.2m to collect data related to discomfort glare. Figure 1 shows the location and directions of the two HDR cameras. An office space is modeled based upon a real office space in Rhinoceros 3D modeling software where room geometry and orientation are assigned to the model. After

that, Radiance materials are assigned to all surfaces using the open-source plugin DIVA 4.0. The model properties and Radiance simulation parameters are presented in Table 1 and Table 2, respectively. It is important to note that the HDR images were taken on a sunny day, January 14th, 2016 from 8 AM to 6 PM in fifteen minute time intervals. Evaglare developed by (Wienold et al., 2004) is used in this study to calculate the results of DGP to compare the HDR images with simulated scenes. Second, Radiance model is used to evaluate the performance of the four proposed shading strategies (see Table 3) to control glare and provide sufficient daylight within the space in comparison with the base case scenario. The yearly hour-by-hour glare for both Loc a and Loc b for view direction perpendicular to southwest window is analysed for all proposed alternatives to identify intolerable and disturbing glare appearance for entire year. Moreover, automated glare control as a dynamic shading strategies applied in DIVA to avoid excessive interior daylighting levels and also block direct sunlight as a main cause of discomfort glare.

## RESULTS

### Comparison between the captured HDR images and simulated scenes

In order to have consistency with captured images, the same 82 scenes were recreated in DIVA to simulate time of the day of each captured HDR image. The results of DGP scores for view 1 and view 2 are plotted in Figure 3 according to four glare levels, with imperceptible glare in green ( $DGP < 0.35$ ), perceptible glare ( $0.4 > DGP \geq 0.35$ ) in yellow, disturbing

Figure 2: The HDR images and the simulations for different glare levels across view 1 and 2.

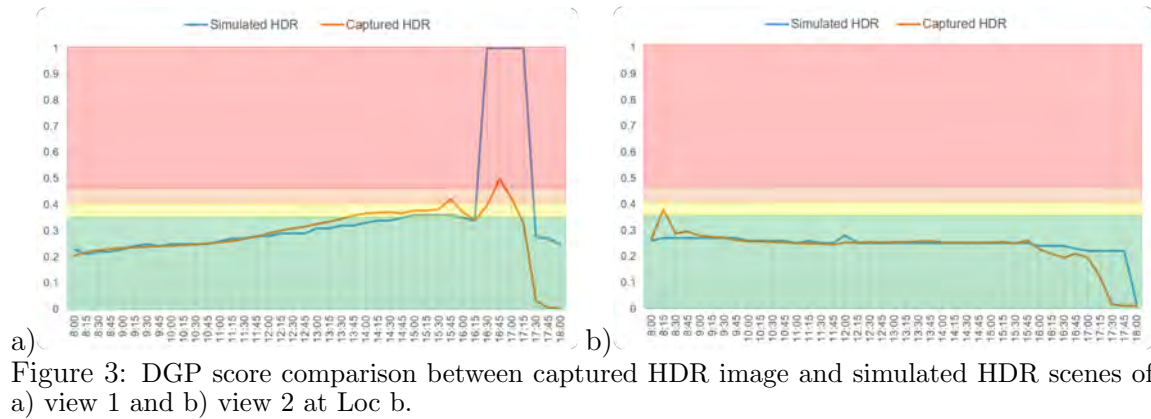

Figure 3: DGP score comparison between captured HDR image and simulated HDR scenes of a) view 1 and b) view 2 at Loc b.

glare in orange ( $0.45 > \text{DGP} \geq 0.4$ ), and intolerable glare in red ( $\text{DGP} \geq 0.45$ ) (Jakubiec and Reinhart, 2010). The captured HDR images and simulations can be compared visually for different glare levels in Figure 2. In view 2, more than 98% of HDR images and 100% of simulations generated DGP values were in the range of imperceptible glare (see Figure 3b). The only exception is at 8:15am, where the DGP value of the HDR image was higher than the simulation one. In contrast, for view 1, although 10% of simulated HDR scenes were fell into the range of intolerable glare, only 2% of captured HDR image were fell within this range (see Figure 3a). Although the amount of DGP for simulations were higher than captured HDR images between 16:15 to 18:00, but for the rest of the time the DGP value for both captured HDR images and simulated HDR scenes are comparable. As the simulated model has no light-shelf that allows considerable amount of direct sunlight hit the sensor in view 1 from 16:15 to 18 which may be the cause of deviation between simulated and HDR images generated DGP values during this period. Taken together, the difference between HDR images and simulations for all 82 scenes are about 16%, these results are in line with those of previous studies and confirm the association between HDR images and simulations which indicate that simulation can accurately predict real lighting spaces in terms of glare analysis, even though, the results of HDR images and simulations may not exactly match together (Rushmeier et al., 1995; Kong et al., 2015).

### Assessment of various shading strategies

In order to improve the visual comfort of the common space, four shading strategies have been proposed to provide a comprehensive annual glare analysis within the space (see Table 3). The total annual hours of occupancy of 3650 is assumed for the purpose of this study. The view 1 and view 3 at loc b are used to analyze the performance of all shading strategies as the view point with extreme amount of sunlight in comparison with

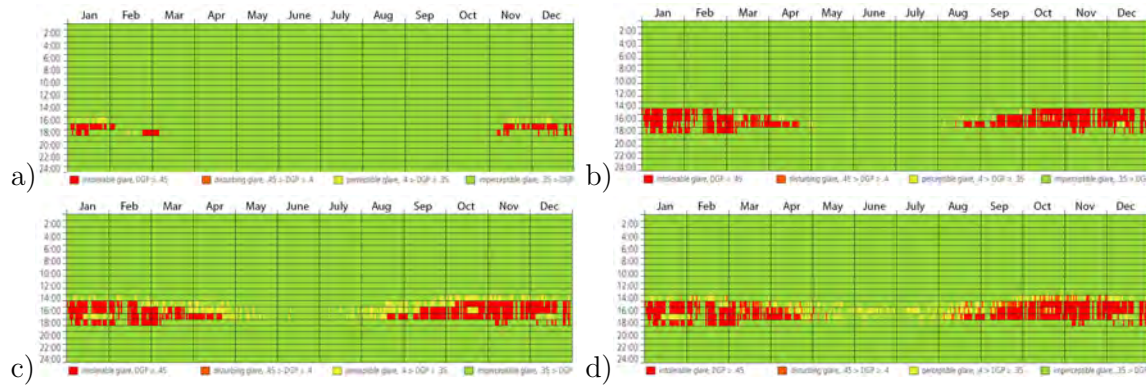

Figure 4: Annual glare calculations of view 3 at Loc a for strategies a)1, b)2, c)3, and d)4

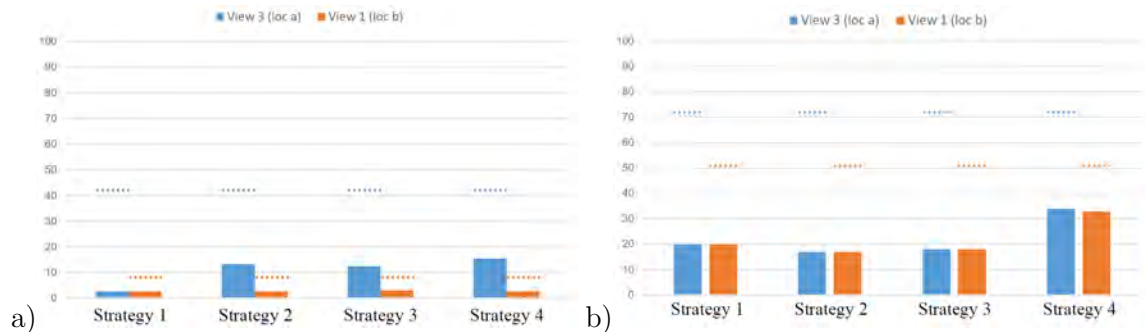

Figure 5: Reduction of a) Annual glare and b) DA of four shading strategies for view 1 and 3.

other view directions. The disturbing and intolerable glare ( $DGP \geq 0.4$ ) as a worse glare condition is reported 47.5% for view 3 and 10.2% for view 1 without a shading device. In addition, sDA and ASE were calculated for the southwest side of the model to analyse daylight sufficiency. The results show that 42.4% of the southwest side has sDA 300lux value for more than 50% of occupied hours, and 34.5% of the space has an ASE greater than 250 hours. As the accuracy of Radiance model is demonstrated, this model is used to investigate the performance of different shading strategies. The results of these four shading strategies for view 3 are presented in Figure 4. The same colours green, yellow, orange, and red represent the four different levels of glare as Figure 2. Vertical axis represents the hours of the day and 365 days in a year are shown in horizontal axis. As the worst glare condition ( $DGP \geq 0.4$ ) occurred during winter when the sun is in the low angles, Strategy 1 performs significantly better in controlling annual glare rather than other strategies for view 3 (see Figure 4). Figure 5a indicates the annual glare reduction of each shading strategies for view 3 and view 1. The results shows that the level of annual glare for location a is significantly higher than location b due to excessive amount of direct sunlight. Strategy 1 has the best potential for controlling glare as it reduces over 40% of glare annually, but the other three strategies can decrease between 27% and 31% of the annual glare in location a. In location b, all the four strategies have the same performance by reducing around 6% of the annual glare. Figure 5b shows the reduction in the percentage of the occupied hours of the year when a minimum illuminance threshold is met by daylight alone. The results indicate that strategy 4 caused the lowest reduction (about 40%) of DA through the space followed by strategy 1. Overall, comparing four shading strategies reveal that Strategy 1 performed better in terms of balancing between daylight provision and control discomfort glare than other strategies.

## DISCUSSION AND CONCLUSION

This study was conducted in an office space as an example to show the importance of considering different shading strategies to control discomfort glare as the most cause of visual discomfort reported by office occupants. For the purpose of this study, four shading strategies were applied to evaluate their potential in controlling discomfort glare and daylight sufficiency. Dynamic electrochromic window which can be switched from 58% visible transmittance ( $T_{vis}$ ) to a fully tinted state with 1%  $T_{vis}$  had a better performance in comparison with other shading alternatives by reducing over 40% of glare annually when excessive amount of sunlight is present. While Venetian blind shows the better performance in terms of DA than other strategies, it allows entering considerable amount of direct sunlight into the interior space. Therefore, Electrochromic glazing had a better performance than other strategies in this study by considering the ability to control glare and provide view to the outside as two important criteria for assessing visual comfort. In addition, the accuracy of simulation tool is determined and can be used by designers in early-stage design process to better understand the performance of various shading strategies by combining both annual glare and point-in-time lighting simulations of the space. A reliable prediction of glare with metrics is an important challenges among designers as visual comfort strongly depends on both daylight availability and the observer's position. Therefore, providing a designer at early-design-stage with direct information related to the level of daylight availability and glare condition within a space will lead to improve occupant's visual comfort. As the quality of the luminous environment produced by EC glazing is considered as an important factor for user acceptance, future research might investigate the non-visual effect of different Electrochromic windows on occupant's health and well-being.

### **ABSTRACT**

In this work a method is proposed to estimate the effect of indoor microclimate on the risk of degradation of ancient materials stored in historical buildings. The method, which combines microclimate observations and dynamic simulation, has shown to be strategic in preventive conservation of historical buildings. Indeed, once the building model is calibrated, it can be effectively used for evaluating the microclimate control solutions on the conservation reducing general degradation risks. The method has been applied to a historical building close to Rome, where deteriorations in ceilings occurred and visitors complain about thermal discomfort. First, the HVAC system in the model has set in order to guarantee both thermal comfort and adequate condition for the conservation of the material. Then, the crack width of wooden ceiling has been estimated by means of an empirical model based on indoor temperature and relative humidity data and validated with the measurements of the crack width. It was found a reduction of annual variation from 0.4 mm to 0.2 mm, experimented by panels, and an improvement of maximum daily variation, especially in winter and summer (less than 0.01 mm on average).

Historical building, microclimate, conservation strategy, dynamic simulation.

### **INTRODUCTION**

In the last years, an increasing attention has been paid to the energy refurbishment of the existing buildings (Mazzarella 2015), both modern and historical buildings, which belong to public institutions (Ascione et al. 2017; Cornaro et al. 2016; Semprini et al. 2016). Even though in Italy the energy retrofit for the historical buildings is not mandatory due to the priority of conservation heritage, several studies about this issue have been conducted by combining experimental data and whole-building dynamic simulation (Bellia et al. 2015; Dalla Mora et al. 2015; Lucchi 2016; Roberti et al. 2017). However, to take advantages of simulations, the calibration of building model is necessary. Currently, most of the calibration methodologies focuses on matching of measured and modelled energy consumptions instead of hourly measured indoor climate data (Paliouras et al. 2015), especially the relative humidity data. Moreover, the optimization of retrofitting solutions (including new control strategies) mainly concerns the energy saving and the conservation of the aesthetic aspect of buildings, while the control of the indoor climate with respect to its interaction with objects is little considered. Among climatic parameters, the relative humidity plays a key role in the degradation and the durability of building components, especially organic and hygroscopic materials. This is very important when valuable artworks and/or building components made of material sensitive to hygrometric variables are within the building.

This paper aims at showing a methodological approach which uses indoor microclimate measurements and simulations for addressing a climate control solution adequate both for the conservation of the valuable wooden ceilings and for the thermal comfort of visitors.

## MATERIALS AND METHODS

A flow chart of the methodology proposed in this study is displayed in Figure 1. First, the calibration of the building model is carried out following two steps: a) the Sensitivity Analysis (SA) for the identification of the most affected input parameters on the building model and b) the genetic algorithms, by means of GenOpt® (Genetic Optimization), for the minimization of the discrepancy between measured and simulated data. Then, the calibrated building model can be used to analyse retrofit/control solutions taking also into account the degradation risk of the materials to preserve and the thermal comfort of the visitors. The workflow can be generally applied to other historical buildings that need for refurbishment or novel control strategies and where the conservation of artworks has the priority. It is worth to note that the methodology takes advantages only if a comprehensive knowledge of the indoor climate and its interaction with the objects is reached.

For this study, the building model was calibrated by using hourly measured data of indoor temperature ( $T$ ) and relative humidity (RH) and surface temperature ( $T_s$ ). Then, the temporal behaviour of the width cracks ( $C$ ) in wooden panels was modelled by means of an empirical model based on  $T_s$  and RH data to predict the effect of the estimated indoor climate on  $C$ .

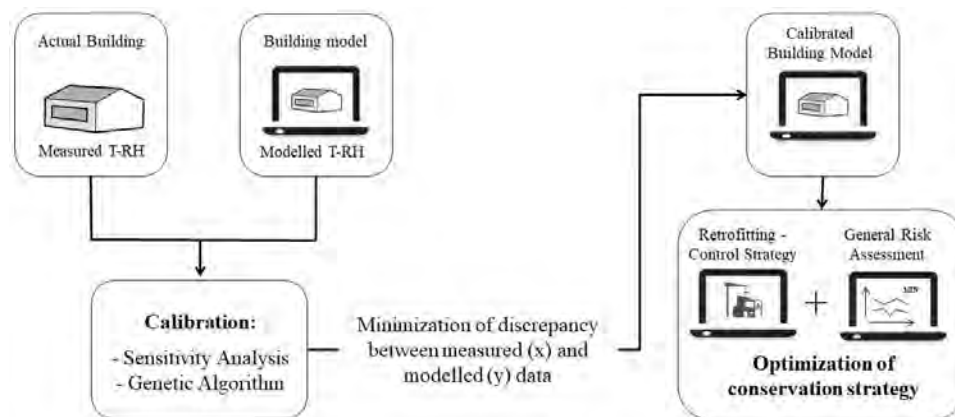

Figure 1 Schematic workflow of methodology.

### The building under study and the field campaign

The “Museo Archeologico di Priverno” is housed in the Palazzo Valeriani-Guarini-Antonelli, in the central Italy at about 70 km SE far away from Rome (Lat. 41.5 and Long. 13.2). It is a three-storey building, built between 13<sup>th</sup> and 16<sup>th</sup> century and restored in 1924-1926. The HVAC is switched on during opening hours both in winter and summer and consists in one or more convection heating/cooling systems with only temperature control in each room. The study is focused on the conservation of wooden ceilings Liberty decorated by Pietro Campeggi (Figure 2a), that suffer from cracks and deformations especially in summer, when high temperatures are experienced in the room. Visitors complain about thermal discomfort due to rigid temperatures in winter and unpleasant warm in summer.

Sensors to measure indoor and outdoor temperature ( $T_{in}$  and  $T_{out}$ ) and relative humidity ( $RH_{in}$  and  $RH_{out}$ ) were installed as shown in Figure 2a and indicated as ‘\*’. Moreover, a sensor for surface temperature ( $T_s$ ) and a crack width meter ( $C$ ) were installed on a wooden panel in room 9, indicated as ‘o’ in Figure 2b. These measurements have allowed to monitor the

stress/strain behaviour of panel (mechanical degradation). For this study the acquisition time was set to 30 min and the monitoring campaign lasted from August 2016 till November 2017.

Figure 2 a) An example of wooden panels with cracks and deformations at the second floor. b) The axonometric cross section of first and second floor of the Museum. Numbers individuate the rooms where sensors were installed: '\*' for T and RH and 'o' for  $T_s$  and C.

### Building dynamic simulation model

Dynamic building simulation for indoor climate analysis was performed using the IDA Indoor Climate and Energy (IDA ICE) 4.8 developed and distributed by EQUA simulation AB.

The geometry of the building model of the Museum was created starting from the architectural survey provided by Arch. Lucia Di Noto and using the hygrothermal properties reported in *MASEA Datenbank* for opaque components. The wall stratigraphy was gathered from literature referred to construction techniques in lower Latium in the Middle Age and was assumed to be unchanged over time except for ceilings. The building model consisted in sixteen zones, but only the zones with sensors were calibrated.

The climate file used to run the model was determined from  $T_{out}$  and  $RH_{out}$  measurements. Wind variables and solar radiation, measured at Maenza station (Lat. 41.5°, Long. 13.2°) belonging to the ARSIAL (Agenzia Regionale per lo Sviluppo e l'Innovazione dell'Agricoltura del Lazio), were also included in the climate file.

The calibration of the envelope of the building model was carried out using hourly T-RH data collecting in two different periods (May and September 2017), when the HVAC was off and no visits occurred. The calibration consisted in two steps through a semi-automatic procedure, as shown in the scheme in Figure 1. The agreement between measured and modelled data was evaluated by using the Mean Absolute Error (MAE), the Root Mean Square Error (RMSE) and the Coefficient of Variation of RMSE (CV-RMSE) (Fabrizio and Monetti 2015).

### Optimization of conservation strategy

Wood panels can be damaged if directly exposed to fast fluctuations of indoor RH and T (Bratasz et al. 2007), which are responsible of changes in the moisture content (MC) of hygroscopic materials. This might cause stresses in terms of shrinkage and/or swelling of fibres with a following deformation up to a definitive fracture if the strain is not elastic. The relationship between the measured crack width (C) and indoor T-RH data has been assessed by using Spearman's rank-order correlation ( $\rho$ ). It was found that C and  $T_s$  are well positive correlated ( $\rho = 0.67$ ), whereas C and RH are highly anti-correlated ( $\rho = -0.81$ ).

From the above outcomes, we have defined an empirical relationship (eq. 1) between crack width ( $C_{sim}$ ) in wooden panel and  $T_s$  – RH data:

$$C_{sim} = a \cdot RH^b \cdot T_s^c \quad (1)$$

The coefficients  $a$ ,  $b$ , and  $c$  were computed by a non-linear multiple regression over the whole period of measurements. They are 6.4343, -0.0575 and 0.0057, respectively. The agreement between  $C$  and  $C_{sim}$  is less than instrumental accuracy. In this study, the eq. 1 is used with modelled indoor variables, as a predictive conservation target, i.e.  $C_{sim}$  will allow knowing in advance if the novel control strategy is addressed in such a way the mechanical degradation risk of wooden panel is minimized.

The optimization of control strategy of indoor climate was addressed to update the set-point controller of the existing HVAC system without any modification of the plant. The HVAC was designed in the simulation environment as simple fan coils. The new control strategy of the indoor climate was tested using a dynamic set-point for  $T$  and RH (Kramer et al. 2017). First,  $T$  was set according to the Adaptive Temperature Limits (ATL) for thermal comfort requirements (Nicol and Humphreys 2002) leaving RH in free-floating. Then, for assessing conservation risks, these  $T$  limits were compared with  $T$  limits computed from the class of control  $As$ , as recommended in ASHRAE (2011), updating the  $T$  dynamic set-point and leaving RH in free-floating. Finally, the modelled RH values were compared with limits recommended in the guidelines to check if the system also guarantees the RH control. The class of control  $As$  provides a seasonal adjustment for  $T$  set point of  $+5/-10$  K and  $\pm 10\%$  for RH with respect to the annual mean and short-term fluctuations of  $\pm 2$  K and  $\pm 5\%$ , respectively. For each step, the estimated indoor variables were replaced in the eq. 1 to analyse the effect of the new control strategy on the crack width with respect to no control strategy, i.e. the free-floating indoor climate. For the novel control strategies in the rooms with wooden ceiling, the peak demand is 8.7 kW in heating hours and 1.5 kW in cooling hours, whereas the annual energy consumption is 21026 kWh and 917 kWh, respectively.

## RESULTS

The results from the Sensitivity Analysis (SA), carried out by means of 18 general input parameters, have demonstrated that the indoor RH of building model is strongly affected by the rate of infiltration, whereas the indoor  $T$  by the thermal bridges. Starting from these outcomes, the building model was calibrated with the most affecting input parameters by using a genetic algorithm. The MAE is, on average, 0.3°C for  $T$ , 1.6% for RH and 0.2°C for  $T_s$ . The RMSE is, on average, 0.4 for  $T$ , 2.1% for RH and 0.2 for  $T_s$ . Finally, the CV-RMSE is less than 2.0% for  $T$ , less than 1.0% for  $T_s$  and less than 5.0% for RH.

Figure 3 shows the histogram plot with the percentage of occurrences (%) of  $C$  when the indoor climate is free-floating (red bars) and is controlled (blue bars). In free-floating indoor climate, about 40% of data corresponds to the bin limits 5.00-5.05 mm, i.e. when, in cold period,  $T$  is low ( $T < 14^\circ\text{C}$ ) and RH is high ( $\text{RH} > 85\%$ ); about 16% of data is in the bin limits 5.25-5.30 mm, i.e. when, in warm period,  $T$  is up to  $31^\circ\text{C}$  and RH is down to 35%. In both cases, the thermal comfort requirement of people is not reached. No significant difference has been detected among the three climate controls described in the previous paragraph. However, the control of the indoor climate allows a minor annual variation between minimum and maximum width of wooden cracks: 0.20 mm instead of 0.40 mm in free floating. This means that, when thermal comfort needs and the assessment of material risks according to ASHRAE (2011) are met, wooden panels would test less stresses and, consequently, strains.

Looking at the histograms of daily span (difference between the maximum and the minimum value) of  $C$  (Figure 4), the free-floating strategy might provoke additional daily stresses and

consequently strains to the wooden fibres over the year. If a control of indoor climate is considered, the daily span is in about 80% of the occurrences less than 0.010 mm. It is worth to notice that the T control, so as designed, guarantees the control of RH as recommended in ASHRAE (2011). This means that the current system can be used, as it is, just updating the set-point controller.

Figure 3 Histogram plot with the percentage of occurrences (%) of crack width when the indoor climate is free-floating (red bars) and is controlled by a dynamic T and RH set-points (blue bars).

Figure 4 Daily span ( $\Delta C$ ) of crack width when the indoor climate is free-floating (red bars) and is controlled by a dynamic T and RH set-points (blue bars).

## CONCLUSIONS AND DISCUSSIONS

The management of historical buildings in Italy is strongly related to the priority of preservation of architectural components. So, the control of the indoor climate should mainly concern the optimization of the current system with respect to the degradation phenomena. This study has revealed that the semi-automatization of calibration methods using hourly measurements of climate variables might be very useful to design a building model as representative as possible of the indoor climate of the actual case. Moreover, it has demonstrated that long-term indoor climate monitoring campaign coupled with the monitoring of crack width of wood might be essential in addressing the optimization of indoor climate control with respect to mechanical degradation of valuable wooden ceilings. Indeed, the indoor climate control, designed so at ensuring both the thermal comfort and the minimization of general degradation risks for objects, seems beneficial also for the peculiar case of the mechanical degradation of wooden panels.

Further simulations will be addressed to investigate the heat and moisture transport inside the wooden panels for modeling the evolution of degradation in the internal layers.

## ACKNOWLEDGEMENT

We thank Sapienza University of Rome for funding the multidisciplinary project “*Preservation, conservation and valorisation of archaeological sites: The case of the ancient site Privernum*”. This research has been carried out within the “*Renovation of existing buildings in NZEB vision (nearly Zero Energy Buildings)*” Project of National Interest (Progetto di Ricerca di Interesse Nazionale - PRIN) funded by the Italian Ministry of Education, Universities and Research (MIUR).

### ABSTRACT

What human and buildings perceived the environmental information is comprehensive information. However, existing indoor environment design methods are often simplified to single parameters for indoor and outdoor environmental prediction and indoor environment design. In order to describe the indoor climate characteristics of the comprehensive impact of outdoor climate, this study uses the ensemble empirical mode decomposition (EEMD) method to establish a multi-parameter integrated outdoor comprehensive environmental information description method based on the information-response theory. The outdoor climate feature description method is applied to the analysis of the amplitude and frequency characteristics of outdoor comprehensive information, which provides a research basis for further exploring the indoor and outdoor environmental response under the multi-parameters interaction.

### KEYWORDS

Feature extraction; natural information; information-response; comprehensive parameters.

### INTRODUCTION

Indoor and outdoor environmental status points are formed under the influence of multiple parameters. Due to the limitations of the test instrument, we can only test a single parameter, but can't acquire a comprehensive environmental parameter. Under this condition, the information transfer process between the indoor and outdoor environments is described by constructing the heat and mass transfer equations. However, it is difficult to simulate building information response combined heat, air, moisture and pollutant simulation environment for whole-building performance analysis (Tariku F et al. 2010). This paper put forward building environment information analysis method transformation from single parameter to comprehensive parameters. In order to build a comprehensive parameter, this paper attempted to combine multi-parameters by EEMD for feature extraction.

### BUILDING ENVIRONMENT INFORMATION ANALYSIS METHOD TRANSFORMATION

All of the orderly linear transfer laws of heat, mass, and fluid can be described using Fourier's law. Based on the above rules, the heat conduction equation, mass diffusion equation, etc. can be derived. However, these linear conduction laws are only correct when the mass and energy transfer processes are not strong. When the transfer process is very strong, it is necessary to consider the interaction between mass and heat transfer. However, the building mass and heat transfer process is actually a strong transfer process. When the steady-state solution equation is used to solve the mass and heat transfer process of a building, it often brings about a large error in simulation calculation. Onsager (1931) put forward the fluxes as linear combinations of the forces, in analogy to Stokes law where the velocity of a body pulled in a viscous fluid is proportional to the drag force. According to Onsager, a thermodynamic system can then be described by a set of linear equations, as shown in Eq. (1).

$$\begin{aligned}
I_1 &= L_{11}X_1 + L_{12}X_2 + L_{13}X_3 + L_{14}X_4 \\
I_2 &= L_{21}X_1 + L_{22}X_2 + L_{23}X_3 + L_{24}X_4 \\
I_3 &= L_{31}X_1 + L_{32}X_2 + L_{33}X_3 + L_{34}X_4 \\
I_4 &= L_{41}X_1 + L_{42}X_2 + L_{43}X_3 + L_{44}X_4
\end{aligned} \tag{1}$$

where  $I_i$  is the conjugated thermodynamic fluxes,  $L_{ij}$  is symmetric matrix,  $X_i$  is the different force.

The above equation has showed that the state point of the outdoor environment was formed by the coupling of multiple factors. The same process exists in human thermal comfort and free-running building. Because of the complexity of solving the above equation, we generally use the theory of reductionism to decompose the overall information transfer process of the building into a single parameter response process. Under such a theoretical system, we have established a series of prediction model for the building thermal transfer, moisture migration, pollutant diffusion and so on. However, some researchers (Hens 2015; Zhang et al. 2017) found that the single parameter transfer process was influenced by other parameters. Therefore, researchers began to try to establish a coupled prediction model with two or three parameters (Kumaran et al. 2008). Due to the influence of factors such as multi-parameter interactions, personnel behaviour, cultural background, and architectural control methods during the actual operation of the building, it is difficult to couple multiple parameters to solve the problem (Zhang & Qin 2011). Therefore, this study proposed that if the outdoor multiple parameters could be converted into a single comprehensive information, the information transmission process of the building can be simulated, as shown in Figure 1.

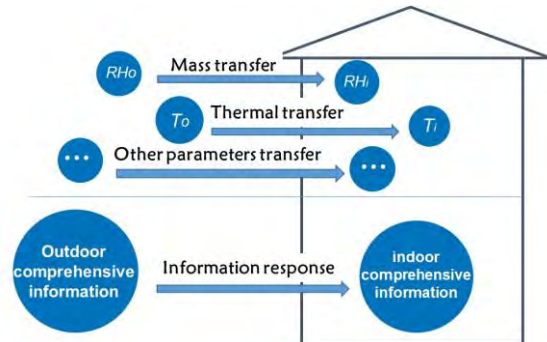

Figure 1. A schematic diagram of the information response of a building.

### INFORMATION FEATURE EXTRACTION METHOD

The outdoor comprehensive information contains multiple parameters such as temperature, relative humidity, solar radiation, wind speed, dew point temperature, vapour pressure, etc. The existing integrated information theory description model mainly establishes the integration of several parameters, such as the PMV index and Universal Thermal Climate Index (UTCI) (Fiala et al. 2012). In addition to the theoretical model, there are some relational models in Chinese traditional culture to analysis the outdoor environment and human health, such as Jiugong Bafeng (Xinying Fan et al. 2017). However, it is difficult to establish a comprehensive information description method for the above model. Chinese people have always believed that there are certain differences in outdoor comprehensive information at different times. The 24 Solar Terms have been formed under the special climatic conditions in China, which is reflected in the basic necessities of life. It means the small-scale climate directly affects people's feelings. Meehl et al. (2001) proposed a conceptual model of multi-time scale coupling of outdoor climate, which means outdoor weather data could be decomposed into different time-scale information for analysis. It provided a certain theoretical

basis for the Chinese to experience climate change on a small time scale. Due to the different time scale characteristics of the outdoor environment parameters, it is very important to choose an appropriate feature extraction method. Norden E. Huang et al. systematically compared several common information decomposition methods, as shown in Table 1.

Table 1. Comparison between Fourier, Wavelet, and EEMD analysis

Characteristic	Fourier	Wavelet	EEMD
Basis	a priori	a priori	a posteriori adaptive
Nonlinearity	×	×	√
Non stationarity	×	√	√
Feature extraction	×	discrete, no; continuous, yes	√
Theoretical base	complete mathematical theory	complete mathematical theory	empirical

Compared with wavelet and Fourier analysis method, EEMD can not only analyze nonlinear problems, but also extract the features of information, such as climate data. Due to the advantages of EEMD in the feature extraction of outdoor meteorological parameters, it was used to analysis the feature of outdoor meteorological information in this study. The original single using the EEMD method can be decomposed into the sum from the high frequency to the low frequency components and the residual sequence. The residual sequence represents the trend of the original sequence, as shown in Eq. (2).

$$x(t) = \sum_{i=1}^n IMF_i(t) + r_n(t) \quad (2)$$

where  $x(t)$  is the original single;  $IMF_i(t)$  is the different frequency components;  $r_n(t)$  is residual sequence (RES).

### SINGAL ENVIRONMENT PARAMETER DESCRIPTION

The feature description process of a single meteorological parameter information mainly consists of three steps. This article takes the outdoor temperature in Zhengzhou, China, from 2014 to 2016 as an example.

(1) First, the outdoor air temperature in Zhengzhou was decomposed using the EEMD method to obtain 12 IMF and one residual sequence. Accumulation of IMF 1~IMF 5 below the time scale of the year gives the high-frequency component of outdoor temperature, ie, high-frequency (HF); Accumulation of IMF 6~IMF 12 at the time scale and above can produce the low frequency component of the outdoor temperature, ie, the periodic change sequence (PCS); summing the PCS and RES to obtain the annual low-frequency cycle (ALC), as shown in Figure 2.

(2) Second, by calculating the same day average of the ALC of meteorological parameters for the period 2014-2016, a 365-day smooth annual average cycle sequence  $ALC_{avg}$  is formed.

(3) Then, by fitting the annual average cycle sequence  $ALC_{avg}$ , Zhengzhou outdoor temperature information feature description model can be obtained, as shown in Eq. (3).

$$y = 13.694 + 14.05 * \sin\left(\frac{\pi(n - 96.131)}{199.234}\right) \quad (3)$$

where  $y$  is the temperature, °C;  $n$  is the number of the day starting from January 1 (e.g. for the 1st January,  $n = 1$  and for the 31st December,  $n = 365$ ); 13.694 was average temperature of Zhengzhou, °C; 14.05 is the amplitude of temperature, °C.

Figure 2. Feature extraction of outdoor temperature in Zhengzhou.

In addition to temperature, any other outdoor weather parameters can also be described as the above model. Through literature research, it is difficult to find the expression of outdoor climate parameters that represent a region. In order to obtain solar radiation mathematical formulas for use in computer software, several mathematical models are given below. Bulut (2007) presented a simple model using sine wave equation (SW) below to predict global solar radiation, as shown in Eq. (4). Kaplanis (2007) suggested the following cosine wave (CW) relationship, as shown in Eq. (5). Some researchers (Zang et al. 2012) presented a daily global solar radiation model in connection with a sine and cosine wave (SCW) correlation which is developed to simulate the long-term measured data as shown in Eq. (6). In the present study, we get solar radiation model by EEMD method in Zhengzhou, as shown in Eq. (7).

$$I = a + b \left| \sin\left(\frac{\pi}{365}(n+5)\right) \right|^{1.5} \quad (4)$$

$$I = a + b \cos\left(\frac{2\pi}{364}n + c\right) \quad (5)$$

$$I = a + b \sin\left(\frac{2\pi c}{365}n\right) + d \cos\left(\frac{2\pi e}{365}n\right) \quad (6)$$

$$I = 12.71 + 5.59 * \sin\left(\frac{\pi(n-72.48)}{187.97}\right) \quad (7)$$

where  $I$  is the daily global solar radiation;  $n$  is the number of the day starting from January 1 (e.g. for the 1st January,  $n = 1$  and for the 31st December,  $n = 365$ );  $a$ ,  $b$ ,  $c$ ,  $d$  and  $e$  are regression coefficients of Zhengzhou, as shown in Table 2.

Table 2. The regression coefficients of different solar model in Zhengzhou

Model	a	b	c	d	e
SW	6.4235	11.678			
CW	12.9363	-5.7068	0.2944		
SCW	12.0955	4.1152	0.9500	-5.8501	0.8580

In this study, the Pearson correlation coefficient was used to analysis the relationship between predicted solar radiation and original data, as shown in Figure 3. The result showed that the EEMD model almost same as other models. However, the EEMD method could be used to other environmental parameters ie, outdoor temperature. Therefore, this study selected the indoor and outdoor temperature of a tested building in Zhengzhou to analyze the frequency characteristics. The testing time is February 12-19, 2015. Figure 4 shows that the building filters outdoor high frequency information (IMF1-IMF5). Low-frequency information (IMF6-IMF9) has a certain influence on the indoor environment. It means the building envelope filter many outdoor environment information which may be benefit for people.

Figure 3. Comparison of several solar radiation models of Zhengzhou.

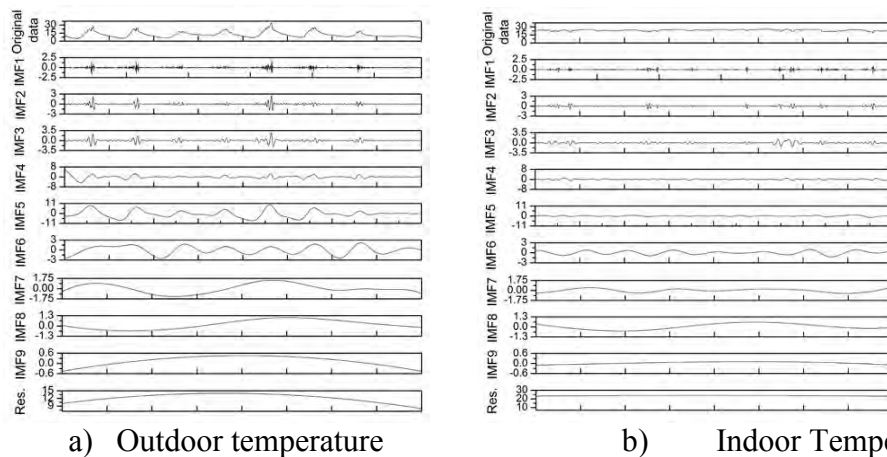

Figure 4. Comparison of indoor environmental information differences about temperature.

## OUTDOOR ENVIRONMENT COMPRESIVE INFORMATION DESCRIPTION

The existing outdoor environment comprehensive parameters are generally described by establishing an equivalent temperature for people and buildings as objects. The environmental parameters considered are often limited. For example, the UTCI index takes into account four outdoor environmental parameters, and the outdoor integrated air temperature takes into account three outdoor environmental parameters. However, the outdoor environment parameters has more than four parameters. In order to describe the comprehensive parameters, this paper build a simple described formula by EEMD method, as shown in Figure 5. The weighting factors of the comprehensive environmental parameters refer to the weights of the meteorological factors during the typical meteorological year of TMY3. This formula expressed the frequency characteristics of the comprehensive information of the outdoor environment. This study uses the EEMD method to attempt to describe the comprehensive information of the outdoor environment. It also needs further discussion. This study provides the basis for further research on environmental comprehensive information - response.

Figure 5. The outdoor environment comprehensive parameters formed process with EEMD.

## CONCLUSIONS

This study proposed analysis method transformation of building environment information from single parameter to comprehensive parameters. Based on the conceptual model of multi-time scale, the described method of single outdoor meteorological parameter was put forward. This study has attempted to obtain the description method of outdoor comprehensive parameters considered weight factor in Zhengzhou region by EEMD.

### **ABSTRACT**

This paper presents the approach developed for the monitoring and assessment of Indoor Environmental Quality (IEQ) in the whole deep renovation process aimed at reducing energy consumptions and improving comfort. The research was performed by the P2Endure project, that aims to provide scalable, adaptable and ready-to-implement prefabricated Plug-and-Play systems for deep renovation of building envelopes and technical systems. The idea is to use IEQ as one of the design criteria supporting the decision-making process, included into the holistic renovation process developed by P2Endure and called “4M: Mapping-Modelling-Making-Monitoring”. For this reason, a set of Key Performance Indicators (KPI) was selected, with the consequent measurement and calculation methodologies. The KPIs are collected and showed together with the analysis of the different IEQ dimensions (thermal and indoor air quality). The data collection has been investigated extensively, taking into account all possible data sources, measurements and surveys (e.g. special questionnaires for children in schools). In addition to traditional devices, the innovative Comfort Eye sensor is used in the proposed framework. This is a low-cost sensing system capable of measuring thermal comfort together with IAQ, applicable for permanent or periodic monitoring and with low disturbance for inhabitants. The overall procedure is presented, also in relation with the deep renovation process. Then, the application of the measurement and assessment tools in real demonstration cases is illustrated with initial results from the monitoring campaign.

Measurement, Comfort, IEQ, Deep renovation, Plug-and-Play

### **INTRODUCTION**

The existing building stock counts 210 million buildings in Europe and 75-90% of these buildings are estimated to still be standing in 2050. Most of Europe's existing building stock – over 90% of the total – has yet to be affected by energy performance requirements<sup>1</sup>. Therefore, the majority of the existing stock is composed by low-performance buildings in terms of energy consumption and IEQ (Indoor Environmental Quality), that will be subjects of renovation in the near future to accomplish 2030 EU targets. Considering that people spend about 90% of their time in indoor environments where microclimatic conditions greatly affect health, well-being and productivity, the renovation approach has to deal with the challenge of reducing the energy use but guaranteeing the optimal comfort. In fact, existing buildings are not able to keep the required comfort conditions because of the poor performance of their envelope and heating/cooling systems (Roaf et al. 2015). Although the renovation is the

<sup>1</sup> BPIE factsheet: 97% of buildings in the EU need to be upgraded

solution to the problem of performance, major attention is provided to the final energy performance and it is very usual that passive buildings design could lead to very tight environments suffering of Sick Building Syndrome. (Yousef et al. 2016) concluded that green building designs don't automatically guarantee that the building designed will be comfortable and will ensure occupants' well-being. Experts recognized and demonstrated that the environmental conditions have a significant effect on building occupants' health, although the general public has only recently started to understand the effect that this relationship can have on their everyday lives and well-being (Sappanen and Fisk, 2006). Detailed analysis and monitoring of building performance during its operations are necessary. In this framework, the EU project P2Endure proposes an innovative approach to buildings renovation, where a set of Plug-and-Play (PnP) technologies are provided within a holistic renovation approach that entails a set of KPIs (Key Performance Indicators) to assess the overall performance under different domains. The IEQ is one of them, and P2Endure developed a dedicated approach for the IEQ measurement and assessment, based on the innovative system called Comfort Eye in conjunction with standard surveying and measurement techniques.

## **METHODS**

### **P2Endure approach for deep renovation**

The P2Endure project is based on a holistic strategy for buildings deep renovation, structured on the 4M approach. The 4M modular process is a stepwise approach for preparing and implementing the deep renovation of buildings making use of PnP based innovative deep renovation products, followed by real monitoring of the resulting performance. The 4M correspond to 4 stages of the renovation process: Mapping, Modelling, Making, Monitoring. In this context, the data collection and monitoring before and after the renovation plays a pivotal role to: i) capture the actual real performance of the building and feed the design; ii) verify the compliance with renovation goals with deep Post Occupancy Evaluation. This paper presents the work done to implement tools for the IEQ mapping and monitoring.

### **IEQ monitoring and assessment protocol**

The IEQ monitoring and assessment protocol has been developed starting from the standard EN 15251 (CEN, 2007), as already performed in the previous experience of (Zangheri et al. 2011). The proposed methodology is based on the evaluation of KPIs and benchmarks according to the buildings classification provided by EN 15251 (Categories I, II, III, IV). Different comfort domains are investigated (thermal comfort, IAQ and acoustic comfort) and for each domain a KPI, expressed as percentage of fulfillment of the criteria according to the targeted Category, is used. According to EN 15251, an acceptable amount of deviation is 5% of occupied hours. The best performance is achieved when there are no deviations outside the design limit. To define an assessment scale, a linear interpolation between the minimum (5%) and best performance (0%) is used. In this way the KPI assigned to each domain is normalized on a 0-100% scale. In addition, a detailed analysis of each domain is performed on measured data to provide insight on building performance and potential pathologies. The scope is the support of the renovation design (before intervention) and verification of renovation results (after intervention).

### **Comfort Eye**

Thermal Comfort is assessed using the predictive (PMV) model. The Comfort Eye is a sensor capable of measuring the PMV for multiple positions in a room. The measuring concept is based on the thermal scanning of indoor room surfaces to calculate the mean radiant temperature with the angle factors method, according to ISO 7726, in function of the room geometry and occupants location. The detailed description of the methodology is presented in

(Revel et al. 2014). The mean radiant temperature is merged with the data (air temperature and relative humidity) acquired by a second sensing node that is placed in the most representative zone of the room. Embedded algorithms allow the calculation of comfort indexes, applying subjective parameters (occupants' activity and clothing insulation) in function of the typical end-use of the building. Furthermore, the second sensing node integrates a CO<sub>2</sub> sensor to provide IAQ monitoring.

Figure 1 The IR scanning device of the Comfort Eye

In the proposed framework, the Comfort Eye is used to measure the IEQ before the renovation to assess the building performance and potential pathologies to be solved in the design phase. In fact, together with comfort and IAQ indexes, information about the thermal performance of building envelope can be extracted from IR thermal maps. The same device is used after the renovation to evaluate if renovation design goal is met.

### Surveys

The P2Endure protocol includes the investigation based on surveys to complement the monitoring data collection. This is particularly important in the case of occupants with characteristics that could differ from generic adults (e.g. office worker). In particular, a survey to investigate the thermal sensation of children was specifically created because of the presence of 3 nurseries within the project demonstration cases. Given the age of the interviewed persons (from 3 to 5 years old), traditional questionnaires could not be used. Thus, a graphical questionnaire, based on previous researches in this field (Fabbri 2013; Vasquez et al. 2014), was prepared together with the teachers. The questions asked to children were related to their feeling (hot/neutral/cold), sensation (happy/sad), thermal preference (colder/neutral/warmer), weather (sunny/cloudy/rainy) and clothing. Each question was asked with a set of images, drawn in function of how children could associate the reply with a representative image (Figure 2).

Figure 2 Graphical questions for children interviews

### Description of the case studies

The IEQ monitoring protocol has been applied in two real demonstration projects where renovation will be applied. A nursery in Genova, located on the second floor of a two-level building, built in 1930s with concrete structure and non-structural brick walls. A nursery in Warsaw, built in 1983. It is in the southern part of the city and is one of 55 municipal nurseries in Warsaw.

## RESULTS

### Results from the monitoring in Genova

The thermal comfort and CO<sub>2</sub> have been measured with standard sensors (Deltaohm Microclima HD 32.3A and Deltaohm IAQ Datalogger HD21ABE), compliant with ISO7730 and ISO7726, located in two different rooms. Winter and summer monitoring was one month long each, with an acquisition time of 5 minutes.

Figure 3 Winter comfort analysis: average operating conditions within comfort zones (a) category compliance of occupied hours for thermal comfort (b) and CO<sub>2</sub> (c)

The detailed analysis of comfort conditions in winter, is reported in Figure 3 a), where the average thermal condition (dark blue dot) is located with respect to comfort zones calculated according to EN15251. The deviation from the average condition (variability) is represented with the transparent blue circle, calculated with Monte Carlo analysis applied to input parameters according to their fluctuation in the time domain. The PMV was calculated with a clothing insulation of 0.9 clo and metabolic rate equal to 1.2 met. The monitoring campaign registered an average PMV of 0.3. The overall thermal sensation is within the optimal comfort range, slightly unbalanced toward warm sensation. The calculation of the percentage of time of building operation within the different Categories is presented in Figure 3 b). For about the 23% the time, the building operated a Category III, which indicates a poor condition. The KPI calculated as weighted average of all the monitored rooms turned out to be equal to 0% for Category II. The indoor air quality has been measured and assessed according to the P2Endure protocol. During winter, windows were mostly kept closed to ensure thermal comfort and the indoor air quality turned out to be poor, the nursery operated mostly as Category III and IV (Figure 3 c). During summer season, both measurements and surveying were performed. Questionnaires were compiled according to the presented methodology, with the support of teachers. A total number of 127 questionnaires were collected presenting a general warm sensation as reported in Table 1.

Table 1 Recap of children surveys in summer

Question	Q1: How do you think is the classroom today?			Q2: When the classroom is (Q1 answ.) how do you feel?		Q3: At this moment you like to feel...		
Reply	Hot	Not hot neither cold	Cold	Sad	Happy	Warmer	No change	Cooler
Number	87	38	3	57	70	20	50	58
Percentage	69%	30%	2%	45%	55%	16%	39%	46%

From the interviews, the warm sensation is prevalent with 69% of replies. This is also confirmed by the higher percentage of children preferring a cooler feeling. At the same time the environmental data were acquired to assess thermal comfort using adaptive model for

naturally ventilated buildings, according to EN15251. Measured data turned out to provide averaged operating conditions in the Category III comfort zone, with a variability that brought the building outside that category (Figure 4 a and b). Concerning the IAQ, in summer, the windows were opened and the building presented a very high performance (Figure 4 c).

Figure 4 Summer comfort analysis: average operating conditions within comfort zones (a) category compliance of occupied hours for thermal comfort (b) and CO<sub>2</sub> (c)

### Results from the monitoring in Warsaw

The Comfort Eye system was applied to Warsaw demo case for testing the first prototype. The installation was performed in March 2018 for 2 days, with an acquisition time of 5 minutes.

Figure 5 Comfort Eye measurement in Warsaw: Thermal comfort a) CO<sub>2</sub> b) Thermal map c)

Figure 5 a) shows the PMV measured in the room during the test, which turned out to provide an average value of -0.15. The comfort is maintained within the acceptable range, providing a KPI of 100% with the fulfilment of Category II criteria. The CO<sub>2</sub> was measured during the two days of testing, but the room was occupied only during the first day. Figure 5 b) shows the CO<sub>2</sub> trend during the occupied and non-occupied period of the first day. The monitoring turned out to provide a poor level of IAQ during the occupied hours with CO<sub>2</sub> concentrations always within the Category III, leading to a KPI equal to 0%. Figure 5 c) shows an example of thermal map, provided by the Comfort Eye, where the elements composing the outer wall of the room are measured. The window area is distinguished by a lower temperature (average of 10°C) with respect to the other parts. The opaque element of the wall registered an average temperature of 16°C, providing a strong deviation from the average room air temperature (22.8°C). This deviation, together with the low window temperature, had an impact in terms of radiant temperature. In fact, a mean radiant temperature of 17.8°C was measured near the wall (50cm of distance, not in front of the radiator). This initial investigation suggests a non-efficient building performance since, although thermal comfort is kept within requirements, the air temperature is kept high to balance the cooling effect of the building envelope.

### DISCUSSIONS

The presented results reveal the importance of the IEQ measurement in buildings renovation process. The demo cases presented issues that need to be addressed by the renovation design.

In both cases, the indoor air quality is poor, especially in winter, suggesting the inclusion of mechanical ventilation systems. Moreover, the envelope performance monitoring is important to highlight masked pathologies, as the low wall and window temperature that can provide discomfort conditions by strong deviations from the air temperature, or, despite the almost optimal PMV, non-efficient use of energy to keep the building comfortable because of the low envelope thermal performance.

## CONCLUSIONS

The proposed paper presents the initial results from the application of innovative IEQ measurement systems in the renovation process. The use of dedicated tools, as the Comfort Eye, can be useful to bring IEQ issues to the attention of the design team. In P2Endure, the monitoring results are going to feed the design of dedicated PnP renovation solutions, as multifunctional panels with embedded ventilation systems. The overall design will thus address not only energy, but also IEQ criteria. After the renovation, the same measurements will be applied to verify the final IEQ result. Finally, the possibility of integrating the measurements all in a unique device, the Comfort Eye, will make easier and less intrusive the monitoring.

## ACKNOWLEDGMENT

This research has received founding from the P2Endure (Plug-and-Play product and process innovation for Energy-efficient building deep renovation) project (<https://www.p2endure-project.eu/en>) under the Horizon 2020 research and innovation programme (Grant Agreement no. 723391). The authors wish to thank the partners for the useful discussions.

### **ABSTRACT**

As the substrate of Chinese traditional painting and calligraphy, the paper and silk are susceptible to optical radiation in the museum illumination and appear mechanical damage such as brittleness, chalking, deformation, etc. However, there is no effective method now of quantitatively evaluating the mechanical damage of cultural relics caused by illumination. In this paper, Raman spectroscopy used in the analytical chemistry field was introduced into the illumination research of the cultural relics in museum. The four light sources with different center wavelengths of 450nm, 510nm, 583nm, and 650nm, which constitute the spectra of the white light-emitting-diode (LED), were used as the light sources. As experimental specimens, the paper and silk specimens were illuminated by the above light sources for half of a year. Raman spectra of specimens before and after illumination were detected. By analyzing the variations of Raman characteristic peak intensity, the relative damage coefficients of four light sources on the microscopic molecular structure of the paper and silk specimens were studied, respectively. Finally, white LED illumination, namely the spectral irradiance distribution (SPD) of white LED, for the paper and silk should be designed according to the corresponding relative damage coefficients, respectively. Simultaneously, the paper proposed a new research method of studying mechanical damage of cultural relics based on Raman spectroscopy.

### **KEYWORDS**

Museum illumination, paper and silk, Raman spectroscopy, illumination damage

### **INTRODUCTION**

Chinese traditional painting and calligraphy (CTPC) are recognized as the treasures of oriental art in the world (Dang et al. 2013). However, according to the photochemical stability grading standard of museum exhibits formulated by the Commission Internationale de L'Eclairage (CIE) (2004), CTPC belong to the highest level of light sensitivity. The paper consisting of plant fibres and silk consisting of protein molecules are used as the substrates of CTPC, both of which are natural organic substances with unstable properties (Proniewicz et al. 2001; Shao et al. 2005). At present, the illumination damage research mainly uses the color difference to evaluate the influence of museum illumination on color fading and discoloration of cultural relics (Dang et al. 2017, 2018; Pinilla et al. 2016; Farke et al. 2016). As non-staining organic substrates, the illumination damage to the substrates is mainly mechanical damage caused by the microscopic molecular structure changes, which cannot be evaluated by the color difference. Therefore, there is an urgent need for a method to study microscopic molecular structure damage of the paper and silk substrates under illumination of museum light sources.

Raman spectroscopy is an analytical method based on Raman scattering principle and an effective method of accurately evaluating the microscopic damage to substances. Like human fingerprints, each substance has its Raman spectral characteristic bands, namely Raman

characteristic peaks, which correspond to the major molecular functional groups of the substance. When the substance is irradiated with the incident light with energy  $E$  ( $E = h\nu$ , where  $h$  is Planck's constant and  $\nu$  is the frequency of light), energy exchange between the substance and the light occurs when photons of the incident light collide with molecules inside the substance, which is manifested as changes of photon frequency and characteristic peak intensity. Huang (Huang et al. 2016) analyzed the content of unsaturated fatty acids in different edible oils by calculating the peak intensity of different Raman spectra. According to Alves (Alves et al. 2016), Raman peak intensities of cellulose's spectral peaks were used to characterize the fibre structure and its changes in different acid and alkali environments. Monti (Monti et al. 2001) evaluated the amount of silk I form in the silk specimens by calculating the Raman intensity ratio. It can be seen that changes in the microscopic molecular structure inside the substance can be further quantified by Raman peak intensity.

The white light-emitting-diode (LED) spectra currently meeting the requirements of low correlated color temperature ( $CCT \leq 4000K$ ) and high color rendering ( $Ra \geq 90$ ) formulated by the lighting code of Museum (2009) mainly include four monochromatic light spectra of red, yellow, green and blue. By adjusting the ratios of them, Red, Yellow, Green and Blue (RYGB) type white LED with low CCT and high Ra can be achieved, which was defined by Dang et al. (2017). Therefore, determining the quantified damage of four monochromatic light spectra on the paper and silk substrates is of great significance for obtaining new white LED spectra suitable for illuminating CTPC.

In this research, Raman spectroscopy was innovatively introduced into the illumination study of museum cultural relics. The four monochromatic light spectra were used as experimental light sources. The peak intensity of the Raman spectra was used as an evaluation index. The change of microscopic molecular structure inside the paper and silk specimens before and after illumination was characterized by the variations of Raman peak intensity. By analyzing the degree of microscopic damage to the paper and silk specimens caused by four monochromatic light spectra, the problem that cannot quantitatively studying the mechanical damage to the paper and silk substrates at present could be solved.

## EXPERIMENT PROCESS

### Experimental specimens

In accordance with traditional techniques, the paper and silk specimens used in CTPC were prepared by the National Museum of China. Then two specimens were cut into the same size and combined together, as shown in Figure 1(a).

Figure 1. (a)The paper and silk specimens. (b) The SPDs of four monochromatic light sources used in illumination experiment. (c) The illumination experiment scene.

### Experimental light sources

Four light sources with different center wavelengths of 450nm, 510nm, 583nm, and 650nm

were fabricated by using a museum-specific tungsten halogen lamp combined with a 20nm wide narrowband filter and an infrared filter. By using a spectrophotometer, the SPDs of four monochromatic light sources were detected, as shown in Figure 1(b).

### **Illumination methodology**

The illumination methodology was in accordance with the previous study, which was clearly defined by Dang et al. (2017). The experimental scene is shown in Figure 1(c).

### **Experiment program**

The analytical process was as follows. First, before the illumination experiment, Raman shift and Raman peak intensity of specimens as a control group was detected by Raman spectrometer, whose resolution was set at  $1.496 \text{ cm}^{-1}$ . The specimens were excited with the 780nm line of a diode laser. After illumination experiment, the Raman data of the illuminated specimens were detected again as the experimental group. Then Raman spectrogram of Raman peak intensity varying with Raman shift was plotted. Raman characteristic peaks of the specimens were selected. Then, the peak intensity values of the selected peak before and after illumination were read by the Origin software. By using Eq. (1), the difference  $\Delta I$  of Raman peak intensities before and after the illumination experiment were obtained.

$$\Delta I = |I_1 - I_0| \quad (1)$$

Where  $I_0$  and  $I_1$  are the peak intensity values of the selected peak before and after illumination, respectively. The smaller the  $\Delta I$ , the lower the microscopic damage degree of specimens. By comparing microscopic damage degree caused by different monochromatic light sources to the paper and silk specimens, the relative damage coefficients of different light sources on the microscopic molecular structure of the paper and silk specimens were obtained.

## **EXPERIMENT RESULT**

### **Paper**

Paper consists of mostly bonded cellulose fibres that are held together by strong intramolecular hydrogen bonds that promote aggregation of single chains into highly oriented structure. These aggregates are ordered up to even 80% 'crystalline forms'. The unordered rest is called 'amorphous form', which was defined by Proniewicz et al. (2001). Owing to the influence of illumination environment and its own characteristics, the microscopic molecular structure of the paper can be easily damaged. Therefore, Raman spectroscopy was introduced to evaluate microscopic damage of different monochromatic light sources to the paper.

Raman spectra of the paper specimens before and after illumination experiment are shown in Figure 2. The abscissa represents Raman shift, that is, the frequency shift of the scattered light relative to the incident light after the incident light is scattered by the substrate specimens. Raman shift is recorded in wavenumbers, which is commonly expressed by inverse centimetres ( $\text{cm}^{-1}$ ) in Raman spectra; the vertical axis represents the intensity of Raman scattered light. The solid Raman spectral line represents the Raman spectra before illumination and the dotted one represents the Raman spectra after illumination. The Raman peaks in the dotted Raman spectral line were obtained by the redshift of the Raman peaks in solid Raman spectral line. Taking the Raman spectra of the paper specimens illuminated by the 510nm light source as an example, the Raman peak at  $895 \text{ cm}^{-1}$  in solid spectral line was red-shifted to  $897 \text{ cm}^{-1}$  in dotted spectral line. The following Figure 3 is analogous.

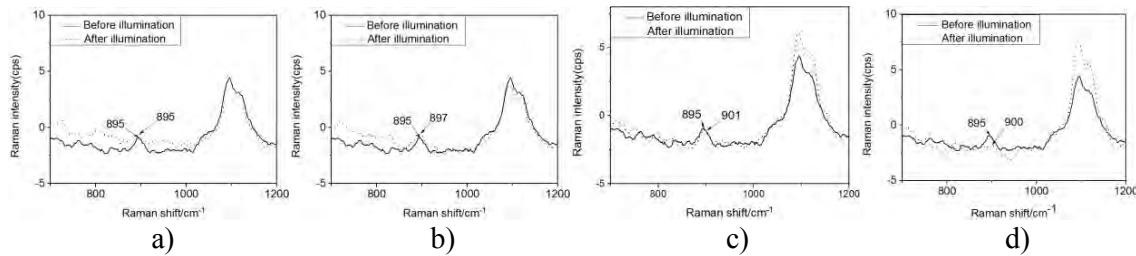

Figure 2. Raman spectra of the paper specimens under illumination of (a) 450 nm monochromatic light spectrum, (b) 510 nm monochromatic light spectrum, (c) 583 nm monochromatic light spectrum, and (d) 650 nm monochromatic light spectrum.

It could be seen from the solid spectral line in Figure 2, the Raman peak with medium intensity is  $895\text{ cm}^{-1}$ . According to Proniewicz et al. (2001), they found that the intensity of  $900\text{ cm}^{-1}$  peak was sensitive to the amount of crystalline versus amorphous structure of cellulose. It was also found  $I_{900}$  was proportional to the amount of disorder in the cellulose (Wiley and Atalla, 1987). Therefore, Raman peak intensity  $I_{895}$  was selected to characterize the microscopic damage of different monochromatic light sources to the paper specimens.

The variations in Raman peak intensity of the paper under four light sources were analyzed. As shown in Figure 2(b), the paper illuminated by 510 nm light source was taken as an example. According to the solid Raman spectral line obtained before illumination, the Raman peak intensity of  $895\text{ cm}^{-1}$  was read by the Origin software as  $I_0$ ; according to the dotted Raman spectral line obtained after illumination, the intensity of Raman band at  $897\text{ cm}^{-1}$  was read as  $I_1$ . By using Eq. (1), Raman peak intensity difference  $\Delta I$  could be obtained. Similarly, the  $\Delta I$  of the paper specimens illuminated by the rest light sources were calculated. By defining  $\Delta I$  0.4278 of the paper specimens illuminated by 450 nm light source was 1.0000, through conversion the relative damage coefficient of four light sources to the paper specimens was 1.0000: 0.9093: 0.3714: 1.9780. The calculation results are shown in Table 1.

Table 1. The comparison of the paper's Raman peak intensity differences under illumination of four types of monochromatic light sources

Measure Light sources	Before illumination	After illumination	Calculation	Through conversion
	$I_0$	$I_1$	$\Delta I =  I_1 - I_0 $	
450nm	-0.9361	-0.5083	0.4278	1.0000
510nm		-0.5471	0.3890	0.9093
583nm		-1.0950	0.1589	0.3714
650nm		-1.7823	0.8462	1.9780

### Silk

Silk fibroin contained in silk is natural polymer fibre protein, which was defined by Shao et al. (2005). Exposure to light will cause significant changes in these organic components of silk.

Raman spectrum changes of the silk specimens before and after the illumination are shown in Figure 3. In solid Raman spectral line, the strongest peak is  $1230\text{ cm}^{-1}$  and medium Raman peak is  $1082\text{ cm}^{-1}$ . According to Shao et al. (2005), the peak intensities at  $1232$  and  $1087\text{ cm}^{-1}$  corresponding to C-N bond decreased after UV/ozone irradiation, indicating that UV/ozone irradiation causes peptide chain breaks and confirming that photodegradation occurs at the C-N bond. Silk phototendering is caused by peptide fission initially at the weaker C-N bond,

which leads to loss of fibre strength (Setoyama, 1982). We selected  $I_{1082}$  and  $I_{1230}$  to comprehensive characterize the microscopic damage of light sources to the silk specimens.

Figure 3. Raman spectra of the silk specimens under illumination of (a) 450 nm monochromatic light spectrum, (b) 510 nm monochromatic light spectrum, (c) 583 nm monochromatic light spectrum, and (d) 650 nm monochromatic light spectrum.

The variations of Raman peak intensities under illumination of four light sources were analyzed. Silk specimen illuminated by 510 nm light source was taken as an example. According to solid Raman spectral line detected before illumination, the intensity values of 1082 and 1230  $\text{cm}^{-1}$  Raman peaks were read as  $I_0$  and  $I_0'$ , respectively; according to the dotted Raman spectral line detected after illumination, the intensity values of the Raman peaks at 1105 and 1256  $\text{cm}^{-1}$  were read as  $I_1$  and  $I_1'$ , respectively. By using Eq. (1), based on  $I_0$  and  $I_1$ , Raman peak intensity difference  $\Delta I$  was calculated; based on  $I_0'$  and  $I_1'$ ,  $\Delta I'$  was calculated. Then,  $\Delta I''$  was obtained by calculating the average value of  $\Delta I$  and  $\Delta I'$ . Similarly, the  $\Delta I''$  of the silk specimens illuminated by the rest light sources were calculated. By defining  $\Delta I''$  10.8402 of the silk specimens under illumination of the 450nm light source was 1.0000, through conversion the relative damage coefficient of four light sources to the silk specimens was 1.0000: 0.7740: 1.1046: 0.3846. The calculation results are shown in Table 2.

Table 2. The comparison of the silk's Raman peak intensity differences under illumination of four types of monochromatic light sources

Measure Light sources	Before illumination		After illumination		Calculation		Average	Through conversion
	$I_0$	$I_0'$	$I_1$	$I_1'$	$\Delta I$	$\Delta I'$	$\Delta I''$	
450nm	9.6050	22.9035	1.4985	9.3297	8.1065	13.5738	10.8402	1.0000

## DISCUSSIONS

There are different damage degrees caused by light sources with different center wavelengths of 450nm, 510nm, 583nm, and 650nm. According to Table 1, the ratio of four light spectra constituting white LED used in illuminating the paper, namely the SPD of white LED, should be based on the relative damage coefficient of 450nm: 510nm: 583nm: 650nm = 1.0000: 0.9093: 0.3714: 1.9780. According to Table 2, the ratio of four light spectra constituting white LED used in illuminating the silk, namely the SPD of white LED, should be based on the relative damage coefficient of 450nm: 510nm: 583nm: 650nm = 1.0000: 0.7740: 1.1046: 0.3846. The larger the influence coefficient value, the greater the damage caused by the monochromatic light to the paper and silk substrates. The coefficients can be used as selection

criteria for WLEDs that are suitable for illumination in museum paper and silk relics

## CONCLUSION

The research method of studying illumination damage based on Raman spectroscopy proposed in this paper can evaluate the mechanical damage to substrates from the microscopic level.

### **ABSTRACT**

Due to hot arid climate in Jeddah, Saudi Arabia, occupants rely on air conditioning (AC) to provide both ventilation requirements and thermal comfort. It is believed that this total reliance on AC have also a significant effect on thermal sensation as well as cognitive performance of building occupants. Using a multi-variable multilevel statistical analysis, the effects of classroom temperature and CO<sub>2</sub> levels on cognitive performance were estimated. Eight neurobehavioral cognitive tests were used to evaluate cognitive performance of 499 female students (16-20 years old). In addition, thermal sensation votes were collected. All participants were exposed to nine different environmental conditions, a combination of three temperature levels 20°C, 23°C and 25°C, and three CO<sub>2</sub> levels: 600 ppm, 1000 ppm and 1800 ppm. The baseline condition levels were set at 20°C and 600 ppm. In this paper the interrelationships between the thermal sensation votes and effects of classroom temperature and CO<sub>2</sub> levels on vigilance (Simple Reaction Test, SRT) and memory tasks (Reversal Learning, RL) are presented. The results suggested that the 'cold' thermal sensations have been linked to significant increase in 'percentage of errors' for both memory and vigilance tasks. Also, the exposure to higher CO<sub>2</sub> levels of 1800 ppm and 1000 ppm have led to a significant increase in the 'percentage of errors' for both cognitive performance tasks compared to the baseline conditions. The study has also confirmed that the significant influence of acclimatization should not be overlooked when setting up the environmental design criteria for buildings in hot arid climates.

### **KEYWORDS**

thermal sensation, temperature, ventilation, cognitive performance, hot arid climate

### **INTRODUCTION**

This study was conducted in Jeddah, which unlike other cities in Saudi Arabia retains its warm climate even in winter. This has consequently led to the total reliance of occupants on air conditioning (AC) for both achieving thermal comfort and providing the prescribed ventilation requirements. Furthermore, due to changing climate an increase in temperature by ~2.5°C is estimated according to regional climate model projections of the average temperature changes (°C) across the Gulf region by 2050 (Alpert et al., 2008). It is also believed that the total reliance on AC for cooling has a significant effect on thermal sensation of buildings' occupants. All these factors have been some of the key drivers of ever increasing energy demand in the Gulf region and a major barrier to adoption of carbon reduction strategies in buildings. For example, it has been shown that only 1°C rise in set AC

temperature could significantly reduce energy consumption by ~6% (e.g. Yamtraipat et al., 2005).

Equally important when it comes to design and operation of educational buildings is the consideration of ventilation rates in classrooms and lecture theatres. However, a limited data is available on actual ventilation rates in educational buildings in Saudi Arabia. AlSubaie (2014) provided evidence based on data collected from 36 primary schools, indicating that classroom ventilation rates in educational buildings in Saudi Arabia do not meet the ASHRAE ventilation rates requirements. What might be the impact of lower ventilation rates on cognitive performance of students in hot arid climates is yet to be determined.

Finally, only recently the government in Saudi Arabia, started to promote gender equality to empower women's education and eliminate gender disparity at all levels of education (AlMunajjed, 1997). This has culminated in the last 10 years which has led to the increase in female enrolments at the university level and capital investment in university sector targeting female students. This specific cultural and behavioral context also offers an opportunity to reflect on design of interdisciplinary studies such as this one combining building science and cognitive performance.

## METHODS

Only temperature and CO<sub>2</sub> concentration levels (no attempt was made to establish if the CO<sub>2</sub> is a pollutant on its own right) were the independent variables which were investigated in the study whilst the other parameters were kept within constant ranges during the exposure conditions (namely: sound levels, lighting intensity, air velocity, and relative humidity). Based on a pilot study which was conducted prior to the intervention study reported in this paper we obtain some evidence on the base line temperature conditions in the case study building, the maximum operative temperature the participants were able to tolerate was 25°C. Furthermore, according to a facility management questionnaire which was disseminated to the educational buildings in Jeddah, the most common set temperature is 20°C. Therefore, the indoor temperatures set during the conditions of exposures were 20°C, 23°C and 25°C.

The intervention study was carried out in a teaching room with a CAV AC system with no direct access to sunlight. CO<sub>2</sub> levels ~1800 ppm were the maximum achieved and ~600 ppm were the minimum achieved. Therefore, the CO<sub>2</sub> levels set during the exposure conditions were 600, 1000, and 1800 ppm. Therefore, nine different exposure conditions combining temperatures (20°C, 23°C and 25°C) and CO<sub>2</sub> levels (600 ppm, 1000 ppm and 1800 ppm) were investigated in this study (Table 1).

Within-subjects design was adopted where the same participants were exposed to the same exposure conditions. Participants performed eight different cognitive tests (only two of which are discussed in this paper, namely: Simple Reaction test (SRT) as a reference to the vigilance tasks involved and Reversal Learning (RL) is a reference to the memory tasks involved). In parallel, the participants evaluated their thermal comfort sensations during the exposures. The actual mean votes (AMV) were collected. The rating scale used for the thermal sensation vote was based on the ASHRAE/ISO seven-point thermal sensation scale, defined as: hot (3), warm (2), slightly warm (1), neutral (0), slightly cool (-1), cool (-2) and cold (-3).

Table 1. The exposure conditions investigated in the study.

Conditions of exposure	Ambient temperature	CO2 concentration level
Condition 1: Temp: 20°C, CO2: 600 ppm	T1: 20°C	CO2: 600 ppm
Condition 2: Temp: 20°C, CO2: 1000 ppm	T2: 20°C	CO2: 1000 ppm
Condition 3: Temp: 20°C, CO2: 1800 ppm	T3: 20°C	CO2: 1800 ppm
Condition 4: Temp: 23°C, CO2: 600 ppm	T1: 23°C	CO2: 600 ppm
Condition 5: Temp: 23°C, CO2: 1000 ppm	T2: 23°C	CO2: 1000 ppm
Condition 6: Temp: 25°C, CO2: 1800 ppm	T3: 23°C	CO2: 1800 ppm
Condition 7: Temp: 25°C, CO2: 600 ppm	T1: 25°C	CO2: 600 ppm
Condition 8: Temp: 25°C, CO2: 1000 ppm	T2: 25°C	CO2: 1000 ppm
Condition 9: Temp: 25°C, CO2: 1800 ppm	T3: 25°C	CO2: 1800 ppm

Base line condition

The analysis of data was based on multivariable multilevel analysis approach which takes into consideration the confounding factors' effect including: thermal comfort sensations, age, physical activity, clothing levels, stress, caffeine intake, sleeping hours, noise levels, set air conditioning (AC) temperature at home, as well as the ethnic background and the number of years spent in the country for non-Saudi participants, as well as the detected symptoms related to the inability to focus. Almost no relevant studies have adopted the multilevel modelling approach except for one recent study by Haverinen-Shaughnessy and Shaughnessy (2015), which employed the multilevel modelling approach to find the association between ventilation rates and indoor temperature with mathematics test scores. However, no statistically significant interactions were found because of the limited sample size. The study was designed to have 90–95% power at 95 percent level of significance. Using this information the sample size was calculated using the following formula, (Daniel, 1999):

$$n = \frac{Z^2 P (1 - P)}{d^2} \quad (1)$$

Where; n = sample size, Z = statistic for a level of confidence (95% level of confidence used, therefore Z value is 1.96), P = expected prevalence or proportion, and d = precision (In a standard situation, d is considered 0.05 to produce good precision and smaller error of estimate). The calculated sample size was 385. However, the size was over-estimated since the duration of the experiment was long (over one year) and many withdrawals were expected, and particularly in this context of study where research consciousness is absent. Finally, 499 female subjects participated in all nine exposure conditions investigated in the study. The data analysis was carried out in three steps, as follows:

- Step 1: a descriptive analysis was performed to check for any patterns due to intra-individual differences by comparing an individuals' performance pattern of across intervention measures. If all performances fall within the mildly to moderately impaired range, the multilevel mixed effect models can be performed. However, if a significant variability in performances across domains is observed, then a specific pattern of impairment may be indicated.
- Step 2: univariable multilevel mixed effect models were then performed to check whether any association is found between the confounders of this study with the outcomes of interest including: age, ethnicity, physical activity, number of years spent in Saudi Arabia (for non-Saudis), trend of use and temperature of AC used at home, the effect of caffeine, sleeping hours, thermal comfort sensation votes, clothing levels, the effect of ambient noise, and the effect of stress owing to personal reasons not related to the exposure conditions, and/or any

other reported symptoms by the participants which impaired their focusing ability including un-tolerable thermal stress sensation.

- Step 3: multivariable multilevel mixed effect models were applied according to the results of the univariable multilevel mixed effect models, which adjusted for the confounders which were found associated with the accuracy and speed of performance. Two models, one for accuracy (i.e. percentage of error), and the other for speed (i.e. time needed to complete a task) were executed to determine the estimated effect sizes of the exposure conditions relative to the base-line condition (Condition 1) for all the cognitive tasks considered in the study after adding the confounders.

## RESULTS

According to the analysis of data, the accuracy (percentages of errors) of the cognitive tasks increased at the different exposure conditions, relative to the baseline condition (Condition 1), after adding the estimated effect sizes of the confounding variables to the zero model and the estimated effect sizes derived from the multivariable multilevel statistical model. The estimated effect sizes are listed in Table 2. For instance, the percentages of errors increased significantly from 2.4% for the SRT test (at the zero model where no confounding variables were added at this stage) to become 5.4% at Condition 2 versus Condition 1 (when CO<sub>2</sub> increased from ranges of 600 ppm to 1000 ppm, while temperature remained constant at 20°C). The increase in the percentage of errors was almost doubled (from 5% to become 9%) at Condition 3 versus Condition 1 (when CO<sub>2</sub> increased from ranges of 600 ppm to 1800 ppm, while temperature remained constant at 20°C), where all reported results were highly significant,  $p < 0.001$ . This trend has continued during all exposure conditions when CO<sub>2</sub> increased from ranges of 600 ppm to 1000 ppm and 1800 ppm, and temperature remained at 20, 23 and 25°C, and particularly when the temperature was set at 25°C. In addition, it is indicated from the Table 2 that significant effects occurred when the variables of ethnicity, number of years spent in the country for the non-Saudi participants, AC temperature set at home in the range between 18 and 24°C, thermal comfort sensations, the reported intolerable thermal discomfort which leads to inability to focus, and other symptoms reported that impaired the focusing ability, were added to the model. By doing simple arithmetic calculations, it was found that the estimated effect size caused by the effects of thermal sensations are the ones responsible for significant amount of the caused effects. With regard to the speed of performance, it was found that the speed of reaction increased significantly during exposure to all the investigated conditions relative to Condition 1.

It is indicated from Table 2 that Saudi participants had significant lower percentages of errors by ~1.5% for the vigilance tasks and ~2.5% for memory and learning tasks relative to the non-Saudis. Also, the inclusion of the confounder of set AC temperature at home in the final model resulted in a significant increase in the percentages of errors for every unit decrease in temperature from 24 to 24°C by an average of ~1%. According to participants' subjective questionnaire responses, the mean AC temperature set by the Saudi participants at home was lower by 2°C, relative to that reported by the non-Saudi participants. An average of ~15% for all tasks was noted for those who reported the symptoms of intolerable thermal discomfort versus which distracted their focusing ability as well as other symptoms like headache, blur eye, heaviness on head for those who did not. With regards to the thermal sensations, it was noted that they account for a considerable amount of the attributed effects. Negative associations for the thermal sensations of cool, slightly cool and slightly warm, relative to neutral, with the percentages of errors for all tasks (higher percentages of errors). However, positive associations with the percentages of errors were observed for perceiving the thermal environment as cold, warm and hot relative to neutral (lower percentages of errors).

Table 2. Changes in percentage of errors for two cognitive performance tasks before and after adding the confounding variables compared to the baseline condition (Condition 1).

The confounding variables considered	Zero model SRT accuracy (error%) estimate (95% CI)	SRT accuracy (error%) estimate (95% CI)	Zero model RL accuracy (error%) estimate (95% CI)	RL accuracy (error%) estimate (95% CI)
Condition 2 vs. 1	2.4 (1.4, 3.4)	5.4 (3.6, 7.1)	3.9 (2.6, 5.4)	7.6 (5.8, 10.4)
Condition 3 vs. 1	5.4 (4.9, 6.8)	9.1 (7.5, 11.6)	8.9 (7.6, 9.3)	16.9 (14.6, 19.4)
Condition 4 vs. 1	3.9 (3.5, 4.2)	7.70 (5.9, 9.5)	-1.9 (-2.4, -1.3)	-5.2 (-6.7, -4.7)
Condition 5 vs. 1	9.7 (9.3, 10.1)	20.6 (15.5, 19.6)	9.7 (9.3, 10.1)	18.1 (15.6, 19.6)
Condition 6 vs. 1	12.1 (11.7, 12.4)	29.1 (26.3, 32.6)	15.1 (14.7, 16.5)	30.8 (27.3, 33.3)
Condition 7 vs. 1	4.4 (3.0, 5.8)	8.4 (6.4, 10.5)	8.8 (8.4, 9.2)	13.9 (11.36, 15.4)
Condition 8 vs. 1	13.9 (13.5, 14.2)	30.3 (27.0, 32.6)	17.3 (16.9, 17.7)	32.4 (29.9, 35.9)
Condition 9 vs. 1	22.1 (21.8, 22.5)	46.1 (43.7, 47.4)	21.6 (20.0, 22.1)	47.6 (43.0, 49.1)
Ethnicity (Saudi vs. other)		-2.2 (-3.4, -1.4)		-2.3 (-3.5, -1.4)
Cold vs. neutral		10.6 (5.1, 7.0)		10.7 (9.1, 11.4)
Cool vs. neutral		-1.5 (-2.2, -0.3)		-0.9 (-1.5, -0.4)
Slightly cool vs. neutral		-2.5 (-3.6, -1.0)		-1.8 (-2.6, -0.1)
Slightly warm vs. neutral		7.0 (4.5, 6.6)		-0.5 (-0.3, -0.8)
Warm vs. neutral		9.1 (5.5, 7.7)		12.2 (7.1, 9.9)
Hot vs. neutral		14.5 (8.3, 10.3)		18.0 (13.0, 15.9)
AC temperature at home (per unit between 18°C-24°C)		-0.9 (-1.1, -0.7)		-0.9 (-1.1, 0.73)
Detected intolerable thermal discomfort vs. not		14.5 (8.3, 10.3)		18.0 (13.0, 15.9)
Other symptoms reported vs. not		16.6 (12.6, 20.8)		17.0 (14.7, 21.8)

## DISCUSSIONS

The aforementioned results indicated that the exposure to CO<sub>2</sub> of 1800 ppm and 1000 ppm have led to a significant increase in the percentage of errors for all tasks, versus 600 ppm. These results agree with Twardella et al. (2012) who reported a significant increase in the percentage of errors when CO<sub>2</sub> levels were 2000 ppm, relative to 1000 ppm in their field study, in assessing the effect of IAQ as indicated by the median CO<sub>2</sub> level effect on the concentration performance of students. Also, Allen et al. (2015) observed that several domains of the decision-making tests decreased significantly and by a very high degree during exposure to CO<sub>2</sub> at 945 and 1400 ppm compared with the levels of 550 ppm. It is worth noting that in this present study that CO<sub>2</sub> is not considered to be a pollutant but an indicator of the efficiency of ventilation. In this regard, numerous studies like Bako-Baro et al. (2012) and Coley et al. (2007) provided evidence that poor ventilation rates in classrooms significantly impair students' attention and vigilance. Moreover, interestingly the inclusion of the confounder of set AC temperature at home in the final model resulted in a significant decrease in the percentages of errors for every unit increase in temperature in the range between 18 and 24°C. Correspondingly, it was found that the subjective ratings of the TSVs of the participants varied considerably by ethnicity. For the Saudi participants, exposure to 23°C reduced their thermal sensations to slightly warm from cool and/or slightly cool at 20°C, while at 25°C

almost all participants perceived the ambient thermal environment as uncomfortably hot. However, the non-Saudi participants perceived the thermal environment as slightly cool and/or neutral at 23°C while more participants reported feeling cold, cool and slightly cool at 20°C. Fewer participants reported feeling hot at 25°C relative to the Saudi participants. According to de-Dear and Brager (1998), human adaptation to the thermal environment, physiological and one's past thermal exposure experience plays a crucial role in human's thermal comfort sensation. Thus, this could be interpreted as the effect of home acclimatization of the most prevailing set AC temperature on mean comfort sensations. It was noted that the thermal sensation votes were very much influenced by the AC set temperature at home. Yamtraipat et al. (2005) supports this suggestion, and indicated that acclimatization to using home ACs could affect thermal comfort sensation considerably.

## CONCLUSIONS

- Temperature setting leading to sensation of cold, warm and hot are suggested to be linked to a significant decrease in accuracy for both memory and vigilance tasks, and also the exposure to higher CO<sub>2</sub> levels of 1800 ppm and 1000 ppm compared to 600 ppm.
- It is of a great importance to consider the effects of acclimatization, AC set temperature at home, and the associated intolerable thermal discomfort and other symptoms that may be caused when developing the thermal comfort standards in this climatic context.

## **Thermal and mycological active protection of historic buildings on the example of the baroque residence of Polish kings in Wilanów**

Robert Wójcik<sup>1</sup>, Piotr Kosiński<sup>1,\*</sup>

<sup>1</sup>University of Warmia and Mazury in Olsztyn, Olsztyn, Poland

### **ABSTRACT**

Protection of the external partitions of historic buildings is a broad topic due to the limited possibilities of interfering with the structure. Restoration restrictions on prevention in the mycological protection of historic buildings are so large that, from the broad list of possible protective measures, practically only the heating of the nodes and the control of air parameters are practically safe. The reason for restrictions is the lack of possibility of introducing architectural changes and the limited possibility of interfering into the structure of external partitions.

A fast method that uses fluorescence was used for quantitative assessment of the mycelium development during the research and design work preceding the revalorization of the baroque seat of Polish kings in Wilanów (Warsaw). Mould mycelium were found mainly in the areas of increased humidity of the substrates. The use of an innovative method of local reheating of thermal bridge areas has been proposed there. Systems for reheating with halogen radiators using various infrared radiation (IR) bands were analyzed. There was also designed an anti-condensation system consisting on electric heating cables. The proposed solutions prevent the development of mould mycelium to a satisfactory degree. Finally, the interior of the palace regained its beautiful appearance and healthy microclimate.

### **KEYWORDS**

Historical buildings, mycological protection, thermal bridges, anti-condensation systems, infrared heating.

### **INTRODUCTION**

Historical buildings, especially those from the Baroque period, are often exposed to moisture and mycological problems. The baroque style developed mainly in Italy, where, due to the warm climate, the departure from the massive Gothic architecture did not result in the mould mycelium growth. Significantly lighter construction, with numerous niches intended for extended architectural details, may result in moisture degradation of the building in less than favourable Central European climate conditions. Mycological problems were found in the royal palace in Wilanów in Warsaw. The building was erected for Polish King Jan III Sobieski in the years 1681-1696, according to the design of Augustyn Locci, stylized on Italian styles. The problems were mainly concerned the surface of thermal bridges within the connection of external walls and ceiling, where in the winter time, condensation of water vapour occurs. An intervention was needed, due to the indoor environment deterioration and threats to the valuable interior design of painting and sculpting. Despite the numerous reconstruction changes resulting from the destruction that occurred during World War II, the architecture of the palace is original and required full protection. It is a particularly valuable combination of European art and the old Polish tradition of construction. One of the most important and difficult problems requiring an urgent solutions in the palace, was the necessity

to increase the surface vapour condensation resistance of the palace enclosure. It is a complicated issue which should be considered individually for each building. (Bomberg et al. 2016, Wójcik et al. 2017). Figure 1 presents the building and its interior designs.

Figure 1. Baroque palace in Wilanów. The façade and ceilings.

In the Baroque historical facilities, the thermal and moisture problems of the external partitions usually concern roofs in the zone of attic walls and cornices. Due to the valuable design of both external and internal façades, the classic procedure of implementation additional thermal insulation was unacceptable in the analyzed case. On the example of the palace in Wilanów it was possible to present the scope of research and computational analyzes that were used to develop innovative solutions in the field of thermomodernization of museum rooms, using local heating of thermal bridges.

#### **ASSESSING THE MYCOLOGICAL CONDITION OF THE SURFACE**

A non-destructive method, based on fluorimetry detection of the enzyme in filamentous mycelium was used (Rylander et al. 2010). A total of 47 surface sampling points were selected. Each sample was taken using sterile cotton swabs from a surface of 9 cm<sup>2</sup>. The selected positions of samplings were characterized with visible surface changes.

The fluorimetry method, a quantitative method, is based on the determination of the mycelium mass density on the tested surface using a fluorocarbon substrate that releases a fluorescence fluorophore under the influence of division process. The intensity of the light emission phenomenon by a substrate excited by electromagnetic radiation depends on the mycelium biomass density. The method serves both to diagnose areas of mycelial growth as well as to control the effectiveness of cleaning the mould, which is particularly important in facilities requiring urgent intervention.

The mycelium density is categorized into three levels:

- category A - up to 25 units - normal level of mycelium- typical for clean surfaces,
- category B - 25÷450 units - level of mycelium above normal - indicates the growth of mycelium,
- category C - more than 450 units - very high mould level - high density of biomass.

Amongst 47 tested samples. 18 were classified in category A, 13 in category B and 16 in category C. The results presented in the Figure 2 clearly indicates that there was a serious mycological problem in palace and it required urgent intervention. It concerned not only the elements of the roof construction, but also the internal surfaces and external walls. Mould growth were closely related to the level of moisture content in the substrate material.

Figure 2. Illustration of the results of the mycelium density as a function of the moisture content in substrate of wooden elements.

An analysis of mycelium distribution, combined with measurements of moisture contents in substrates and with IR detection, clearly indicated that excessive cooling of the surface during the low outside temperature periods caused growth of mould. At first, the hygrothermal state of attics over the endangered museum rooms was analyzed. Unfortunately, two of required conditions for mould growth were fulfilled there: periodically an air temperature over 25°C and wood moisture content over 8%, theoretically it corresponds to relative air humidity around 40%. It was found during the investigation, that the air humidity in the closed zones of roof trusses exceeded 76% at 19°C. The moisture content in wood elements reached 90%. Poorly ventilated attics underwent heating during the insolation of the roof, while night cooling of the roof sheet caused 'morning dew' of the inner surfaces of the not insulated roof covering. Thus favoured the wetting of the timber roof construction. Fortunately, the protection of the roof truss zone was relatively an easy task. The problem can be solved by improving ventilation and by using chemical protection of elements. More complicated and difficult was to solve the problem of ventilated and full roofs, where the risk of excessive cooling occurred in the joints of ceiling and attic walls.

### HYGROTHERMAL SIMULATIONS OF THE AREAS OF THERMAL BRIDGES

When it is impossible to avoid thermal bridges in the renovated building, their impact on additional heat demand for heating the facility ought to be calculated as well as the risk of condensation and mould growth in areas of lowering temperatures on internal surfaces. Particularly endangered, during insulation, areas of roof and wall joints are those adjacent to geometrical type thermal bridges.

Temperature field analyzes were performed using the Finite Element Method in Autodesk Simulation Multiphysics 2013 software. The heat flow distribution is presented in the form of coloured diagrams. Calculations of thermal bridges include two or three dimensional heat flow analyzes. The sample calculation results of wall-roof joints are shown in Figure 3. Boundary conditions: standard conditions (based on ISO 6946),  $t_i=20^\circ\text{C}$ ,  $t_e=-20^\circ\text{C}$ , indoor air relative humidity 55%. The calculated dew point 10.7°C. Figure 3a presents the first corner. The computational calculated temperature in the corner was 12.12°C, what indicated on no water vaporization on the inner surface, but IR measurements indicated that the risk was present. Much more serious situation is presented in Figure 3b where the computational temperature was 5.85°C. The interior insulation of such knee wall will cause the movement of the temperature front into the wall and cooling the ceiling-wall joint (Figure 3c). Even, if the interior insulation layer was implemented, full protection against condensation would not be obtained (8.73°C). The periodically condensation of water vapor during the lower outside

temperature periods can be eliminated by installing infrared radiators or by performing an anti-condensation installation consisting of heating cables or mats and control automation.

Figure 3. Temperature distribution in the flat roof section. a, b) roof corners, c) interior insulation of the corner – incorrect solution due to the dew point.

### SELECTION OF THE METHOD FOR HEATING OF THE NODES

The IR radiators were investigated as the periodically solution to increase the temperature of the excessively cooled internal surfaces of the partitions. Generally, wave emission in the range  $0.76\div 1000\text{ }\mu\text{m}$  can be used to increase the surface temperature of partition. However, the most effective radiators that can be used to heat the surface operate in one of the IR range:

- IRS (Infrared Short) - shortwave radiation, IR wavelength  $1.2\text{ }\mu\text{m}$
- IRM (Infrared Medium) - medium wavelength radiation, IR wavelength  $3\text{ }\mu\text{m}$ ,
- IRL (Infrared Long) - long wave radiation, IR wavelength  $5\text{ }\mu\text{m}$ .

The division is contractual, because the ranges of emitted spectra waves overlap.

Originally, convection was the basic form of energy exchange in the palace rooms, only partially it was radiation. The use of additional radiators means that the transfer of heat to the partition surfaces will depend mainly on the temperature difference between the emitter and the partition surface. Thus, the length of emitted wave plays the main role. In the analyzed case, IR should be absorbed mainly by water vapor molecules. This is possible only when the energy of intra-particle vibrations is on the same level as the energy of the quanta of IR. The phenomenon of IR absorption by moisture should bring significant benefits. Infrared radiator, depending on the temperature, emit an energy wave length in the range  $1.2\text{-}5.6\text{ }\mu\text{m}$ . Due to the drying properties, quartz-halogen heaters with a temperature of wolfram fiber of about  $2\text{ }000^{\circ}\text{C}$  give the best results. On the other hand, in museum conditions (gilded surfaces), other aspects of IR emission should be taken into account. An important role is played by the effect of reflecting radiation – changing the direction of the wave propagation at the boundary of the surface with the internal environment. In practice, surfaces requiring heating to a safe level are very diverse. Thus, there is simultaneous almost perfect reflection, reflection scattering and absorption on such surfaces. The surface can thus absorb energy in a very diversified range depending on the reflective properties and the ratio of surface roughness to wavelength. So, the longer the wave and the smoother surface, the weaker the scattering. From this point of view, longer waves have the significant advantages of evenly heating the surface. Quartz-halogens, which emit the highest energy, but in the range of shorter reflected waves pose a threat to the polychrome. The share of radiation in the total energy balance would be too diverse in the case of valuable decorations, so it should be considered as disadvantageous phenomenon.

For the sake of problems related to one-side cooling of the partition joints, it is recommended to use the anti-condensation installation, for example the author's IN method (Polish patent nr

212791 – the method of insulation building partition from the inside). Positive results of the first implementations of the method in the historic town hall in Mrągowo and Social Security building in Bartoszyce influenced the choice of the IN method for the palace. In this case, the heating cables were designed from the attic side. Local reheating of excessively cooled areas prevents condensation due to local energy transfer. The method is easy to install, and what is more, it does not pose a threat to polychrome. The heating system may be constructed of the intelligent cables that detect other heat sources such as solar radiation and automatically adjust their heating power to receive the heat by environment (Figure 4). More heat is generated in cooler areas (e.g. window covers), less in warmer areas (e.g. the heater zone). Two parallel supply wires are embedded in a conductive polymer core. With decreasing the ambient temperature, the core of the conductor shrinks microscopically and the number of electric paths in the core increase, thus results in increased heat generation. Due to the variable power of the heating cables, the system is high efficient, because it only slightly increases heating costs. The system can be implemented in various insulation and finishing material solutions.

Figure 4 A self-regulating heating cable with possibility of adapting heating power to ambient temperature. 1-power supply cables, 2-conductive polymer, 3-insulation cover, 4-screen, 5-outer cover.

According to the patent description, in order to eliminate the negative impact of excessive cooling of the thermal bridges zones, the thermal insulation material should be placed leaving gaps for the heating conductors and temperature sensor. The heating system is initiated by the small controller located in a flush-mounted box (diameter of 60 mm). The thermal insulation layer can be covered with tight vapor barrier (e.g. in accordance with the principles of the single-sided internal barrier method) or panels separated by specially shaped joints with the function of linear reverse capillarity. The heating cable installed in critical heating areas can be treated as a supplement to the existing heating system, however, due to the small and variable power of 5 to 20 W/m, depending on the ambient temperature, the range of influence is limited to the most cooled zone of the thermal bridge. This sufficiently eliminates harmful phenomena associated with the cooling of the partition surface, condensation of water vapor and the development of mould. During warmer spring and autumn days, external partitions can be effectively protected when the basic heating is turned off, because the temperature in the connector is regulated by the automatically activated anti-condensation system. The areas exposed to surface moisture condensation of the water vapor remain dry, making the rooms hygienic and clean, as dust does not settle as on the wet surfaces.

Figure 5 Temperature distribution in the heated node in winter. a) no heating b) heating

Positive thermal effects were obtained by placing the heating cable in the decorated attic of the palace (presented in Figure 1). The cable was placed on the outside, invisible to users. Thanks to this, it was possible to preserve historical matter without any interference in its structure. The obtained results for winter season (same boundary conditions as for Figure 3) are shown as false-color temperature distributions in Figure 5.

## DISCUSSION

An implementation of the anti-condensation system was examined also on the thermal bridges presented in the Figure 3. Under the same boundary conditions as the 1<sup>st</sup> simulation ( $t_i=20^{\circ}\text{C}$ ,  $t_e = -20^{\circ}\text{C}$ ), in case of the corner 3b, the 5W power of heating cables resulted in rising the corner temperature up to  $18.01^{\circ}\text{C}$  ( $12.16^{\circ}\text{C}$  more). While in case of the internal insulation layer (Figure 3c), the temperature of the contact point insulation-wall raised up to  $13.09^{\circ}\text{C}$  ( $4.36^{\circ}\text{C}$  more). Both results are above the dew point.

## CONCLUSIONS

The following conclusions can be made on the basis of mycological studies, analyzes and calculations:

1. The fluorescence method used to determine the mass of mycelium allows a full quantitative assessment of the mycological risk of the building.
2. Placing the insulation in the roof slope layers does not solve the problem of excessive cooling of internal surfaces in the areas of thermal bridges occurrence.
3. Good effects are achieved in the case of full roof by the introduction of heating of the attic zones with ventilation ensuring that the attics maintain a temperature of not less than  $20^{\circ}\text{C}$ , and humidity up to 55%.
4. In the case of flat and ventilated flat roofs, adequate protection against condensation in the thermal bridge zone can be achieved by introducing linear heating with self-regulating heating cables.
5. The hygrothermal calculations showed the correctness of the designed solutions, while maintaining the appropriate materials and proper ventilation performance of individual layers. Not insulated alcove knee wall require additional thermal energy supply. The use of shortwave radiation to avoid periodic condensation of moisture on their internal surfaces can be dangerous for the durability of polychrome.
6. The optimal solution seems to be performing the air heating of the attic with the air nozzles directed partly to the knee walls and the implementation of an intelligent anti-condensation installation consisting of heating cables and control automation.

### **ABSTRACT**

In this paper the subjective evaluation of the indoor environment of a secondary school in Treviso (Italy) is presented. Field campaigns have been carried out during the winter season in order to assess people overall satisfaction about the environment, their behavior towards discomfort and their interactions with the building and the systems. A specific questionnaire has been elaborated, paying particular attention to the occupants target and to the questions needed to grasp not only the comfort feedbacks, but also the dynamics and the individual students' attitudes that can influence the building energy performance. A first general evaluation has been elaborated for all the comfort areas (i.e. thermal, visual, acoustic and air quality) applying the method proposed by the EN 15251 for thermal comfort to all the comfort aspects. Then, further analyses have been implemented focusing on thermal conditions, in order to integrate the results and to check if an average comfort evaluation can be significant and representative of all the spaces in the building. Results show that specific classrooms conditions seem not to match completely the overall general analysis, even if representative differentiated spaces were selected for the analysis.

### **INTRODUCTION**

In the last decade, many works on Indoor Environmental Quality (IEQ) and Post-Occupancy Evaluations (POEs) in educational buildings have been performed on primary schools, secondary schools, and universities, aiming at a better understanding of the indoor conditions, especially focusing on thermal comfort. Nevertheless, beyond the thermal aspects, recent studies have also investigated the overall environmental comfort by considering various indoor aspects (Ricciardi and Buratti, 2018; Jamaludin et al. 2017). These works are based on field measurements, occupants' surveys, or a combination of them (Corgnati et al. 2007). Generally, POE is applied for a better understanding of occupants' comfort perception as well as for the estimation of students' thermal comfort ranges in comparison with the European standards (EN 15251,2007, ASHRAE,2017) however, integrating both the objective and subjective approaches, allows quantifying both the physical phenomena and the occupants' experience (Peretti and Schiavon, 2011). The two methods have been used together for analyzing the subjective parameters most correlated with quantitative results (Ricciardi and Buratti, 2018), as well as to investigate the impact of the IEQ on students' performance (Mishra and Ramgopal, 2015; Liu et al. 2015; Mongkolsawat et al. 2014). Personal perception has been also used to find the energy management strategies most suitable to ensure both energy efficiency and indoor quality (Kolokotsa et al. 2005; Zinzi et al. 2016). However, only few works focus on the behavioral response of students (Wong and Khoo, 2003; De Dear et al. 2015; Kim and De Dear,

2018) or try to investigate people preference in different environment and ventilation conditions (Dias et al. 2011, Chen et al, 2014).

This paper presents the results of subjective survey campaigns carried out on an educational building during the winter season of the scholastic years 2016-17 and 2017-18, with the aim of investigating the overall indoor environmental quality as perceived by students along with their opinions on the causes of discomfort and their reactions towards it.

## METHOD

The selected building is a secondary school in the Municipality of Treviso, in the North-East of Italy. It has been chosen as reference among a set of 41 educational buildings using the approach presented in Pistore et al. (2016). Built in 1985, it hosts about 1150 students aged 14 to 18, and consists of 4 floors plus a basement, for a total floor area of 12,605 m<sup>2</sup>, a heated volume of 50,845 m<sup>3</sup> and a compactness ratio of 0.35. Four main wings compose the building (Figure 1): offices and administration face North-West, while the classrooms are located all around the building, with a transparent envelope area of about 2,074 m<sup>2</sup>. The conditioning system consists of two different types: an all air system for the most part of the school, and radiators in a small classrooms area. Seven classrooms located on different floors and with different exposures have been selected, because of their representativeness according to EN 15251 (2007).

Figure 1. School ground floor map (left) and classrooms external and internal view (right).

A specific questionnaire has been elaborated and administered to 168 students during the regular classes. Five field campaigns have been carried out, from December 2016 to February 2018, only in the winter period with the heating system turned on. Subjective comfort responses have been assessed in seven selected representative classrooms, located on different floors and different areas of the building, in order to obtain a significant mapping of the environmental conditions inside the whole school as prescribed by EN 15251 (2007). An application on tablet devices has been used to administer the questionnaires, consisting of six different sections: general student information, general comments, lighting and visual environment, thermal environment and air quality, acoustic environment. The sections about the comfort areas have been structured consistently and, in order to make comparison analysis more homogeneous, with the same evaluating scales. In more details, a sensation vote scale, according to (EN ISO 10551,2002), (ASHRAE, 2012) and Annex H of EN 15251 (2007), rated from the lowest (-3) to the highest (+3) level a specific aspect, with 0 being the neutral condition. A Likert scale was

used for assessing occupants' satisfaction, in ascending order of satisfaction from 1 to 7 according to (EN ISO 10551,2002) and (ASHRAE,2012). Finally, the survey included a scale of preference, according to Annex H of EN 15251. In order to investigate the causes for discomfort, multi-choice questions have been introduced along with some specific questions about their habits when actions to modify the environmental conditions are required. Questions did not include technical terms (for instance lighting level was used instead of illuminance, air temperature for thermal environment, etc.) to be more understandable to pupils.

## RESULTS

In order to evaluate the overall indoor environmental quality inside the school, the method prescribed in EN 15251 – Annex I.4 (2007) has been applied. Although it is proposed only for thermal comfort and air quality, it has been extended to the other comfort areas. Likert 7-points scale answers have mainly been taken into consideration for the assessment of the satisfaction (votes larger than or equal to 4 have been considered as satisfied). In addition, for the visual and thermal comfort, some more detailed information have been reported, such as the percentage of answers in the sensation votes and in the preference vote scales.

Although 44 % of them report high lighting levels (Table 1), this does not cause much discomfort to the students: almost 84 % are satisfied, 71 % do not prefer any change and the remaining are almost equally preferring lighter and darker conditions. This is a very interesting outcome, which suggests how comfort is not always associated with a condition of neutrality.

Also in terms of thermal comfort, only 27.4 % of students perceive a sensation of neutrality, but, also in this case, 51 % are satisfied and 41 % would not have any change. Since satisfaction is lower and almost half of the population would prefer warmer temperatures, this aspect will be further investigated in the discussion section.

Also air quality raises some concern, with only 55 % people satisfied, despite the fact that most of the building is served by an all air system.

Finally, students seem to be very satisfied with both the acoustics (89 %) and the acoustic insulation of the building towards the outdoor noises (71 %).

## DISCUSSION

Figure 2 shows an overview of the declared causes of discomfort and the behavior of students when annoyed by the environment.

Concerning the lighting environment, part of the occupants reports high lighting conditions, but only 10 % of the students take action towards it, whereas 44 % and 38 % rely on schoolmates and on the teacher to operate shades (Figure 2a), revealing a certain inertia.

Regarding the thermal conditions, the majority of the students (62 %) generally feel thermal discomfort during the first hours, from 8 a.m. until about 10 a.m., suggesting inefficiencies in the heating system operation. Occupants themselves relate this to the system regulation, but also to draughts and to surface temperatures (Figure 2b) and, in order to enhance their thermal sensation, 53 % of the students declared to take action to modify their clothing level.

In terms of air quality, 64 % of the occupants perceive unpleasant odours, with the result that windows are opened from 2 to 5 times per day, usually during intervals. This is confirmed also by the behavioural report: 42 % use to act towards discomfort, but still a great share rely on schoolmates and teachers (Figure 2c).

Regarding the acoustics, even if satisfaction is high, occupants report being annoyed by noises from adjacent spaces: this may indicate an issue in the acoustic insulation of internal walls and floors. Also in this case, students reveal to be very passive users: half rely on teacher's help to close doors and windows, and a quarter of them does not act against discomfort.

However, when a large building is considered, satisfaction and preference votes could hide some specific problems related to different spaces and conditions in the building.

Table 1. Classification of the environment based on occupants responses

Lighting	Satisfaction (≥ 4)	83.9%						
	Sensation	-3 (Low)	-2	-1	0	1	2	3 (High)
		1.2%	0.6%	7.1%	47.0%	13.1%	26.2%	4.8%
	Preference	Lighter		Unchanged			Darker	
		12.5%		71.4%			14.3 %	
Temperature	Satisfaction (≥ 4)	51.2%						
	Sensation	-3	-2	-1	0	1	2	3
		3.6%	13.1%	20.2%	27.4%	23.2%	10.1%	1.2%
	Preference	Warmer		Unchanged			Colder	
		49.4%		41.1%			8.3%	
Air quality	Satisfaction (≥ 4)	54.8%						
Acoustics and insulation	Satisfaction (≥ 4) acoustics	88.7%						
	Satisfaction (≥ 4) insulation	70.8%						

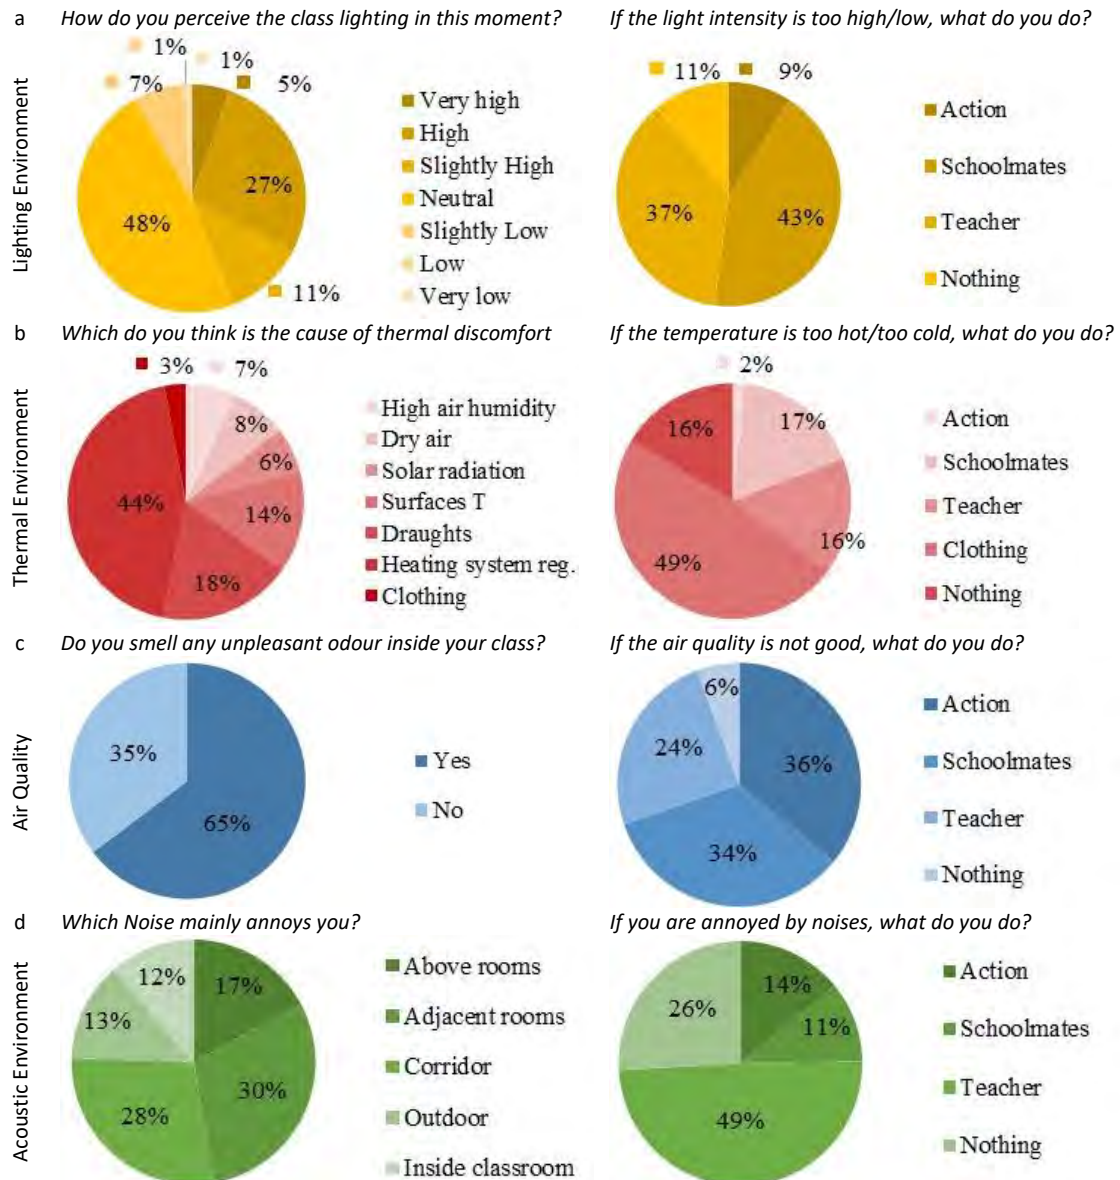

Figure 2. Causes of discomfort (left) and students behavior towards discomfort (right)

Considering the lower satisfaction for thermal conditions, a deeper analysis has been devoted to specific features of the classrooms, namely the different floor and the different heating

system. In particular (Figure 3), the satisfaction with air temperature increases from 44 % on the ground level, to 82 % on the 3<sup>rd</sup> floor. On the ground floor, 45 % of the students perceive a temperature from slightly cool to cold, contrarily to the 3<sup>rd</sup> floor spaces, where discomfort is caused by temperatures slightly warm (50 %). Focusing on the ground floor, where discomfort is higher, it appears that classrooms heated by different systems perform very differently. Occupants in spaces with an air system declared much greater dissatisfaction with the thermal environment (54 %), due more often to cool temperatures. In rooms with radiators, on the contrary, students reveal to be more satisfied (78 %) and, in case of discomfort, this is caused by warmth, consistently with what happens on the 3<sup>rd</sup> floor.

This shows that, sometimes, an overall evaluation of a building is not an easy task. In fact, as in this case, an average of the sensation votes, as reported in Table 1, could not be representative of every room in the building.

*How much are you satisfied with the air temperature in your classroom?*

Figure 3. Comparison of subjective thermal perception in different classrooms

## CONCLUSIONS

In this paper, the evaluation of the indoor environment of a secondary school building is reported. An average evaluation has been elaborated for all the comfort areas, with an attempt to extend the prescriptions of Annex I.4 about thermal comfort also to the other areas. A further analysis has been implemented focusing on thermal conditions, in order to check if an overall comfort evaluation can be significant and representative of all the spaces in the building. Results show that the use of all the occupants' answers sometimes does not reflect the peculiarities of some parts of the building even if representative differentiated spaces are selected, thus compromising the potentiality of surveys in detecting problems about the building operation. Moreover, the study reveals that young students aged from 14 to 19 are very passive towards discomfort: this is an important aspect to be further investigated, especially in a shared environment, as school is, and considering all the factors involved in a peculiar young environment with its own internal dynamics. Understanding and recognizing patterns in occupants' behavior would surely be a step forward in grasping information useful for energy consumptions evaluations and for adopting new strategies.

## ACKNOWLEDGMENT

The authors would like to thank the Municipality of Treviso, the Head and the members of ISISS Da Collo of Conegliano for making the school available for this research.

## **Comparison between qualitative and quantitative measurement in assessing thermal comfort in an elementary school**

### **ABSTRACT**

We compare qualitative and quantitative measurements to assess an elementary school building's thermal comfort. Quantitative measurements of the physical environment are useful but not sufficient, since different people respond differently in the same indoor environment. A qualitative survey of the school employees shows the thermal comfort level has a 3.73 out of 7 score and 40% of subjects rated it unsatisfactory, even though the temperature and humidity level are measured within the comfort range recommended by ASHRA 90.1 – 2004. This gap occurs because human metabolism is not taken into account in current design guidelines, even though there is a clear correlation between human metabolic level and perceived thermal comfort. The gap between design guidelines and occupants' thermal comfort presents an opportunity to improve indoor environmental quality. School buildings are especially challenging because they have a mix of adult and child occupants with widely varying metabolic rates. Therefore, an elementary school was used as a case study to compare differences between quantitative and qualitative measurement. We conducted a series of simulations to compare the thermal comfort in relation to adult and children's metabolism and their thermal responses. We demonstrate that the negligence of occupants' metabolism can lead to inaccurate design guidelines for the physical environment's thermal comfort. Our results could potentially improve design manuals to accommodate buildings with mixed occupants to maximize comfort levels.

Thermal comfort, metabolic rate, qualitative and quantitative, elementary school, adaptive model

### **INTRODUCTION**

Most elementary schools in United States were built during the 1950s to 1970s and are in need of renovation, modernization and repairs (Sheryl, et. Al, 2017). One of the most critical issues among those public schools that were built prior to active mechanical systems is the lack of control of thermal comfort of the interior environment (U.S.ED, 2012). As the design standard evolves, new buildings optimize indoor environment comfort, especially thermal comfort via active mechanical systems. However old facilities are designed with passive strategies which try to create a steady singular environment. Maintaining a comfortable indoor environment while simultaneously preserving energy will be a major challenge for both designers and school administrations.

Clients are usually given three options for old school buildings: demolishing, renovating, and retrofitting. To get a better understanding of existing school buildings and to understand the targeted area of improvement through retrofitting, we took a case study that focuses on an elementary school built prior to active mechanical systems. We measured an elementary school facility in Maryland, USA, which is in climate zone 4 according to IEC (International

Energy Code). The building is a 44,200 square foot educational facility approaching the end of its expected life cycle. Constructed in 1968, the building envelope consists primarily of CMU block with a single layer of brick veneer, gypsum roof assembly, and a hollow core concrete slab finished with terrazzo over a plenum space for gas furnace duct system. The primary massing of the building is one story with partial double height at the gymnasium. School classrooms are installed with a water-based heating system, which are non-adjustable, and with window-mount air conditioners.

The assessment of thermal comfort in elementary school is challenging because both adults and children use the space relatively equally. Many people have conducted research focusing on regional climate and indoor environment and its impact to students' health and learning process (Sheryl. et.al. 2017). Research shows that thermal comfort may have a direct impact on working efficiency and learning ability in an enclosed environment. Even though the current ASHRAE considers an adaptive model when measuring thermal comfort, assessing thermal comfort in buildings that are built with passive strategies requires an additional evaluation to gain the users' responses.

## METHODS

### Qualitative

The first step of evaluating the building performance was to take qualitative data, which helps to understand which part of the building needs to be improved. We distributed an occupancy survey among 19 faculty and staff. The survey had 11 questions, covering comfort and satisfaction ratings on lighting, daylighting, thermal, acoustic and air quality. Survey respondents were provided the opportunity to respond on a scale of 1-7 for each question; responses measured as 3 or under were regarded as "dissatisfied." Survey results were anonymous and unbiased regardless of staff occupation and working locations.

In the thermal comfort portion, we asked the participants two questions. The first was to identify whether they could adjust the thermal comfort level of the rooms, and the second was to evaluate the overall thermal comfort of their work environment.

**Part 1 - Indoor Environmental Quality**

Room number

## Quantitative

In this survey, measurements included CO<sub>2</sub> levels in parts per million, decibel levels, lux levels, humidity percentages, and air temperature. Instruments used included portable digital CO<sub>2</sub> meters, digital sound level meters, digital light meters, and digital psychrometers. We split into three groups, and measurements were acquired from all locations of the school at approximately 1:30 pm on February 7th, 2017.

Psychrometers graph is one of the best way to represent temperature and humidity as the parameter of thermal comfort. To further expand our data analysis we utilized the CBE thermal comfort tool developed by Center for the Built Environment in UC Berkeley. The model is based off Gail and Brager's original research ASHRAE RP-884, now the new ASHRAE 2004 standard hypothesized a thermal conform model called 5h3 adaptive model. This model accounts for behavioral adjustment, physiological and psychological adaptation within a built environment. (Richard and Gail, 1998) The fundamental principal of adaptive model for thermal comfort is to acknowledge human behavioral adjustment, physiological and psychological adaptation within a built environment. (Richard and Gail, 1998)

Thermal comfort in buildings built before active mechanical control is achieved by passive strategies and natural ventilation. Constructing active control in these buildings would be expensive and require significant maintenance, therefore retrofitting is one of the best options for minimal energy consumption.

## RESULTS

### Existing Conditions

We found an average thermal comfort satisfaction level of 3.9 out of 7. Of 19 responses, 40% ranked 3 or lower. (*fig 1*) Surveyed occupants had access to operable blinds/shades, permanent heaters, doors to interior space, operable windows, and room air conditioning units. Occupants did not, however, have access to customizable thermostats, portable fans, adjustable vents in wall or ceiling, portable heaters, or ceiling fans. (*fig 1b*). In other words, humidity of 33.5%. Recorded temperatures ranged from 22 °C to 26 °C and humidity ranged from 27.7% to 38%. (*fig 2*). We used this data to generate a psychrometric chart, applying the metabolic rate of a seated adult with average summer clothing (given the outdoor conditions on February 7th were quite temperate). The result was outside the noted range of accepted thermal comfort. (*fig 3*)

Figure - 1.a) Thermal comfort satisfaction. b) Thermal comfort control flexibility

Figure - 2. - Air temperature vs humidity

Figure - 3. Psychrometric chart based on a seated adult

We concluded from the qualitative and quantitative data that the thermal comfort in the building under study was unsatisfactory for adults. We next simulated the children's thermal comfort using the same physical environment. The two most prevalent methods for determining the thermal comfort of individuals are the adaptive method, and the rational method. The adaptive method involves surveying the occupants to determine the most comfortable conditions for users. Problems with this method include environmental variability and inaccuracy of survey reports in terms of reproduction. A key stipulation of the adaptive approach is "*if a change occurs such as to produce discomfort, people react in ways which tend to restore comfort.*" (Nicol and Humphreys, 2002). According to De Dear's research on adaptive model, the adaptive process also predicts that persons in warmer climates will prefer warmer temperatures indoors, whereas persons in colder climates will prefer cooler temperatures indoors (1998).

The rational method, according to Nicol and Humphreys (2002), involves an index which develops a model for thermal comfort based on variables listed above such as metabolic rate and clothing insulation. We used both the rational and the adaptive method when analyzing our case study school in Maryland.

## Simulation comparison of thermal comforts

Interestingly, the resting metabolic rate is reduced from infancy to adulthood by 1.5-2 times according to Son'kin and Tambovtseva (2012). Taking this fact into account, we produced a series of psychometric charts using CBE comfort simulation analyzing isolated variables between persons with a metabolic rate of 1 (adults) 2 (children), assuming an indoor temperature of 23.8 °C and a relative humidity level of 50%. The variables included high air speed, low air speed, and varying clothing. We found each variable tested made either the adult control or child control uncomfortable. However, we produced a chart overlaying child comfort over adult comfort, where airspeed was adjusted for children and clothing insulation was adjusted for adults.

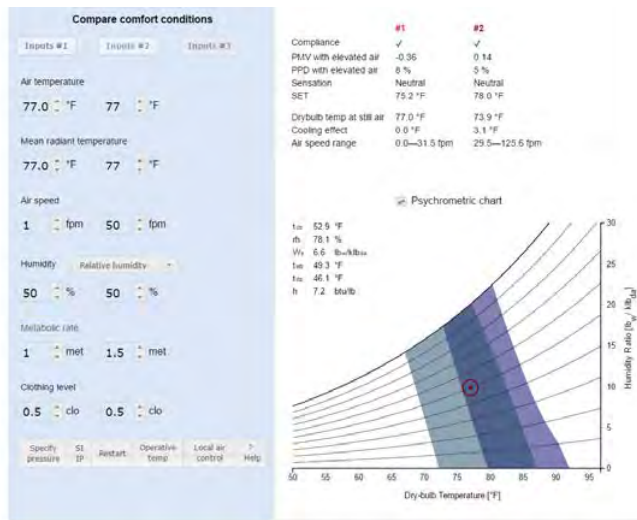

Figure.4 - Simulated thermal comfort comparison of pupils and adults in the same environment due to different metabolic rate.

## DISCUSSIONS

This research produces thermal comfort for both adults and children via the rational index. The overlaying result shows that using the adaptive model could produce a comfortable condition for everyone, which would require either one of the occupancy group adjust clothing level or activity level (direct relative to MET rate).

To adjust air speed, a building could either upgrade the HVAC system to be active or zoned to cater to either students or faculty. Another option which reflects the survey is to increase the use of portable devices that allows the faculty to control the ventilation rate. Elementary school usually tend to have a student-teacher ratio between 15:1 and 20:1. Priority of improving thermal comfort would be given to students. Faculty and staff in classrooms would adjust their clothing levels to adapt to the higher air speed conditions.

Taking both qualitative and quantitative data into account mitigates some of the limitations of both data sets. However, neither rational nor adaptive methods provide accurate thermal comfort for students (Zahra, et al 2017). One of the concerns for conducting pupil-focused qualitative surveys is that students have not yet developed a complete and comprehensive perception of thermal comfort. To minimize the potential impact on the qualitative data, we

decided to adopt the simulation result to generalize the possible thermal comfort responses from pupils. Surveys for children, especially 5<sup>th</sup>-grade and below, may require a different writing style to be properly understood than surveys for adults. The school administration may consider providing thermal comfort education to allow the students to express their feelings accurately and respond to indoor environments properly.

## CONCLUSIONS

As many school facilities approach the end of their life cycle, it is critical to reconsider the design of the school facilities. Because implementing an active HVAC system for a whole building might be too economically challenging to be feasible, it is useful to learn and assess occupants' thermal comfort from multiple perspectives. Having a comprehensive assessment for a school facility that in need of future repair and renovation will help the school administrators identify potential problems, minimizing the discrepancy between design and end product of the architect. More importantly, better assessments of school facilities will enable more accurate responses to occupants' sick-building syndrome and eventually create better and healthier environments for both young and adult occupants.

## **Empirical assessment of summertime overheating risk in new, retrofitted and existing UK dwellings**

Rajat Gupta\* Matt Gregg, and Robert Irving

### **ABSTRACT**

This paper statistically assesses the hourly internal summertime temperature datasets gathered during the summer of 2013 (May to September), from 63 dwellings across the UK. The sample consisted of unmodified dwellings (existing); dwellings with varying levels of fabric improvements (retrofitted) and dwellings constructed to higher levels of the Code for Sustainable Homes (new). Indoor and outdoor temperature data from bedrooms and living rooms from these homes were collected at five-minute intervals using temperature sensors. These data were processed and analysed for summertime overheating, using both static criteria (CIBSE Guide A) and the criteria associated with the EN15251 adaptive thermal comfort model (CIBSE TM52). The results show that despite a relatively cool summer, sufficiently high temperatures were found in a high proportion of dwellings, which were found to be overheated according to the CIBSE static temperature criteria, although the prevalence of overheating was found to be much lower when assessed by the adaptive method. Considerably higher temperatures were found in bedrooms, much higher than living rooms. Interestingly, dwellings with higher levels of insulation experienced overheating twice as frequently as uninsulated dwellings. Given the prevalence of overheating found across the sample, it is necessary to carefully consider this risk during the design and retrofit of homes, to avoid the growth of domestic air-conditioning in future.

### **KEYWORDS**

Dwellings, overheating, UK housing, adaptive thermal comfort, indoor air quality

### **INTRODUCTION**

Despite the relatively mild climate of the UK, concern has increased about summertime temperatures in dwellings due to the effects on occupant health of high temperatures and the possibility that these may occur more frequently with the forecast rise in global temperatures. Though overheating may be prevented by the use of air-conditioning, this will add, undesirably, to greenhouse gas emissions through increased energy use and refrigerant emissions. As most UK householders turn their heating off in the summer even when temperatures are comparatively cool, the fabric of the dwelling can provide a cool buffer against hotter weather. It is therefore important to study internal temperatures in dwellings to observe the relationship to construction, dwelling type and occupant characteristics.

With the implementation of the higher level of fabric efficiency under current UK Building Regulations, overheating in newly-constructed dwellings has become a concern, particularly due to the perception that it is caused by the 'excessive' levels of insulation required to reduce heat energy consumption and hence CO<sub>2</sub>e emissions to meet the requirements of the UK Climate Change Act. With the focus on overheating has come a realisation that both the definition of, and the criteria for assessing overheating in naturally-ventilated residential buildings are inadequate (CIBSE, 2013).

Previous studies examining summer temperatures in UK dwellings have included Lomas and Kane (2013) who found, in a study of 230 dwellings in Leicester, that a sizeable proportion had temperatures outside the ranges anticipated by the BS EN 15251 model. Beizaee et al. (2013) performed a similar study based on 207 dwellings across the UK. This study found that a large proportion of living rooms and bedrooms had more than 5% of their occupied hours above the CIBSE recommended temperature thresholds of 25°C and 24°C respectively. Across the regions of the UK, warmer homes were found in the South East, the East, East and West Midlands, with cooler homes in the North East, North West and Yorkshire. The oldest dwellings (pre-1919) were found to be significantly cooler than more modern homes, solid wall houses cooler than those with cavity wall construction and detached homes cooler than those of other built-form types. This study also found that dwelling temperatures in cooler UK regions were correspondingly cooler than those in warmer regions, inferring from this that a further level of adaptation, dependent on region, is required.

The objective of this paper is to combine data collected from several studies to examine the variations between the different methods of assessing overheating and to examine the relationships between temperature and other environmental variables. The study is significant in that it contains data gathered from existing houses, both with retrofit energy efficiency improvements and without, and new houses built to the highest energy efficiency levels under the UK standards current at this time (DCLG, 2006). This allows the examination of the differing effects of built-in and retrofit energy efficiency measures and unimproved housing, whereas the previous studies lack the ability to make these distinctions.

## **METHOD**

This study is based on data collected between 1 May and 30 September 2013 in nine different locations in the UK, ranging from Swansea in the west to Tyneside in the north and west London in the south. The data analysed for this paper come from one large-scale monitoring study and three smaller studies. The large-scale study, known as EVALOC, covered 57 existing dwellings in six locations across the UK. The dwellings in these locations include a mix of existing (unchanged) and retrofitted dwellings. For EVALOC, temperature data were collected via sensors linked to a wireless network within the house, from which it was transmitted to a webserver for accumulation and download as required for analysis. In some dwellings data were also acquired by individual 'button' loggers for direct download to a PC.

The three smaller studies each consisted of two new-built dwellings and were carried out as Building Performance Evaluation (BPE) studies, being accompanied by a detailed survey of the occupant satisfaction with the dwellings and a comparison dwelling as built with the original design. Because of the higher level of air-tightness enforced by Code for Sustainable Homes, all these houses have mechanical ventilation with heat recovery (MVHR) installed to provide ventilation and prevent condensation from excess humidity. Temperature data for the BPE studies were collected every five minutes from wireless sensors transmitted to a data-hub and uploaded over Global System for Mobile Communications network to a website for acquisition. The environmental data were limited to a period of between three and nine months with some gaps in the data due to the limitations of the data loggers. Sufficient data were collected over the summer period to assess overheating.

In all the studies, external temperature and RH were also collected by the same methods for all dwellings with the exception of C3 and C8 where external temperatures had to be extracted from nearby weather stations due to equipment failures. Table 1 lists the communities of dwellings and their relevant characteristics.

Table 1. Characteristics of study dwellings

	<b>Location (Code) / setting</b>	<b>No. of dwellings: Date of construction mix</b>
EVALOC	Community 1, South Wales (C1) / rural elevated	Total 11: pre-1919, 1919-44, 1965-80, 1981-90, post-1990
	Community 2, Merseyside (C2) / suburban sheltered	Total 12: 1919-44, 1945-64, 1965-80, 1981-90
	Community 3, North East (C3) / suburban sheltered	Total 10: 1919-44, 1945-64, 1965-80

	Community 8, London (C8) / urban sheltered	Total 2: new-build BPE
	Community 9, Midlands (C9) / urban sheltered	Total 2: new-build BPE

### Overheating assessment

Research on overheating in dwellings commonly employs two different methods of assessment published by the Chartered Institution of Building Services Engineers (CIBSE). For overheating criteria in non-air-conditioned buildings, CIBSE's Environmental Design Guide A (CIBSE, 2006) suggests that values for indoor comfort temperatures should be 25°C for living areas and 23°C for bedrooms. CIBSE notes that temperatures are expected to be lower at night with people finding that sleeping in warm conditions is difficult, particularly above 24°C. Environmental Design Guide A provides static benchmark summer peak temperatures and overheating criteria:

- 1% of annual occupied hours over 28°C in living rooms
- 1% of annual occupied hours over 26°C in bedrooms

For adaptive thermal comfort, the BS EN 15251 (BSI, 2008) criteria were developed taking the outdoor conditions and human adaptation into account by identifying comfort limits based on a running mean of external temperature and the quality of the thermal comfort required. Based on this, the CIBSE TM52 (CIBSE, 2013) document suggests a series of criteria by which the risk of overheating can be assessed or identified. The first criterion suggests that the number of hours during which the internal temperatures are 1 K higher or equal to the upper comfort limit during the period from May to September should not exceed 3% of occupied hours. For the adaptive assessment, the 'running mean' comfort temperature range was calculated using the external temperatures acquired for each locality.

For both methods of assessing overheating, priority is given to those hours during which each room is occupied. For this study, it is assumed that living rooms are occupied between 7 am and 11 pm and bedrooms are occupied for the remaining hours from 11 pm till 7 am. Treating only these periods as significant for overheating could be considered somewhat restrictive since a considerable proportion of the population work shifts and will need to sleep during the day at times of higher outside noise levels, precluding window opening etc.

## RESULTS

Regarding external temperatures, localities in the north (including urban) and those in the rural localities of the south had the lower temperatures. Those in the urban areas of the south had the highest temperatures. Overall the analysis illustrated a fairly mild climate with only short intervals of high temperatures and comparatively low minima, which should enable householders to use night-time cooling if necessary. From cooling degree day (CDD) analysis it would appear that localities C1 and C5 had considerably warmer summers than usual, C3 and C7 somewhat warmer, C2, C8 and C9 were, more or less, as would be expected and C4 and C6 considerably cooler.

### Overheating in bedrooms and living rooms

The most significant result from static overheating analysis for bedrooms is that only one dwelling, C3-H06, out of 63 dwellings in the dataset, does not exceed the 26°C limit. Five dwellings out of 34 with cavity wall insulation and two out of 24 dwellings without wall insulation experienced significant periods of >30°C temperatures. Of the modern houses in the BPE studies, only one, C7-H02, maintains temperatures close to the CIBSE requirement. *Note that the dwellings in C7 were unique in that they are constructed of heavy-weight hempcrete, whereas the other BPE dwellings are light weight timber construction.* Results for overheating assessment using the adaptive method indicates that far fewer houses are judged to overheat under these criteria, six out of the 34 with cavity wall insulation and three out of the 24 with no insulation. Similarly, fewer instances of overheating were found using the adaptive vs. static method in Gupta and Gregg (2017). In contrast to bedrooms there are considerably lower levels of overheating in the living rooms, indicated by the fact that only two houses, C4-H02 and C8-H01 were judged to experience any significant proportion of the summer period >30°C and only a further two, C1-H03 and C8-H02 had periods >28°C. There is also a similar lower level of overheating according to the adaptive method, with an identical list of dwellings being identified in the cavity wall insulation category plus only one in C4-H04 in the uninsulated category.

### Adaptive overheating analysis by dwelling characteristics

For dwelling types, the variation across built form is comparatively small, apart from a small sample of flats (n=2) where overheating durations are at least twice to four times the others. For the house types, the variations do not entirely reflect that expected from the differences in exposed outside walls. Mid-terrace houses, with the least exposed area have, as might be expected, the highest degree of overheating in as far as bedrooms are concerned. However, semi-detached houses, which would have been expected to have similar characteristics to end-terraces, are much warmer in bedrooms, but similar in living rooms; and end-terraces have the lowest values of all, at 25% of the semi-detached values. For dwelling age analysis, the most obvious group suffering from comparatively higher levels of overheating are those built between 1981 and 1990, where bedrooms exhibit twice the overheating as the next highest group and where living rooms are also significantly affected. The new-builds have highest level of overheating in living rooms.

The results of the insulation analysis show the insulated dwellings experience overheating approximately twice as frequently as those without; more dwellings with a percentage of occupied hours above comfort temperatures by the adaptive method (Figure 1). The analysis also considered whether the insulation was included in the house as-built or was the subject of a subsequent improvement, either before or after 2008 (pre-2008 insulation standards were lower). Again, dwellings with the highest standard of insulation installed as part of the build, post-2008, were assessed as experiencing the highest level of overheating and those with no

insulation as the lowest. The results of the analysis by UK region show little connection between the relative warmth of the 2013 summer and that of the 20-year average, since the dwellings in Wales, where 55.8% higher CDDs were experienced, were almost entirely devoid of overheating and the highest degree of overheating was experienced in London where the actual CDD showed little difference from the 20-year average.

Figure 1. Percentage of hours over comfort temperature (EN BS 15251) by wall insulation. *Note: dwellings are ordered by lowest to highest percentage for bedrooms in each category.*

## DISCUSSION

Of the 63 dwellings, only two were found to have bedrooms not exceeding the recommended temperature of 26°C and 17 (27%) were found to have bedrooms exceeded 30°C. Conversely, only three (4.7%) of the living rooms exceeded 30°C, and 22 (34%) had temperatures less than 26°C. In addition, considerably higher temperatures were found in bedrooms than in living rooms. There are wide variations in temperatures between bedrooms and living rooms even in the same dwelling. Overall, it was found that about 74% (42) of bedrooms had higher maximum temperatures than the living room, with this variation being about 1.5°C, whilst, across the remaining 26% (15), the difference was about 0.5°C. It is considered that the higher bedroom temperatures are attributable to the greater exposure to solar irradiance than living rooms since these are largely located at ground floor level rather than bedrooms which are located on the first floor. Given these findings it is important to consider for new-build and retrofit opportunities that bedrooms are equipped to adaptively cool the space, e.g. daytime shading devices designed for seasonal use.

Dwellings with insulated walls appear more prone to overheating than those without, particularly those built to the most modern specifications. However, it would appear that this tendency is moderated in high thermal mass dwellings such as C7-H01 and C7-H02. The coupling of high thermal mass and progressive insulation standards would benefit from further research as a potential solution to this apparent problem which is projected to be more problematic as the climate changes.

The adaptive method assessed far fewer rooms in the dwellings as overheating compared with the fixed temperature criteria of the static method. It could be argued from these results that the adaptive method adjusts better to changes in external temperature since it will adjust the assessment of overheating to correspond to the occupants' perception. However, it is important to note that the adaptive method was designed within the non-domestic context and

would benefit from a domestic counterpart as there is currently no dynamic overheating assessment method designed specifically for UK dwellings.

A *domestic* overheating method will need to be tested in all dwellings types, forms and ages since it is likely that any methods used to assess overheating will, in the future, be incorporated into UK government policy and, hence regulations affecting the design of and provision of cooling systems in, social housing, the efficacy of such methods are economically significant. If the required method over-estimates overheating and causes excessive rates of cooling system installation, this will lead to increase in initial building costs and, once such equipment is installed, it will inevitably be used, resulting in increased energy use (and costs) for cooling. If overheating is simultaneously associated with high levels of insulation, then this may lead to a reduction in insulation levels, resulting in excessive energy use for space heating. Conversely, if the method employed underestimates the extent of overheating, this is likely to result in higher levels of health problems, particularly for the elderly, with consequent cost increases for the health services, as well as the distress for the occupants.

## CONCLUSION

This study, based on data collected during the summer of 2013 in nine different locations across the UK assessed the prevalence of summertime overheating in bedrooms and living rooms in existing, retrofitted and new-build dwellings. The overheating levels in the dwellings, which were all deemed to be ‘free-running’, i.e. unheated during the period, were assessed using both static and adaptive thermal comfort criteria. Examined from the point of view of the occupants’ health, the significance of the accurate assessment of overheating in dwellings is fairly obvious. However, its significance for the policy and practice of designing new, low-energy homes and energy-efficiency retrofit measures is more subtle. Inaccurate assessment of overheating may leave occupants with houses that are uninhabitable during the hotter days of the year, if underestimated, but if overestimated may cause the installation of many unnecessary air-conditioning units. Moreover, if the causes of overheating were to be wrongly attributed, for example, to high levels of insulation, then many opportunities for energy saving in the heating season might be lost through under-insulation. This is particularly relevant for UK social housing where standards are more rigorously applied.

### **ABSTRACT**

The elderly population is more vulnerable to poor indoor environmental quality. They also spend a larger portion of their time indoors than the general public, further exacerbating the associated health risks. As part of a larger study which aims to understand the health risks for the elderly population resulting from extreme heat events in Houston, TX, this study gathered empirical data on thermal comfort and air quality in existing assisted living facilities and in individual homes of the elderly. We made continuous measurements of indoor dry-bulb temperature, relative humidity, carbon dioxide (CO<sub>2</sub>) levels and occupancy status in 25 buildings during summer months in 2016 and 2017. Then, using the measured data, we calculated the percentage of hours in which the thermal discomfort index or CO<sub>2</sub> levels were above healthy thresholds for each site. Our results show that the indoor discomfort index and/or CO<sub>2</sub> level exceeded the safe thresholds for at least 5% of the time in two-thirds of the buildings tested. Considering that research suggests more extreme summer weather in this region in the future, the results of this study highlight the need to consider changes in building management and occupant behavior as well as targeted improvements in the building stock to minimise adverse health impacts. In addition, the results also highlight a potential trade-off between thermal comfort and air quality in these building; air-tightening of the buildings will result in better thermal comfort at the expense of higher CO<sub>2</sub> levels, especially in buildings with a higher number of occupants.

### **INTRODUCTION**

In the United States, the majority of people, especially older Americans, spend ~90% of their time indoors (Klepeis et al., 2001). As a result, there is a growing awareness that much of the exposure to unhealthy environmental conditions may occur indoors. For example, Chan et al. found that a healthy person in a poorly ventilated indoor environment was 3.8 times more likely to suffer from a heat-related condition compared to outdoors (Chan et al., 2001). Sensitivity to heat and air pollution is equally important. Older adults are more sensitive than the general population to heat because the ability to regulate body temperature and physiologically adapt to the heat lessens with age (Kim et al., 2012; Luber and McGeehin, 2008). Likewise, older adults may experience more adverse health effects than the general population to air pollution as respiratory function declines with age (Wang et al., 2010). For

example, exposure to moderate to high levels of carbon dioxide (CO<sub>2</sub>), with its well-documented negative impacts on cognitive function (Allen et al., 2016; Satish et al., 2012), may be more detrimental to the elderly than other age groups. Therefore, considering the population ageing in the U.S (Wiener and Tilly, 2002), there is a growing interest in understanding the indoor environmental quality to which the elderly are exposed. Hence, this study focuses on indoor CO<sub>2</sub> levels and thermal comfort in a sample of buildings with elderly occupants in Houston, TX, the largest city in Texas and the fourth largest city in the United States. We performed continuous measurements of CO<sub>2</sub>, dry-bulb temperature, and relative humidity in a sample of homes over summer months of 2016, and 2017. Post-processing the data and interpreting it using applicable metrics revealed a general picture of the indoor environment in the sample homes.

## METHODS

### Measuring indoor environment variables

We had ongoing measurements of CO<sub>2</sub>, dry-bulb temperature, relative humidity, and occupancy status in a sample of 25 buildings during summers of 2016 (6 buildings) and 2017 (19 buildings). These buildings were either individual homes, or small assisted living facilities and were selected to represent different locations and income levels. In each building, a set of two to four HOBO MX1102 loggers (Figure 1) were installed at various locations to record environmental parameters. The measured variables were recorded in at least two rooms (namely, a bedroom and the living room) in each building. We made regular visits to each site to calibrate CO<sub>2</sub> sensors to outdoor conditions (~400 ppm). As demonstrated in Figure 1, to the extent possible, we tried to avoid placing sensors near non-human sources of CO<sub>2</sub> (e.g., plants) or heat sources (e.g., electric appliances). Occupancy status was recorded via HOBO UX90-005 Occupancy/Light Data Loggers and was used to filter out the unoccupied hours during which no exposure took place.

### Post-processing the data

To better represent the data from long-term measurements, we calculated metrics for each site based on available thresholds. While there are numerous studies, guidelines, and thresholds for assessing indoor thermal comfort, most of them are not applicable for our purpose. The reason is that the zone of homeothermy (within which body can maintain constant core temperatures) is broader than the zone of thermal comfort (within which individuals report satisfaction with the thermal environment (Bianca, 1968). From the limited available guidance

for generating suitable metrics of indoor overheating in residential settings, we selected the Discomfort Index (DI), the average of dry-bulb and wet-bulb temperatures. The DI metric has been suggested as a potential surrogate for overheating by Epstein and Moran (2006), and Holmes et al. (2016). We used the following equation to calculate the wet-bulb temperature which is needed to derive DI (Stull, 2011):

$$T_{wb} = T_a \operatorname{atan}[0.151977 (RH\% + 18.313659)^{1/2}] + \operatorname{atan}(T_a + RH\%) - \operatorname{atan}(RH\% - 1.676331) + 0.00391838(RH\%)^{3/2} \operatorname{atan}(0.023101RH\%) - 4.686035 \quad (1)$$

Here,  $T_{wb}$  is the wet-bulb temperature ( $^{\circ}\text{C}$ ),  $T_a$  is the dry-bulb temperature ( $^{\circ}\text{C}$ ), and RH is the relative humidity. Regarding the overheating threshold, we assumed a DI index of  $24^{\circ}\text{C}$ , over which “the heat load is moderately heavy and individuals would feel very hot” (Epstein and Moran, 2006). At two extremes of relative humidity, a DI of  $24^{\circ}\text{C}$  is associated with dry-bulb temperatures of  $36.5^{\circ}\text{C}$  (at  $\text{RH}=0\%$ ) and  $24^{\circ}\text{C}$  (at  $\text{RH}=100\%$ ), exceeding almost all thermal comfort thresholds commonly used. This shows that a DI threshold of  $24^{\circ}\text{C}$  is considered as an upper limit for the zone of homeothermy instead of the zone of thermal comfort. For  $\text{CO}_2$  levels, we considered a threshold of 1200 ppm. According to Allen et al. (2016) the decline in cognitive ability (even under typical activity levels) is easily observed above this threshold. It should be mentioned that for both parameters, the thresholds we selected are reported for the general public. The fact that elderly are more vulnerable to heat and  $\text{CO}_2$  will make the results presented here conservative.

## RESULTS

We calculated the total number of hours that DI or  $\text{CO}_2$  were above the defined thresholds. An important consideration is that we did not have sensors logging data at all sites simultaneously. However, since all measurements took place over summer months (for at least one month in each location), the general outdoor conditions were similar enough that a side by side comparison of all buildings is still valid. Figure 2 shows the percentage of hours above thresholds for both DI and  $\text{CO}_2$  for all 25 buildings.

Figure 2. Summertime DI and  $\text{CO}_2$  levels inside sample buildings. Data from authors' measurements over the summer months of 2016 and 2017. Dotted, horizontal line indicates that safe thresholds were exceeded 5% of the time.

According to the Chartered Institute of Building Service Engineers (McLeod et al., 2013), buildings are considered to experience long-term overheating if they exceed the safe thresholds for more than 5% of the time. As the data suggests, DI and/or CO<sub>2</sub> exceed the safe thresholds for more than 5% of the recorded period in 15 out of the 25 buildings. Notably, in this graph, an inverse relationship is observable between high CO<sub>2</sub> levels and overheating. Generally, homes with high DI values seem to have low CO<sub>2</sub> levels and vice versa.

## DISCUSSION

The results presented here highlight the fact that a considerable portion (almost a third) of the sample buildings of elderly residents in Houston, TX are overheating during summer months. Considering the health implications of heat, especially for the elderly, as well as the predicted warming in Houston due to local (urban heat island effect) or global (climate change) signals (Georgescu et al., 2014), the observed conditions could be regarded as a significant public health issue. Notably, all these buildings had air conditioning. According to the U.S. Census Bureau, more than 99% percent of buildings constructed over the last three decades in the southern U.S. were equipped with AC. Hence, our sample represents the general building stock of the region with respect to AC prevalence. However, existence of AC equipment does not guarantee its effective operation. For example, building #1, the building with most overheated hours in our sample, had AC. However, based on our post-measurement surveys, the AC system was not functioning well, and the residents do not have the financial resources to properly maintain or repair it. In addition to this, the loss of power during outages is another mechanism that can lead to severe overheating. Hurricane Harvey, which happened during our measurement campaign, caused at least 5 of our sample buildings to lose power. While in this instance, the relatively low outdoor temperatures during and subsequent to Hurricane Harvey (a maximum outdoor temperature of 24 °C), as well as completely overcast skies, helped maintain indoor conditions below overheat levels, the outcome could have been different if the power outage occurred under a different scenario. A recent example of this happened during Hurricane Irma in Florida where 8 senior citizens died in a nursing home because of the resulting power outage and AC loss (Reisner et al., 2017). We believe that this is mostly due to the overdependence of the current building stock on AC technology. Lightweight construction with minimum regard for passive mitigation strategies lead to buildings that are highly vulnerable to extreme heat, power outages, and climate change (Baniassadi and Sailor, 2018; Nahlik et al., 2016; Sailor, 2014). The other important aspect, emphasized by the measurements, is the role of ventilation, namely, window-opening. As seen in Figure 2, there is an observable inverse relation between overheating and CO<sub>2</sub>. In general, residents of buildings that have difficulty maintaining thermal comfort, would resort to ventilation by opening the windows. However, while this mitigates indoor CO<sub>2</sub> levels which are largely controlled indoor sources, it can increase exposure to outdoor pollutants such as ozone, its secondary bi-products, and particulate matter. Therefore, not having proper running AC not only leads to overheating, but can also indirectly increase exposure to outdoor pollutants. On the other hand, more air-tight buildings in our study with functioning AC, exhibited consistently comfortable indoor thermal conditions, but in some instances experienced high CO<sub>2</sub> levels. Building number 24 is an extreme example of this. This building was a senior living facility with 10 elderly residents and full-time staff. This led to very high CO<sub>2</sub> levels as the managing personnel did not operate the windows. Notably, this building was categorized as a facility whose residents are cognitively impaired (e.g., diagnosed with Dementia-Related Disorders).

## CONCLUSIONS

In this study, we used long term measurements of CO<sub>2</sub> levels and thermal comfort conditions in 25 buildings with elderly residents in Houston, TX. Our post-processing of the measured data showed that at least a two-thirds of sample buildings exceeded the CO<sub>2</sub> threshold of 1200 ppm or were overheated for at least 5% of the measurement period. These results suggest that many elderly citizens, in particular, those with limited financial resources, are exposed to indoor environments that potentially adversely affect their health and well-being. In addition, the observed inverse relation between overheating and high CO<sub>2</sub> levels suggests that window opening is a strategy consistently used by occupants in overheated homes. While this helps curb indoor CO<sub>2</sub> levels, it exposes occupants to more outdoor pollutants. Considering predictions that suggest a more extreme climate in Houston in the coming decades, and a building stock that is highly dependent on AC, the situation is likely to worsen. Future research should focus on developing easy-to-implement and market-ready building construction and operation strategies to reduce the dependency of buildings on AC and increase indoor air quality.

## ACKNOWLEDGEMENT

This research was supported in part by Assistance Agreement No. 83575401 awarded by the U.S. Environmental Protection Agency. It has not been formally reviewed by the EPA. The views expressed in this document are solely those of the authors and do not necessarily reflect those of the Agency. ## Method for Detecting Contaminant Transport through Leakages in a Condemned School

Fredrik Domhagen\*, Paula Wahlgren<sup>1</sup> and Carl-Eric Hagentoft<sup>1</sup>

<sup>1</sup>Chalmers University of Technology, Sweden

### ABSTRACT

Many schools in Sweden, have problems with the indoor air, affecting the wellbeing and health of both pupil and teachers. Contaminants in the air, such as mold spores, radon, odors, and VOC, cause problems and it can be difficult to find the contaminant source, in particular if it is within the building construction. The aim of this project is to investigate air leakage paths and pressure differences in a school building with IAQ problems and to analyze how these parameters are related to contaminant transport. An increased knowledge of how contaminants are transported will then form the base for an improved strategy for dealing with renovations of schools with IAQ issues. The main method of investigation in this initial part of the project is blower door measurements and leakage paths detection. A method to use CO<sub>2</sub> from dry ice as tracer gas for leakage detection is under development and tested in a condemned school building. Results presented in this paper show that it is possible to use this method to determine whether air leakages are coming from the crawlspace or from elsewhere.

### KEYWORDS

air infiltration, tracer gas, air leakage detection, dry ice, contaminant transport

### INTRODUCTION

There are several types of contaminants in indoor air, such as mold spores, radon, VOC (volatile organic compounds) and odors. The sources for these contaminants are both located in the rooms, in the building envelope and outdoor. The contaminants sometimes result from excessive moisture levels in the building envelope, which can cause increased emissions and mold growth. There are several studies showing possible contaminant sources that are connected to the building envelope and to moisture (for example Bornehag, 2005; Täubel, 2011, Cai G-H et al, 2011). In an investigation covering 220 schools and pre-schools, Hilling (1998) found that there are large deficiencies in maintenance, moisture safety, building airtightness and air treatment in Swedish schools.

The current work focus on the contaminant transport by air that moves through leakages in the thermal envelope. This requires a pressure difference (by wind, stack effect or ventilation) and a leakage path. Commonly, the pressure distribution is such that air infiltrates from a crawlspace, to the indoor air, bringing contaminants. The pressure at ceiling level often cause moist air to infiltrate attics, causing mold problems. However, in 10 % of the time, the pressure difference is adverse, such that mold contaminated attic air infiltrates into the indoor air (Sasic, 2007). The amount of air that passes through the building envelope and the origin of the air entering the building depends on the overall airtightness of the building and on the leakage path distribution (Sikander et al. 2009). The contaminant transport in the current work is investigated by numerical simulations, by tracer gas measurements (CO<sub>2</sub>) and by measuring pressure distributions in a school building. Both field measurements and laboratory measurements have been performed to develop the measurement equipment and procedure.

## METHODS

There are several ways to detect leakages in buildings, for example tracer gas, smoke, thermography (in combination with pressure differences), acoustic methods etc. However, in this work thermography in combination with CO<sub>2</sub> as a tracer gas is used. CO<sub>2</sub> is present in the atmosphere (at levels of approximately 400 ppm) and is produced in the building by occupants, from gas cylinders or from sublimation of dry ice.

CO<sub>2</sub> is chosen for several reasons, it does not easily react with other gases and it mixes well with air since its density is of similar order of magnitude as for air (slightly higher). CO<sub>2</sub> meters to use for measuring the CO<sub>2</sub> concentrations are easily found on the market and are often cheaper compared to other gas meters. CO<sub>2</sub> can be purchased as dry ice (CO<sub>2</sub>-ice) which is used in the following experiments. Dry ice sublimates (in atmospheric pressure) at a temperature of -78.5 °C and has therefore to be handled with care in order to prevent frost damage.

Figure 1. To the left: Icebox with dry ice, fan and heater. In the middle: Thermographic image of leakage at location L4. To the right: Image of leakage at location L4.

In this project, dry ice is used in an attempt to design a test methodology that is easy to use and inexpensive. The dry ice is placed in an insulated box, called icebox see Figure 1, with a fan to produce a steady air flow and on a scale to determine production rate. An electric heater is covered by the ice inside the box in order to increase the rate of sublimation. The advantages of dry ice compared to a gas bottle is that a higher production rate is achievable, a bottle can produce about 0.5 g/s (Konder 2008). The icebox used in this paper has a production rate of about 0.7 g/s, something which can be increased by using a higher power output on the heater. Initial tests are performed in laboratory to study production rates and distribution of CO<sub>2</sub> in a room. Laboratory tests of the ice box showed some stratification of the CO<sub>2</sub> in the room, which is why the icebox is complemented with two desktop fans, placed at some distance from the icebox, with the purpose of improve the mixing of air and CO<sub>2</sub> to prevent stratification. Other ways of dispersing CO<sub>2</sub> as dry ice were tested to estimate the sublimation rate, ease of use and repeatability. Spreading out 0.5 kg dry ice on the floor in a room with an air temperature of 20 °C had an average sublimation rate of 0.7 g/s. Interestingly, using a fan to blow air over the ice decreased the sublimation rate to 0.4 g/s. The reason to this is thought to be that more water condensates on the dry ice and works as thermal insulation. Submerging dry ice in boiling water had the highest average sublimation rate, 3.0 g/s. However, this method was the most inconvenient. If room tempered water was used, ice formed around the dry ice which stopped the sublimation. Field tests are performed in a school building in order to study real leakage paths. The principle of the field tests is to introduce CO<sub>2</sub> to one volume of the test building and measure change in CO<sub>2</sub> concentrations in adjacent volumes, in most cases in combination with applied pressures.

### Field measurements

The method is tested in a condemned school with IAQ problems. The school is situated in Gothenburg, on the west coast of Sweden, and has gone through a number of renovations in an attempt to improve the IAQ but none have been successful and the school now awaits deconstruction. The school has a crawlspace and after investigations it was concluded that the main problem originated from the crawl space and that emissions from wood preservatives is a contaminant source. Measures that has been taken to improve the IAQ is constructing ventilated floors on top of the original floor, exhaust ventilation in the crawlspace that draws air out from the crawlspace causing a negative pressure, and installing an air cleaning system. The ventilated floor is ventilated through small ducts exhausting air at roof level. Additional ventilation systems have also been installed in addition to the original ventilation system.

Figure 2. The figure to the left shows the floor plan with locations of CO<sub>2</sub> meters (L) and locations of blower door (BD1 and BD2). The figure to the right shows the crawlspace together with locations of the icebox and CO<sub>2</sub> meters (C1 and C2).

CO<sub>2</sub> meters are placed at positions L1 to L4, see Figure 2. L1 is inside a cupboard (with open doors) that contains electrical wiring from the crawlspace. L2 is close to the corner between an interior wall and the exterior wall. L3 is located by a crack in an internal wall-to-floor connection in the corner of one of the classrooms. L4 is beside one of the interior door-frames that has large cracks in the door framing.

The test procedure to detect leakages consisted of releasing CO<sub>2</sub> in the crawl space and detecting it at leakage positions (L1 to L4) in the classrooms. Different pressure situations were investigated (each during approximately one hour), but during the tests the crawlspace had a higher pressure than the classrooms. Pressures differences were created using blower door equipment placed either in a hatch between the indoor and the crawlspace (BD1), referred to as Case 1, or in an exterior door (BD2), referred to as Case 2. To ensure that there was an over pressure in the crawlspace, the pressure difference was measured and the fan speed of the blower door adjusted accordingly. The CO<sub>2</sub> was released at two different locations in the crawlspace and measured at 1-2 locations in the crawlspace, and 3-4 locations in the class rooms next to leakage positions. Leakages were found both in the middle of the building, where all incoming air is from the crawlspace, and close to external wall where some of the incoming air is outdoor air. An initial scan of leakage points was made by ocular inspection and thermography. Thermography reveals the leakage positions but not if the air is clean air from the outside or contaminated air from the crawlspace. The measurements were made during wintertime so the temperature of the crawlspace was approximately 8 °C, outdoor temperature 0 °C and the indoor temperature 20 °C.

The aim of the field measurement was to investigate **a.** the influence of the location of the CO<sub>2</sub> source (icebox) on the CO<sub>2</sub> distribution in the building, **b.** the effect of different locations of the blower door, **c.** how the pressure difference across the floor construction affects the CO<sub>2</sub> concentration at the leakage positions.

### RESULTS OF THE FIELD INVESTIGATION

Two cases are investigated, Case 1 when the blower door is placed in the hatch down to the crawlspace (BD1, Figure 2) and Case 2 when the blower door is situated in an exterior door (BD2, Figure 2). The principle airflow paths for each case are illustrated in Figure 3.

Figure 3. Shows the principle airflow paths dependent on the location of the blower door (thick arrow) where the lower rectangle represents the crawlspace and the upper rectangle represents the classrooms.

Figure 4 shows measured CO<sub>2</sub> concentrations for Case 1. Note that at the end of the measurement period the CO<sub>2</sub> meter is moved from position L3 to position L4. The results show that the concentration levels at L1 and L4 are affected by leaking air from the crawlspace (to a high degree in the cupboard at L1) whereas no significant change in concentration can be seen at L2 and L3. In Case 1 the pressure difference over the floor construction was about 35 Pa throughout the entire measurement period.

Figure 4. CO<sub>2</sub> concentrations measured at different locations in Case 1 (blower door in crawlspace hatch). New location for one meter at 46 minutes (from L3 to L4).

Figure 5 shows measured CO<sub>2</sub> concentrations for Case 2. After 21 minutes the pressure difference across the floor construction was changed from 5.7 Pa to 4.4 Pa (by decreasing the blower door fan speed), which resulted in an increase in CO<sub>2</sub> concentration in L1 from 1500 ppm to 2300 ppm. Concentration levels at L1 are affected by leaking air from the crawlspace, similar to Case 1. However, L2 is reaching higher concentration levels than in Case 1. One possible explanation could be that the air leakage path inside the construction is affected by the relations in pressure between indoor, crawlspace and outdoor, which will be further investigated. Measurements also showed that CO<sub>2</sub> concentrations were higher when the icebox was placed in the air volume directly beneath the cupboard with L1, i.e. in location C2 compared to location C1 further away.

Figure 5. CO<sub>2</sub> concentrations measured at different locations together with the pressure difference over the floor construction in Case 2 (blower door in exterior door frame).

Different pressure differences across the floor construction will result in different CO<sub>2</sub> concentrations in the classrooms. A higher fan speed will then result in higher air flow rate upward through the floor but also to an under pressure in the classrooms and more outdoor air entering the building which dilutes the CO<sub>2</sub> concentration. It may therefore be difficult to anticipate if it is better to have a high or low pressure difference over the floor construction in order to maximize the concentrations levels at the measurement points. However, in this study it became clear that a lower pressure difference gave higher CO<sub>2</sub> concentrations in Case 2 with pressure difference of approximately 5 Pa (Figure 5) compared to Case 1, pressure difference 35 Pa (Figure 4). The outcome of these effects has also been confirmed in numerical simulations.

When investigating the correlation between changes such as CO<sub>2</sub> production, icebox location and pressure difference, the delay in response in the CO<sub>2</sub> concentrations at the different leakage points is a few minutes, typically three minutes. This corresponds to a leakage path of 10 m in length, 5 mm in height and at a pressure difference of 5 Pa. If the height is decreased to 4 and 3 mm, the time increases to 4 and 8 minutes respectively. This effect will be further studied in future measurements.

The method for detecting air leakages will be improved with the goal of making quantification of leakages possible. This could be done by creating a steady CO<sub>2</sub> production

and measure the change of the mean concentration in the air volumes inside a building. Methods of dispersing CO<sub>2</sub> will also be investigated to make leakage detection more efficient.

## CONCLUSIONS

Tracer gas measurements, using CO<sub>2</sub> from dry ice is used in combination with forced pressure differences in order to investigate contaminant transport in a school building. The measurements showed that:

- For the investigated cases, a lower pressure difference over the floor construction (with overpressure in the crawlspace) results in higher concentrations at measurement locations. The reason is that the crawlspace becomes less ventilated when the pressure difference is lower and therefore the leaking air has a higher concentration of CO<sub>2</sub>.
- It is possible, with the described icebox method, to determine if the leaking air is coming from the crawlspace or from elsewhere. This method is cheaper and simpler compared to conventional tracer gas methods.

Suggested procedure for detecting air leakages from a crawlspace to the indoor environment

1. Use blower door to either pressurize the crawlspace or depressurize the indoor space.
2. Performing a leakage search to find leakages in the construction. This can for instance be done using a thermal camera.
3. Measure CO<sub>2</sub> background concentration prior to starting the CO<sub>2</sub> production in the crawlspace.
4. Add CO<sub>2</sub> to the crawlspace, for instance by using the icebox method presented earlier in this paper.
5. Measure CO<sub>2</sub> concentration at locations that in step 1 proved to have air leakage.
6. Locations with CO<sub>2</sub> levels high above CO<sub>2</sub> background concentrations will have air coming from the crawl space.

Each test step is preferably performed until steady-state conditions are reached, and at least for 15 minutes.

### ABSTRACT

Lighting, thermal and acoustic are three main components of indoor physical environments affecting people's satisfaction, productivity and health. Good physical environments in shopping centers not only improve the environment atmosphere but also increase the customers' satisfaction. This study aims to find correlations between the physical environments and the satisfaction levels. Firstly, an objective measurement of physical environments had been carried out in four shopping centers. Then, a subjective evaluation was carried out in a real scene laboratory by changing four kinds of illuminance and three types of Correlated Color Temperatures (CCTs), which aims to find the relationship between the lighting environment and people's lighting, thermal and acoustic satisfaction. Moreover, the interaction of satisfaction levels were also explored. The results of field study showed that lighting and acoustic environments have a wide fluctuate range in four shopping centers. The experiment found that illuminance has a significant effect on lighting satisfaction and is best at 1000 lux (lx). The thermal and acoustic satisfaction were not directly influenced by lighting parameters; however, they had the interactions with lighting satisfaction, which showed that lighting environment would enhance the satisfaction levels of thermal and acoustic environments when it was satisfied.

### KEYWORDS

Shopping centers; Physical environments; Satisfaction level; Interaction

### INTRODUCTION

With the improvement of people's demand for shopping, indoor environment quality (IEQ) is more and more important for shopping centers. As a part of the indoor environment, physical environments- lighting, thermal and acoustic- greatly affect consumers' satisfaction levels (Zhao et al. 2015; Jin et al. 2017).

For satisfaction evaluations, several studies have attempted to find the relationship among lighting, thermal and acoustic environments. Huebner et al. (2016) confirmed that CCT can affect people's thermal comfort. Ma and Nie (2014) found improving lighting environment quality reduced the noise annoyance and increased the acoustic comfort. Geng et al. (2017) indicated that when the thermal environment was satisfying, it raised the "comfort expectation" of lighting and acoustic factors. Above studies showed that physical environments will strengthen or weaken each other. However, most of the studies focused on residential, office, campus buildings, etc. (Ma and Nie, 2014; Geng et al. 2017; Ricciardi and Buratti, 2017), and seldom refers to shopping centers. Therefore, it's necessary to explore the physical environment satisfaction for shopping centers.

As for the research method, field study is frequently used in shopping centers (Zhao et al. 2015; Jin et al. 2017). Through field study, physical environments can be measured accurately, however, satisfaction levels of customers are usually influenced by many nonphysical factors like spatial and social parameters (Meng et al. 2013), which influenced

the accuracy of physical environment evaluation. Therefore, a new method should be provided to improve the evaluation accuracy.

In summary, this study combined the methods of field measurement and experimental evaluation, aiming to quantitatively and accurately reveal the correlations between indoor physical environment and satisfaction in shopping centers. In addition, the interactions among different factors were explored. And the research results can be utilized to improve the physical environment and consumers' satisfactory in shopping centers.

## METHODS

### Field measurement

Field measurement were conducted in four shopping centers in winter and summer of 2017, and the buildings' information was shown in Table 1. The field measurement parameters included the illuminance, CCT, air temperature and sound pressure level. Testing time were selected in business hours (10:00 AM to 10:00 PM) and the test information was shown in Table 2.

Table 1. Information of the four shopping centers.

Shopping Center	Built year	Total area (thousand $m^2$ )	Total numbers of floor
H-S	2016	125	5
F-S	2016	92	6
S-S	2011	150	6
D-S	2014	113	7

Table 2. Test information.

Indoor environment	Parameter	Measurement instrument	Measuring range/ accuracy
Lighting	Illuminance	CL-500A	0.1-100,000 lx / $\pm 2\%$
	CCT	CL-500A	$>5$ lx / -
Thermal	Temperature	TSI model 9545	$-10-60^\circ\text{C} / \pm 0.3^\circ\text{C}$
Acoustic	Sound pressure level	Nor140	15-140 dB A / -

### Experimental evaluation

#### Overview of experiment

In order to find the correlations between physical environments and their satisfaction levels, a series of experiments were carried out in a laboratory with variable space and environment during January 2018 at Tianjin University (see Fig. 1 a)). A typical clothing store (see Fig. 1 b)) was simulated by an actual space, which total area was  $48\text{ m}^2$  and 4 meters high. During the experiments, illuminance and CCT were set as the variables and other physical parameters were the control variables. The range of illuminance and CCT were respectively 200 lx, 500 lx, 1000 lx, 1500 lx and 3000 Kelvin (K), 4500 K, 6000 K, and the air temperature and sound pressure level were set to  $23^\circ\text{C}$  and 75 dB A, which based on the previous field measurement in four shopping centers.

#### Participant and questionnaire

A total of 27 students from Tianjin University took part in the experiment and Table 3 shows the information of participants. To ensure the experimental results not affected by other factors, participants were instructed to wear the same type of clothing for each test. The information of the questionnaire consisted the satisfaction of lighting, thermal and acoustic environments. Satisfaction votes were used the ASHRAE (2013) 7-point scale as follows: strongly dissatisfied (-3), dissatisfied (-2), slightly dissatisfied (-1), neutral (0), slightly satisfied (1), satisfied (2), and strongly satisfied (3).

Table 3. The information of participants (mean value  $\pm$  standard deviation).

Gender	Sample size	Age(y)	Height(cm)	Weight(kg)
Male	13	21.2 $\pm$ 3.26	177.2 $\pm$ 4.54	67.7 $\pm$ 7.35
Female	14	20.2 $\pm$ 3.38	162.2 $\pm$ 7.53	53.4 $\pm$ 6.50
Total	27	20.7 $\pm$ 3.29	169.4 $\pm$ 9.78	60.3 $\pm$ 9.97

### Experimental procedure

The satisfaction experiment lasted three weeks and the time was from 19:30 to 21:30 each day. Twelve types of lighting environments were selected in the experiment, and each environment condition lasted 20 minutes, including 9 minutes' adaptation time and 11 minutes' testing time (see Fig. 1 b) and c)). In adaptation time, participants were required to sit in a preparation room (500 lx; 4000 K) whose overall environment was constant. Meanwhile, the illuminance and CCT of the clothing store were changed through the controllable lighting system. In testing time, participants were asked to move around in the clothing store, and the first 10 minutes were utilized to experience the shopping environment and the last 1 minute to fill in the evaluation questionnaire. The experimental procedure for each day was shown in Fig. 1 d).

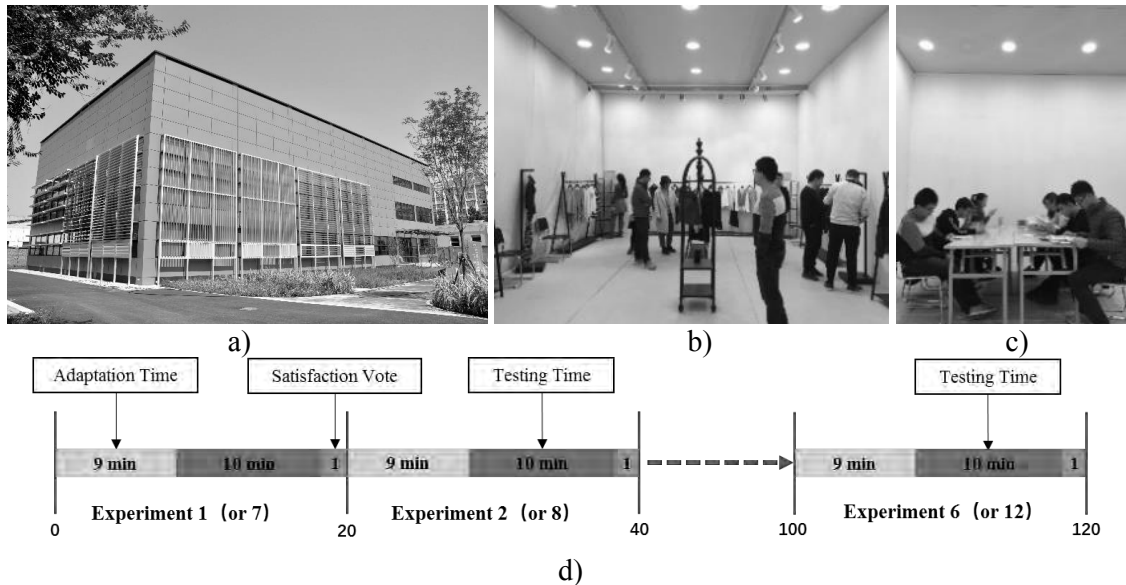

Figure 1. a) Variable space and environment laboratory, b) Testing time, c) Adaptation time, d) Experimental procedure.

## RESULTS AND DISCUSSIONS

### Objective environmental measurement

Fig. 2 shows the objective measurement results of illuminance, CCT, air temperature and sound pressure level of the 4 shopping centers. For lighting parameters, building H-S has the largest illuminance fluctuation between 431.8 lx and 2512.4 lx, and the average illuminance of the other three is between 224.9 lx to 1587.5 lx, which is mostly controlled above the lower limit of illuminance (300 lx) in Chinese standard GB50034 (2014) (see Fig. 2 a)). The result of CCT shows that building D-S has the largest fluctuation between 2828 K and 6398 K, and others are concentrated between 3000 K and 4000 K (see Fig. 2 b)).

The air temperature was respectively measured in summer and winter (see Fig. 2 c)). Through the comparison of measured levels and the thermal comfort standard GB50736 (2012) in

China, it is found that all shopping centers have a qualification rate above 70%, respectively H-S (72%), F-S (84%), S-S (91%), D-S (96%). In terms of indoor acoustic environment, S-S building has the smallest fluctuation between 68 dB(A) and 77 dB(A), while others stay at a high level and mostly fluctuate between 65 dB(A) and 85 dB(A) (see Fig. 2 d). Through further analysis, the high noise level is mainly due to the background music and personal talking.

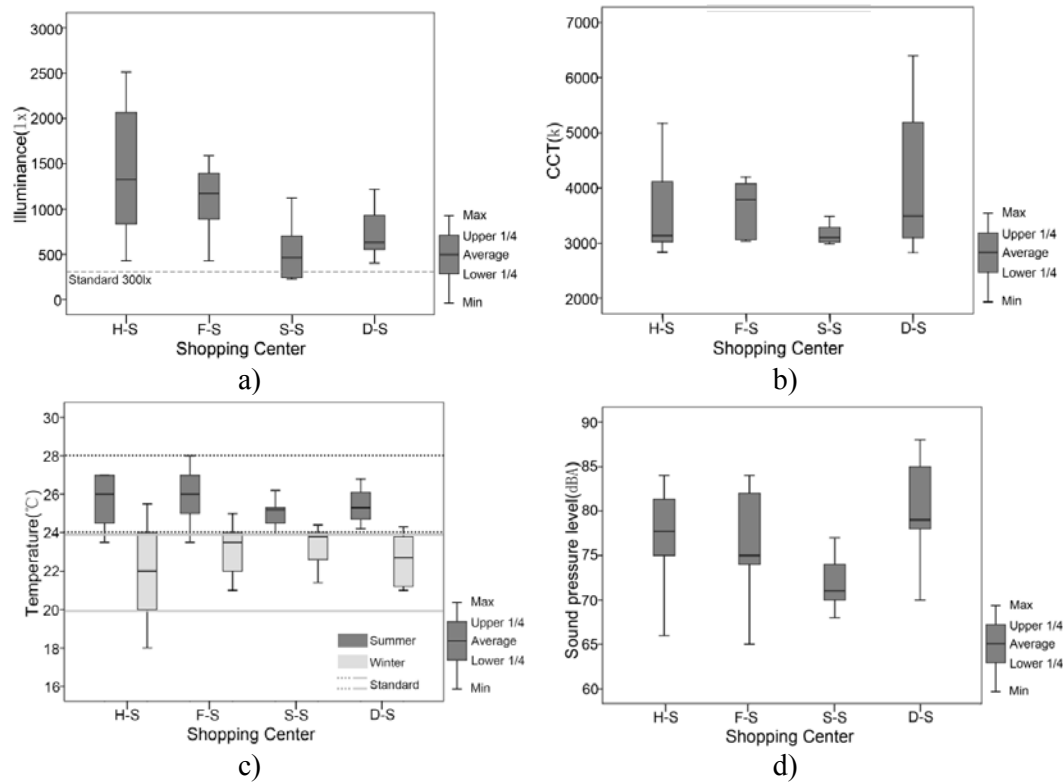

Figure 2. Objective measurements of indoor a) Illuminance, b) CCT, c) Temperature, d) Sound pressure level.

### The impact of lighting parameters to satisfaction

The correlation analysis between lighting environment (illuminance, CCT) and people's satisfaction of lighting, thermal and acoustic environments is shown in Table 4. The correlation R value between illuminance and lighting satisfaction ranges from 0.532 to 0.648 ( $p < 0.01$ ), while the correlation R value between CCT and lighting satisfaction ranges from 0.204 to 0.292 ( $p < 0.01$  or  $p < 0.05$ ) in two illuminance environments (200 lx, 500 lx). However, there is no significant difference in the correlation of thermal and acoustic satisfaction with lighting environment (illumination, CCT).

Fig. 3 shows the relationship between the illuminance parameter and satisfaction level in three different CCT environments. Each point represents the mean value of the satisfaction level in the same illuminance and CCT environment. When the satisfaction level is larger than 0, it indicates that subjects are satisfied with the environment. Fig. 3 a) shows subjects are satisfied when the illuminance isn't lower than 500 lx, and the highest evaluation level occurs when the illuminance is 1000 lx and CCT is 4500 K. Moreover, between 200 lx and 1000 lx, participants feel more satisfied under the light of 6000 K and 4500 K than 3000 K. These result shows that Kruithof's rule (1941) of lighting comfort maybe not applied to the lighting environment preference for Chinese consumers. Fig. 3 b) and c) show that both thermal and

acoustic evaluation are satisfied and have small fluctuations in different lighting environments. The range of thermal satisfaction is from 0.39 to 0.87, and the acoustic satisfaction is from 0.69 to 1.13.

Table 4. Relationships between Lighting parameters and evaluation of satisfaction.

Lighting parameters	Conditions	Lighting	Thermal	Acoustic
Illuminance	3000 K	0.648**	0.003	-0.072
	4500 K	0.606**	-0.070	-0.103
	6000 K	0.532**	0.042	0.044
CCT	200 lx	0.292**	-0.044	-0.045
	500 lx	0.204*	0.045	-0.132
	1000 lx	0.146	-0.102	0.019
	1500 lx	-0.164	0.124	0.045

\*  $p < 0.05$ ; \*\*  $p < 0.01$

Figure 3. Relationships between illuminance and a) Lighting satisfaction, b) Thermal satisfaction, c) Acoustic satisfaction.

#### The interaction of satisfaction level

Pearson correlation between lighting evaluation and satisfaction of thermal and acoustic environments is shown to be significant ( $p < 0.01$ ), and the correlation coefficient  $R$  is 0.250 and 0.219 respectively. Fig. 4 shows the voting results of thermal and acoustic environment at different lighting satisfaction level. When the lighting evaluation changing from “dissatisfied” to “satisfied”, the dissatisfaction rate of thermal and acoustic is reduced by 34.47% and 17.74% respectively. The result shows that good lighting satisfaction can raise people’s evaluation of thermal and acoustic environment in shopping centers.

Figure 4. Satisfaction votes of a) thermal environment, b) acoustic environment under different lighting satisfaction votes.

## CONCLUSIONS

On-site measurement shows that the range of illuminance was mostly from 500 lx to 1500 lx and the CCT was from 3000 K to 4000 K, the temperature qualification rate above 70% and the range of sound pressure level mainly from 65 dB A to 85 dB A. Satisfaction level experiment found the highest level of lighting satisfaction occurred when the illuminance was 1000 lx. From 200 lx to 1000 lx, subjects prefer the lighting environment with middle and high CCT. Moreover, the thermal and acoustic satisfaction were not directly influenced by lighting parameters; however, they had the interactions with lighting satisfaction, which showed that lighting environment would enhance the satisfaction levels of thermal and acoustic environments when it was satisfied.

### **ABSTRACT**

A novel methodology to overcome the main limit of the Daylight Glare Probability DGP (i.e. the heavy computational time for an annual analysis of the DGP profile in one point) is presented. This uses a proxy based on the vertical illuminance ( $E_v$ ) at the eye level. To do so, the most suitable value of  $E_v$ , to substitute DGP, is found by means of a comparison to the corresponding DGP value through a fault-detection diagnosis technique.

The methodology was applied to a representative enclosed office with one South-facing window (Window-to-Wall Ratio of 50%) located in Turin. The glazing was assumed to have different transmission properties (specular and scattering) with different visible transmittances (in the range 3%-66%). The error in the estimation of the DGP classes calculated through the eye vertical illuminance was evaluated, for an analysis period of a whole year.

The main advantages of the methodology proposed lie (i) in a significant reduction of the computational time required for its application and (ii) in the possibility of evaluating glare conditions not only for one or few points, but for a grid of points across a considered space. Its main limitation lies on its inability to quantify the exact DGP value, returning instead, at every time-step, the DGP class of performance.

### **KEYWORDS**

Daylight simulation; Daylight Glare; DGP spatial resolution.

### **INTRODUCTION**

Glare sensation is one of the most important aspects to control when dealing with visual comfort related to daylight. Daylight Glare can be caused either by a too high solar radiation in the occupants' visual field or by the presence of objects whose luminance is considerably higher than the background average luminance. Currently, the most widespread and validated metric to numerically assess daylight glare condition is the Daylight Glare Probability (DGP) (Wienold and Christoffersen, 2006), which expresses the percentage of people dissatisfied with the visual environment. The DGP is view-dependant, which means that its validity applies only to a specific point in the space and to a specific direction of observation. Moreover, due to its calculation algorithm, evaluating DGP on a yearly basis requires a heavy and time-consuming computation (Carlucci et al., 2015).

An attempt to simplify the DGP algorithm was made by Wienold (2007) to reduce the computation time required, by devising a simplified algorithm accounting for vertical illuminance ( $E_v$ ) hitting the eye only. This metric, called DGPs (simplified DGP) showed a strong correlation to DGP for situations in which no direct sunlight hits the eye only, making thus its application unsuitable for a wide range of situations.

Kleindienst and Andersen (2012) developed a different simplified algorithm to evaluate DGP, the DGPm: this considers the apertures (windows, skylights, etc...) as the only luminance

sources in the scene, not accounting thus for the light reflected by internal surfaces. Despite its advantages (a more efficient computation algorithm than DGP, a better correlation to DGP than DGPs, possibility of a spatial glare evaluation), the application of DGPm remained limited as it was implemented on a non Radiance-based simulation software only. Another attempt to simplify the evaluation of DGP was made by Torres and Lo Verso (2015): they correlated the DGP to the cylindrical illuminance in the same point. Even though they obtained a good correlation to DGP, their approach is limited to the specific calculation point. In this framework, the paper presents a novel methodology to assess DGP by means of a proxy based on vertical illuminance values measured at eye level only. Such a methodology is able to significantly reduce the computation time, as the annual DGP profile for one point only needs to be calculated. Moreover, it allows the glare sensation to be assessed not only for a point in the space, but for the whole space analysed.

### STEP-BY STEP DESCRIPTION OF THE NOVEL METHODOLOGY

The novel methodology proposed is presented for a representative case-study, which is an enclosed office located in Turin (45.06°N, 7.68°E), 3.6 m large, 4.5 m deep and 2.7 m high. A 3.3 m large and 1.5 m high window (Window-to-Wall Ratio = 50%) is located in one of the short walls, oriented South. The window was assumed to be alternatively equipped with 13 different glazing types, each with a specific transmission property (specular or scattering) and different visible transmittance ( $T_{vis}$ ). The glazing features are summarised in Table 1.

Table 1. Glazing types considered in the study.

Scattering glazing															Specular glazing									
T <sub>vis, diffuse</sub>	12%	15%	23%	34%	45%	T <sub>vis, specular</sub>	3%	12%	15%	23%	34%	45%	55%	66%										

Three points in the office were identified to be representative of the different glare conditions occurring in the different parts of the room. They are all located 1.2 m above the floor, i.e. the height of the eyes of a seated person. For all the points, the observation direction was assumed perpendicular to the window, so as to evaluate the worst-case scenario (see Fig. 1).

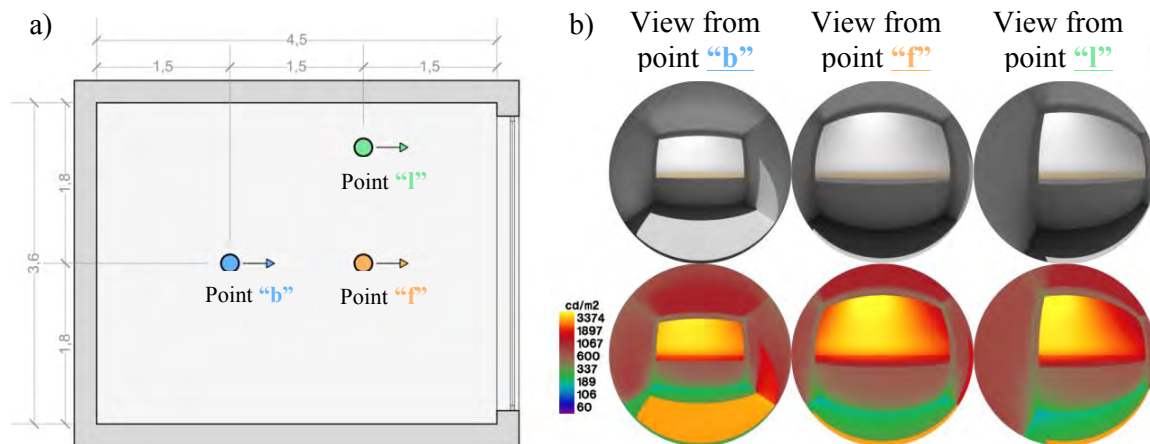

Figure 1. a) office plan with the locations and observation directions of the three points selected, b) example images and luminance images illustrating the view from each point.

For each point, DGP and  $E_v$  values at eyes were calculated through DAYSIM simulations during the course of a year (time-step: 1 hour) whenever daylight was present (night hours were not considered). This operation was repeated for each glazing type. As a result, an

annual database for each glazing type was built, containing a pair of values for each time-step: a DGP value and an  $E_v$  value. The procedure is then structured in three steps.

**Step 1.** The goal of this phase was to define the most suitable  $E_v$  values to be used as threshold for each DGP comfort class, defined by Wienold (2009). Table 2 summarises the DGP classes with the relative DGP thresholds ( $DGP_{thr}$ ).

Table 2. Daylight glare comfort classes with relative DGP threshold values.

Daylight glare comfort class	DGP thresholds
Imperceptible	$DGP < 35\%$
Perceptible	$35\% \leq DGP < 40\%$
Disturbing	$40\% \leq DGP < 45\%$
Intolerable	$DGP \geq 45\%$

Practically speaking,  $E_v$  and DGP were compared for each time-step as metrics to identify a glare/non glare condition, using the DGP thresholds as validation reference. For each DGP threshold ( $DGP_{thr}$ ), the optimal  $E_v$  threshold ( $E_{v,thr}$ ) was found by means of a fault-detection diagnosis technique. Four sceneries were possible:

- True Positive (TP): a condition in which  $E_v > E_{v,thr}$  is associated to  $DGP > DGP_{thr}$
- True Negative (TN): a condition in which  $E_v < E_{v,thr}$  is associated  $DGP < DGP_{thr}$
- False Positive (FP): a condition in which  $E_v > E_{v,thr}$  associated to  $DGP < DGP_{thr}$
- False Negative (FN): a condition in which  $E_v < E_{v,thr}$  is associated to  $DGP > DGP_{thr}$ .

The fault-detection diagnosis technique was applied to every annual database previously determined (each relative to a specific glazing type and a single point). Being the *faults* represented by FP and FN cases, the  $E_v$  value minimising the FP+FN value was assumed as threshold for each DGP class. The result of this analysis was a triplet of  $E_{v,thr}$  (one for each  $DGP_{thr}$ ) for each of the three points in the space selected and for every glazing type. A total number of 39  $E_{v,thr}$  triplets was obtained in this phase.

**Step 2.** The calculation of the annual DGP for a single point in the room is a necessary assumption to reduce the computational time. Therefore, to be able to perform a simplified spatial evaluation of glare throughout the room, the  $E_{v,thr}$  triplet for one point in the space was used as thresholds to assess glare for the other points. This needs to be repeated for each point of the room, i.e. applying its specific triplet of  $E_{v,thr}$  as thresholds for all the other point. The goal of this phase is to determine the errors that are committed when applying this procedure. The error committed in the estimation of DGP was quantified again in terms of FP+FN. This was evaluated for every  $E_{v,thr}$  and for every glazing type considered. Output of this phase are, for every glazing type, three triplets of errors for each point selected (one for  $DGP_{thr}$  of 35%, one for  $DGP_{thr}$  of 40% and one for  $DGP_{thr}$  of 45%).

**Step 3.** Aim of this phase is to identify the most suitable point in the space, among the three considered, to be used to determine the only annual DGP profile and hence the  $E_{v,thr}$  values. To do so, for every point, the average error committed for all the glazing types was calculated for each  $DGP_{thr}$ . The optimal  $E_{v,thr}$  triplet was eventually found to be the one minimising the average error committed.

## RESULTS

The results of each of the three steps exposed above are shown in the following sub-sections.

**Step 1.** Figure 2 shows the results relative to Step 1, i.e. the  $E_{v,thr}$  values obtained in correspondence of the  $DGP_{thr}$  values for every glazing type and for each of the three points in the room. As one could expect, the results show that the  $E_{v,thr}$  values obtained for a  $DGP_{thr}$  of 35% are nearly always lower than the ones obtained for a  $DGP_{thr}$  of 40%, which are in turn lower than those obtained for a  $DGP_{thr}$  of 45%. It is also possible to observe a common trend for the three  $DGP_{thr}$ :  $E_{v,thr}$  values tend to grow as  $T_{vis}$  increases, either for specular or scattering glazing types, up to a maximum  $T_{vis}$  value (which varies depending on the  $DGP_{thr}$  considered). Over this  $T_{vis}$ , the  $E_{v,thr}$  values fluctuate around nearly the same value. For all the  $DGP_{thr}$ , a huge difference in the  $E_{v,thr}$  values was observed for the three calculation points for lower  $T_{vis}$  values (considering the same glazing), while as  $T_{vis}$  grows, this difference becomes almost negligible. The error committed when assessing glare with the  $E_{v,thr}$  values found, calculated as  $FP+FN$ , is in the range 0.33% - 7.24% for  $DGP_{thr}$  of 35%, 0.33% - 6.50% for  $DGP_{thr}$  of 40% and 0.29% - 5.01% for  $DGP_{thr}$  of 45%.

Figure 2.  $E_{v,thr}$  values obtained, for every glazing type considered, for each  $DGP$  threshold

**Step 2.** Figure 3 shows the results relative to Step 2, i.e. the error committed when estimating the  $DGP$  class (error computed as  $FP+FN$ ) by using the  $E_{v,th}$  values found for a given point for all the three points. The results show that, for each  $DGP$  threshold and for every point, higher errors are committed for glazing, either specular or scattering, with lower  $T_{vis}$ . As  $T_{vis}$  grows, lower errors are committed. Analysing then the errors committed for the three calculation points, it is possible to observe that point b (located in the back part of the room) shows the most cases with higher errors. For most of the other cases instead, the errors obtained for the three points are similar.

**Step 3.** Figure 4 shows the average error committed for all the glazing types when estimating  $DGP$  by means of the  $E_{v,thr}$  obtained for each of the 3 points in the room. For every  $DGP_{thr}$ , the results confirm that the average error committed when assessing glare by means of  $E_{v,th}$  triplets relative to point b are higher than the ones relative to the other points. Similar average errors were instead obtained for point f and point l. In more detail, it is possible to observe that average errors committed for  $DGP_{thr}$  of 35% and 40% are lower for point l, while the average error relative to  $DGP_{thr}$  of 45% is lower for point f.

Figure 3. Error committed in the estimation of the DGP classes, for every glazing type, using the  $E_{v,thr}$  values relative to each point in the room.

Figure 4. Average error committed, for every point, for each  $DGP_{thr}$ .

## DISCUSSION

The novel methodology proposed allows the DGP to be assessed in a simplified way by means of a proxy based on vertical illuminance hitting the eye. Being a simplified methodology, it only allows the glare comfort class for DGP, and not the exact value, to be determined for a given  $E_v$  value.

Using a proxy based on vertical illuminance implies an average error in the estimation of the glare comfort class, which was quantified to be, for every  $DGP_{thr}$ , lower than 3% of the cases analysed. Such a value is considered acceptable by the Authors. The advantage of the present methodology lies in the reduction of the computation time necessary for the calculation of the annual DGP values in a grid of points across a space. In fact, the DGP for all the points in the space is assessed by means of one annual DGP computation for a single point in the room; for this point the triplet of  $E_{v,thr}$  corresponding to the three  $DGP_{thr}$  is calculated and used to estimate DGP for all the space. As an example, for an office such as the case-study used in this study, the computation of spatial DGP for a grid of points with a mesh of 0.5m x 0.5m (48 points) would require a computational time 48 times higher than that necessary to apply the novel methodology presented. Assuming to use an i7 processor (8 cores), the evaluation of full DGP would require 12 hours, against the 15 minutes necessary for the proposed methodology. The difference in the computation time would of course even grow as the size of the room (and the number of calculation points) increases.

## CONCLUSIONS

The paper presented a novel methodology for the estimation of DGP across a space by means of a proxy based on vertical illuminance hitting the eye appears. The methodology proved to be robust, with an average error committed below 3% for all the cases considered. Its main advantage consists in its ability to significantly reduce the computation time required for the calculation of DGP for a whole space. It may therefore be used to improve the visual comfort assessment, evaluating glare sensation not only for a few points in a space, which is currently the common practice, but for a grid of points across the whole space considered.

Future work consists in an extensive validation of the proposed methodology for different directions of observation, different geometrical features of the space analysed (depth, width, Window-to-Wall Ratio, etc...) and different orientations and climates.

### **ABSTRACT**

The objective of this research is to demonstrate the application of an optimization framework to assess and improve the impacts of workstation properties in relation to the performance of electrochromic glass regarding daylight and visual comfort. This framework is executed through a simulation-based parametric modeling workflow of an open-plan office to optimize partition layout, height, direction to windows, and materiality in response to annual glare probability (DGP) and climate-based daylighting metrics. In this paper, different office layouts equipped with Electrochromic glass, located in a mixed-humid climate has been simulated with DIVA plug-in for Rhinoceros/grasshopper software to maximize the daylight and reduce the visual discomfort.

The results of the optimization study show that the visual comfort and daylighting can be increased from 17 % to 36 UDI (100–2000 lx) while maintaining the percentage of occupied hours glare between 3.1 and 4.1. Considering these two aspects, the workstation with opaque 42” partition height in perimeter and 60” in Interior (“Pre 42\_Int 60”) layout in 10° oriented towards the south perform the best with the Electrochromic user-based schedule.

### **INTRODUCTION**

According to a broad range of studies, the quality of office environment is influenced by office layout, furnishing, and lighting quality (Kim & de Dear, 2013; Lee & Guerin, 2009). Although the previous studies believe that partitions in an open plan office spaces provide privacy for employees as the first objective in the design process, the robust role of partition layouts in the better distribution of daylight into the space and occupant visual comfort can not be undermined (Paper, Carolina, Modaresnezhad, & Nezamdoost, 2017). Lighting has a significant direct impact on office workspace, as the studies show daylit offices increase employees’ comfort, productivity, satisfaction, health, and well-being (Kelly, Painter, Mardaljevic, & Irvine, 2013). However, overlit spaces can cause glare and visual discomfort, especially with sunlight penetration when the amount of daylight is not sufficiently controlled. There are internal and external design strategies to control the daylight. The electrochromic glass as a dynamic shading device is used to both prevent and control undesirable daylight and solar radiation (Sbar, Podbelski, Yang, & Pease, 2012).

Recently, by allowing the occupants to control the stage of tinting in glazing through a timed override, the window can be darkened only when the occupants are exposed to excessive daylight and the presents of glare, otherwise, it permits daylight penetration in the space (Arnold, 2010). In this case, the attributions of occupant locations (office layout properties, partition’s height, materiality and direction to windows) become crucial to provide visual comfort (Modaresnzhad, M Nezamdoost, 2017). Nevertheless, daylight buildings are rarely studied in terms of the impact of interior design strategies on the user-based performance of electrochromic glass. This study outlines the daylight performance of workstation strategies based on the user- based control of electrochromic glass to 1. Maximize daylight illuminance while minimizing visual discomfort and 2. Find the optimum solution for the future office layout refurbishment.

## METHOD

In order to study the daylight performance and visual comfort of multiple workstation designs scenarios, a simulation-based design workflow was developed in grasshopper. The workflow consists of modeling the existing workstation and the façade in an office building and analysing different scenarios of workstation attributions based on the annual climate-based daylight. In the optimization process, the occupant comfort feedback (levels of comfort) is used to find the optimum attributions of the workstation model that will provide the optimum daylight and visual comfort. An overview of each step is as follows:

### 1. Geometry Creation

Building the base case

For the purposes of this study, one section of an office building in warm and humid climate was modeled as illustrated in Figure 1. The office layout is divided into a core, interior (6 to 14m) and perimeter (1 am to 5 am) zones to represent the typical floor plan of high rise office building that is rotated 45° clockwise from the north axis. In order to examine daylighting and visual comfort of the occupants, the south-east orientation in the 20th floor (without exterior obstruction) is chosen as a critical orientation that receives a significant amount of morning exposure.

Figure 1. Office plan with workstation layout

### 2. Modelling the Shading Device

The exterior envelopes are modeled with switchable Electrochromic windows with the same window position and size illustrated in Figure 1, the Electrochromic window is switched based on user preference level into three tinted states as stated in table 1, based on their visual comfort (manual glare control). In this case, occupants can activate shading systems as their visual discomfort increases ( $DGP > 0.4$ ).

Table 1. Workstation design scenarios

<b>Electrochromic Glass</b>	65 EC Clear state	60%
	EC Tinted state 1	30%
	EC Tinted State 2	2%

### 3. Defining the Workstations properties

The 56 alternative workstation partition designs are modeled based on the four variables including partitions' height, material, and direction to the window and layouts as indicated in Table 2. The layouts consist of three configurations: 1. "Pre 42\_Int 60": 42" partition in perimeter zone and 60" partition height in the interior zone. 2. "Pre 40, 48\_In 60": the partition height gradually increased from perimeter zone to the interior zone (40" to 60"). 3. "Pre 60\_Ver: 60" partition in the vertical (y-axis) of the workstation in the perimeter zone.

Table 2. Workstation design scenarios

Layout	Pre 42 Int 60	Pre 40,48 In 60	Pre 60 Ver
Height	W 42"	W 48"	W 60"
Material	Translucent Ref .4 Trn 20	Transparent 88 Trn	Opaque 88 Ref
Orientation	Perpendicular to window	10° to the south	10° to the North

### 4. Simulation

Annual glare simulation is conducted to calculate the Daylight Glare Probability (DGP) for multiple camera views based on the occupants' view directions. As the occupants of perimeter zones are exposed to daylighting, the shading device (EC) assumed to be tinted by occupants when glare becomes uncomfortable. This value is calculated for the location of occupants at the eye level (1.2m) that points directly at the screen of the monitor.

An annual climate-based daylighting simulation is executed utilizing the plug-in DIVA-for-Rhino 5.0 to quantify the annual daylighting performance of each scenario, the "Useful Daylight Illuminance" or UDI (Nabil & Mardaljevic, 2006) is used to measure the annual percentage of time that a sensor point receives an amount of daylight that is sufficient for office work while avoiding glare.

### 5. Optimization

In the last phase of the workflow, the outcomes are examined relative to one or more performance goals. The best trades between designed daylighting objectives; visual comfort and interior design strategies are explored to reach a series of possible optimum solutions.

As the quality of daylight and avoidance of glare are equally important, subtracting percentage of occupied hours DGP (g) from the percentage of the space with a  $UDI < 100\text{-}2000\text{lux}$  larger than 50% (u) yields a single maximization objective (both UDI and DGP are in the range [0, 100]). It turned this result into a minimization objective by subtracting it from 100.

$$\min f(x) = 100 - \bar{u}(x) + \bar{g}(x)$$

## RESULTS

The following section, first, compares the results of 56 scenarios of workstation designs based on the following variables and second, the best optimized solutions are analysed and compare with the base case scenario.

#### Height

The highest UDI values were recorded for 42" height partition, in perpendicular orientation to windows (28 %) that in comparison to base case scenario 11% was improved. As it was expected, by increasing the partition height, the amount of daylight that enters into the space reduces, which consequently decreases the percentage of the  $UDI < 100\text{-}2000\text{lux}$  during occupied hours. The lowest percentage of occupied hours glare is recorded for the 60" height partition according to base case layout (3.7%). The percentage of occupied hours that occupants are exposed to glare are (3.7 %, 4.1%) for the 42" and 48" respectively and

unexpectedly the value for the 48" slightly is more than 42" due to the reflection of partition surfaces.

#### Material

The UDI value in figure 2a, implementing transparent material, brings more daylight into the study space. As it was expected, UDI values were reported higher in transparent partitions (with 88% visual transmittance) in comparison to the 20% visual transmittance in translucent partitions (base case), while the percentage of glare for both materials have quite similar values (2.9% and 3.1%). In opaque partitions (85% Reflection), the UDI value is less than the transparent material (20 to 25), however, it is slightly more than the translucent material (20% to 17%) and even the high glare value and more hours shading did not make significant differences.

#### Orientation

The orientation investigation of daylighting's impacts on translucent materials with 30% and 50% VLT was conducted and illustrated in figure 2 c) respectively. It shows that the UDI values for workstations with perpendicular partitions to the window (base case) are relatively low (17 %). Regardless of rotation direction, the UDI values of rotated partition are higher than in the partitions with orientations perpendicular to the windows. In the workstation with 10° rotated towards the south and north directions, UDI values are more than the base case (22% and 19%). Although the workstation with 10° rotation towards the south has higher UDI value in comparison with others, the percentage hours of visual discomfort is considerably high (6.4%). The workstation with 10° rotation towards north are not exposed to daylight and the percentage of glare hours and shading hours in all states are significantly lower than the base case and other. This led to higher UDI value for the workstation with direction towards north even in comparison with perpendicular partitions to the window (19%)

#### Layout

As the plots illustrated in figure 2 d) the UDI and Glare values reveal that in the translucent partitions all alternatives have the better performance in comparison with the base case scenario. The highest useful daylight illuminance (UDI) belongs to the workstation with 60" vertical partitions oriented perpendicular to the windows (Pre 60\_Ver) and the workstation layout with 42" partitions in perimeter zone and 60" partitions in interior zone (Pre 42\_Int 60) that both are almost identical (28%). The lowest values were recorded 2.9% in a layout with 60" partition in the vertical axis of the workstation in perimeter zone (Pre 60\_Ver) that prevent excessive daylight into the space and where the occupants are located. The UDI value of "42, 48 PR\_ 60 In" workstation layout is more than base case scenario (24%) but the glare value is quite similar to "Pre 42\_Int 60" workstation layout (3.7%).

#### Overall

Based on the simulated plots illustrated (Figure 3), the base case scenario has good performance regarding the visual comfort and low occupied hours of glare (3.1%). However, the daylight in the base case scenario is the lowest ranked value (17%) that is recorded in which the 60" partitions block the daylight and reduce the UDI significantly. The best scenarios belong to a workstation with opaque partition layout in 10° oriented towards the south ("Pre 42\_Int 60") illustrated in Figure 4. The hours which the EC is fully shaded, is low and the reflected diffuse light of surfaces in perimeter zones are also low due to the absence of high reflective partitions. Therefore the 4.1% hour of glare provide the more unshaded hours that led to more daylight entering the space and recorded the highest value of useful daylight illuminance (36%). According to the ranking, the workstation with 60" vertical opaque partition in the perimeter zones for the case rotated 10° towards the south (Pre 60\_Ver) could provide a balance between daylight and glare (32 UDI and 4.1 DGP). This scenario would be considered as a good alternative for the first ranked scenario if the level of privacy considered.

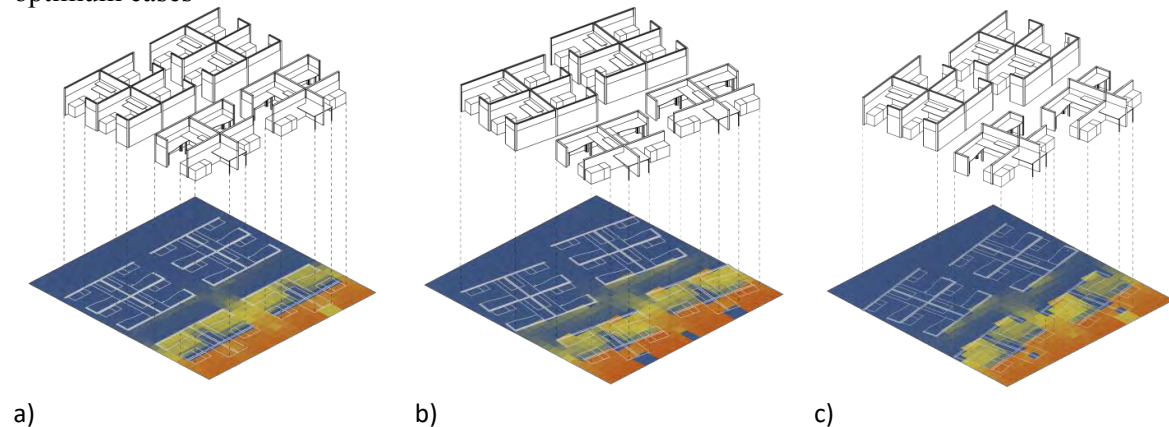

Figure 4. The layout and The Daylight Autonomy. a) Worst case (Base case), b and c. optimum cases

## Discussion

Generally, the ranges of workstation properties are limited to certain degrees and materials and they could be expanded to different choices. For instance, because of the high reflectivity of selected opaque surfaces, the reflection of diffuse light can cause more glare and lead to more shading time while the other opaque material with lower range of reflectivity could produce less glare that reduce the shading time.

Electrochromic glass works with different schedules beside the visual comfort. The energy and thermal schedules in some cases are in contrast with daylighting and visual comfort and their impact on the occupants' visual comfort at workstation needs to be studied and explored for the possible trade-off among all other parameters.

## Conclusion

This paper presented an optimization method, used multi objective workflow with visual comfort and daylight simulation, and applied them to selected optimal values of design parameters associated with workstations (partition height, layout, direction to windows and materials) in an office building equipped with EC (user-based schedule) to deliver optimum daylight values while minimizing Glare Probability in the course of the year.

Considering the workstation design layouts into the simulation of dynamic shading (EC glass) makes the relation of UDI and Glare interdependent so that the daylight depends on the glare value. For instance, although the lower percentage of glare in high partition (60") reduces the shading hours and allows more daylighting that enter into the space, however, the high partition height prevent the penetrations of daylight.

The result of optimized scenarios show improvements of UDI ranging from (65% to 100%) across a diverse range of layouts and partition properties while simultaneously reducing visual discomfort varying degrees (between 4% and 17%) depending on variables. For instance the workstation with opaque ("Pre 42\_Int 60") partition layout in 10° oriented towards the south is one of the optimum scenario that increase the performance of EC regarding daylight and comfort. This study tries to raise the awareness and attention of manufacturers and designers to the performance of workstation in relation to the user-based scheduled EC.

### ABSTRACT

The increase in building energy performance mainly focused on the improvement of physical properties (thermal and optical) of individual components of building envelope. Very good isolation parameters can be easily achieved for opaque elements like walls and roofs. However, improvement of glazed component parameters is still required. Improving thermo-physical properties of window can be achieved using phase change material (PCM). Presented work is a part of extensive research project including the analysis and experimental investigation of window integrated with PCM layer. This modification changes the thermal properties of glass unit and effects on visible light transmission through the window.

The main purpose of the presented work is numerical analysis of the daylight conditions in the office room equipped with PCM window. The research was done for two geometrically identical indoor spaces varying by the window orientations: eastern and western respectively. Simulation was performed using a coupled validated simulation tools: ESP-r and Radiance. First software was used to model analyzed rooms then using second computational environment the illuminance and daylight factors in selected points were determined. Optical data of glazing unit equipped with PCM were appointed experimentally and adjusted to the numerical model. Simulations were carried out for characteristic sky conditions and selected days of year. Assessment of daylight availability in each room was done based on obtained values of illuminance and daylight factor in selected points. Five cases of the triple glazed window were considered: standard one and equipped with PCM layer positioned in the inner or outer cavity in liquid or solid state. Obtained results show that window with PCM in liquid state does not significantly reduce the daylight availability in room regardless the PCM position. However, window with PCM in solid state significantly decrease the light transmission through the window consequent in insufficient daylight conditions in analyzed rooms.

### KEYWORDS

daylighting, PCM layer, light transmission, ESP-r, Radiance.

### INTRODUCTION

Visually comfortable environment in building provide good ability to work and health of occupants. Appropriate visual conditions can be achieved by ensuring required lighting levels, illuminance uniformity and access to daylight. In traditional building the daylight availability is provided by the windows. However, glazing components are commonly the weakest building envelope element considering thermo-physical properties. One of the ways to improve the thermal capacity properties of window is integration of phase change materials (PCM) with glazing unit. Recently many studies about application of PCM in glazed elements of building envelope were published. The first article presenting parametric study of PCM glass system describes numerical and experimental investigation of window with PCM (Ismail and Henriquez, 2002). During last few years, many PCM technologies for the translucent and transparent building envelope, such as windows, shutters and other shading

devices (Silva et al., 2016) as well as roof glazing (Liu et al., 2018) were developed. Majority of the available researchers focuses on the analysis of thermal and optical parameters of PCM included into double glazing window on a laboratory scale (Gowreesunkera et al., 2013; Goia et al., 2014). Some of the studies consider adding of the additional container with PCM to double glazing window (Weinlader et al., 2005). Lastly, Giovannini et al. (2017) presents the analysis of impact of a double glazed unit with PCM layer in solid phase on the luminous environment and on the visual comfort in room equipped with such glazed unit.

Presented work is part of wider research project SOLTREN concerning the extensive analysis and experimental investigation of triple glazed window integrated with PCM layer considering effect of proposed solution on energy performance and visual comfort in experimental room. Double glazed windows have insufficient thermal properties in moderate and cold climatic conditions, therefore analysis of triple glazed window equipped with PCM layer is performed. Research described in this paper provides preliminary studies of impact of PCM layer on daylight availability in analyzed office room. Impact of PCM state, position in triple glazing unit and orientation of the window is considered.

## METHODOLOGY

Analysis was performed using coupled ESP-r and Radiance tool. ESP-r, a modelling tool for building performance simulation, was chosen for energy analysis of proposed PCM window. Whole geometry and material properties was defined using ESP-r program. Subsequently, the simulation of daylighting was made by Radiance engine. Connection of ESP-r and Radiance allow calculating energy performance and illuminance simultaneously for one geometry model of analysed zone. However, ESP-r and Radiance coupling permit only for limited lighting analysis such as visualisation or calculation of illuminance and daylight factors for defined grid points. Glare can be calculated using only UGR coefficient which is not suitable to large-area light sources like windows (Carlucci et al., 2015). Therefore, in presented paper the daylight availability assessment will be made based on obtained illuminance and daylight factors.

Analysis was performed for 4 characteristic days of spring equinox, summer solstice, autumn equinox and winter solstice which occur respectively in March, June, September and December. In each selected day simulations were made for 3 characteristic hours during typical work profile for office: 9 a.m., 12 p.m. and 3 p.m.. In further part of paper each simulation step will be named by month and hour: III 9, III 12, III 15, VI 9, VI 12, VI 15, IX 9, IX 12, IX 15, XII 9, XII 12, XII 15. Furthermore, analysis was performed for two identical office rooms differentiated by the window orientation: eastern and western. Two standard sky conditions: CIE clear sunny and overcast sky was taken into account for all cases. The following 5 window types were considered:

- A - standard triple glazed window,
- B - triple glazed window filled with PCM in liquid state positioned in the outer cavity,
- C - triple glazed window filled with PCM in liquid state positioned in the inner cavity,
- D - triple glazed window filled with PCM in solid state positioned in the outer cavity,
- E - triple glazed window filled with PCM in solid state positioned in the inner cavity.

Window cavity filled with PCM was 16 mm depth. The characteristic of each glazed unit type were determined based on the previously performed measurements with experimental window component and artificial sun (Table 1). Cases A, B and C were modelled as glass material when cases D and E were introduced as translucent material.

Table 1. The characteristics of modelled types of windows

window case	A	B	C	D	E
light transmission [-]	0.71	0.64	0.55	0.06	0.03

Simulations for all described cases were made for 0.5 m density grid points filling the whole room and located at the height of working plane at the level of 0.75 m. Daylight factor and illuminance in all points for the clear sunny and overcast sky were calculated. Analysis of obtained results with particular attention on points located at the position of occupants working plane was performed.

### CASE STUDY

Analysis was conducted for individual office cells representing the existing experimental office rooms. Dimensions of analysed zone are respectively width, length and height: 2.6 m, 4.4 m and 2.6 m. Window is situated in a centre of the exterior wall at the height of 0.7 m and dimensions of the glazed unit are 1.1 m of width and 1.1 m of height. Each office room is occupied by two workers. Both occupants working plane are located in the middle axis of the office room and at the distance of 1.5 m (1<sup>st</sup> working plane) and 3.0 m (2<sup>nd</sup> working plane) from the window. The RGB values of the interior surfaces of walls, floor and ceiling were determined based on the measurements using spectrophotometer Konica Minolta CM-2500d.

Analysis was performed for the location of the office rooms in the Central Europe under the temperate climatic conditions. Furthermore, analysed office rooms were located at the level of 4th floor which corresponds with real location of the experimental rooms.

### RESULTS

Analysis of the obtained results was divided into three parts: comparison of the effect of PCM layer position on daylight conditions at first working plane, investigation of the illuminance distribution in whole room and detailed assessment of daylight availability in all considered simulation steps. Obtained results were named with two letters, first describe orientation and second type of window.

#### Daylight conditions at working plane for different position of PCM layer

Two positions of PCM layer were considered: in outer and inner window cavity. In Figure 1 are presented graphs of illuminance at 1<sup>st</sup> working plane obtained for windows with PCM in liquid and solid state positioned in outer and inner cavities of eastern oriented window for clear and overcast sky conditions.

Figure 1. Illuminance at 1<sup>st</sup> working plane for eastern oriented window for a) clear, b) overcast sky conditions

It can be noticed that position of PCM layer has impact on illuminance calculated at working plane. Illuminance for cases with PCM located in outer cavity (B, D) is higher than for cases with PCM located in inner cavity (C, E) regardless the state of PCM. Described differences are the highest for clear sky conditions at 9 a.m. for all presented cases, which is caused by the solar beam radiation incident directly through the eastern oriented window. The same dependence was noticed for western oriented window at 3 p.m. For the other cases the divergences between illuminance calculated for both position of PCM layer is lower because of operation under only diffused solar radiation.

### Illuminance distribution in analyzed office room

In Figure 2 were presented illuminance distribution in analysed office room with eastern orientated window (cases E\_A, E\_B, E\_D) in spring equinox at 9 a.m. for CIE clear sunny sky. It can be noticed that illuminance distributions for cases A and B have a similar shape and only a level of illuminance for window with liquid PCM is slightly lower. However, distribution of illuminance in these cases is uneven, level of illuminance is very high near the window and significantly lower in further part of room, which may cause visual discomfort of occupants. On the other hand, illuminance distribution for case D is more uniform, however level of light at both working planes is too low considering minimal requirements of 500 lx for office work.

Figure 2. Illuminance distribution in analysed office rooms with a) A, b) B, c) D type of eastern oriented window in spring equinox at 9 a.m. and for CIE clear sunny sky.

### Daylight availability at working plane

In last part of the paper the results of illuminance and daylight factors at 1<sup>st</sup> working plane were presented for the A, B, D type of window and both orientation: eastern and western (Figure 3). It can be seen that for clear sky conditions maximum levels of illuminance for eastern and western oriented windows occurs respectively at 9 a.m. and 3 p.m. according to operation of direct solar radiation. Nevertheless, maximum values of illuminance for cases with western oriented window are higher than for cases with eastern oriented window. Level of illuminance for other cases, when only diffused solar radiation operates, is comparable between eastern and western cases.

Considering illuminance requirements for office space at the level of minimum 500lx, it can be noticed that sufficient illuminance is reached only for clear sunny sky conditions (at 9 a.m. for eastern oriented window, at 3 p.m. for western oriented window and at 12 p.m. in summer solstice for both orientations) for cases of standard window and window with liquid PCM. Implementation of liquid PCM decrease illuminance in all cases, however it does not influence the number of cases meeting the requirements of 500 lx. Whereas cases with PCM layer in solid state influence significantly on illuminance level, in all cases below required 500 lx.

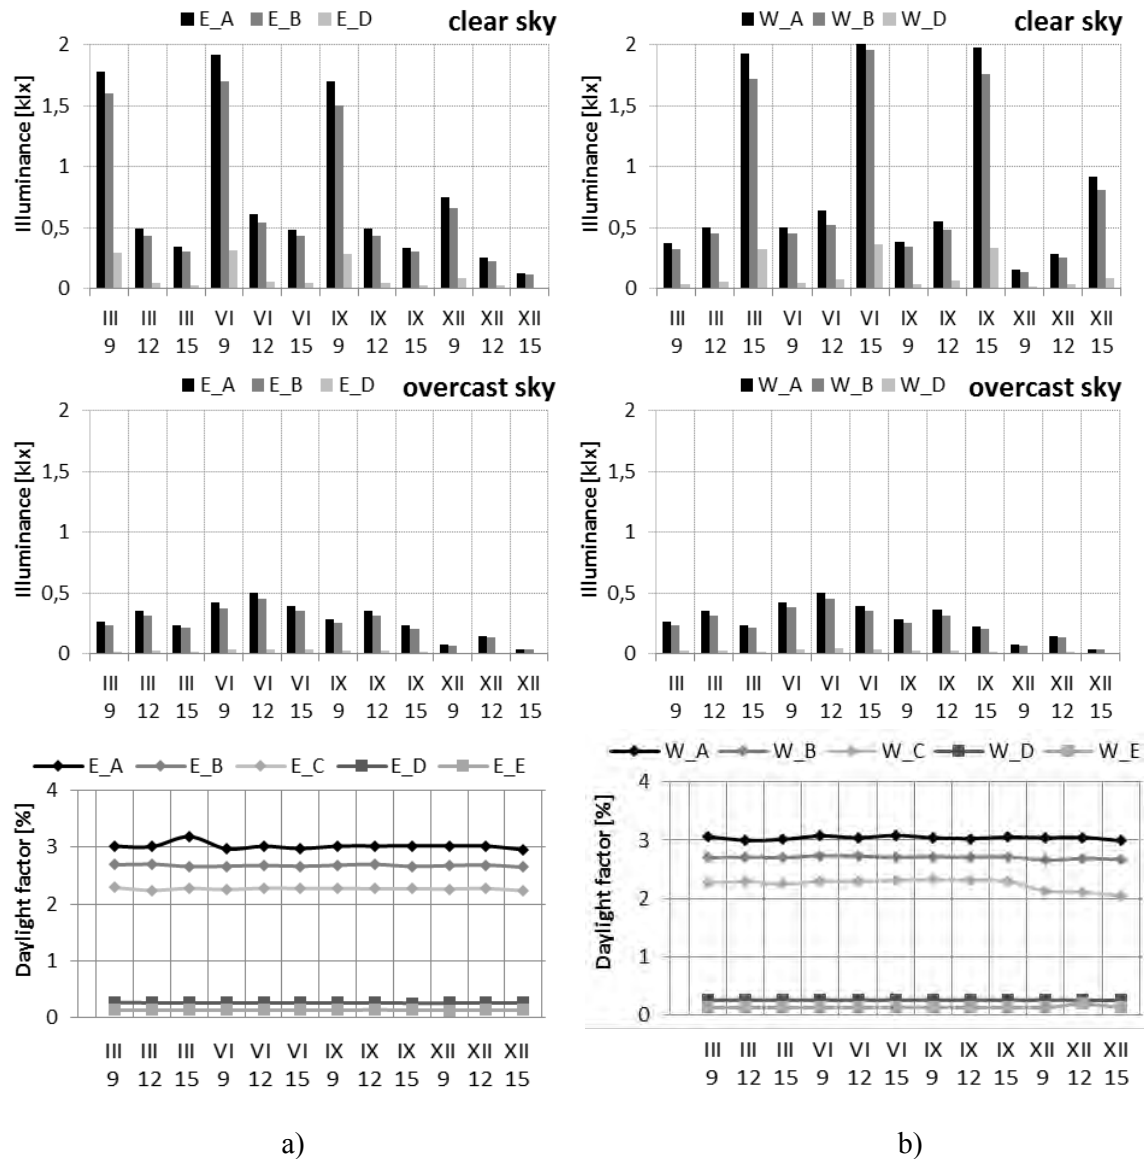

Figure 3. Illuminance and daylight factor and at 1<sup>st</sup> working plane for a) eastern, b) western oriented window.

Levels of daylight factors are constant during all analyzed days and hours with only slight fluctuations. Differences for eastern and western oriented window are insignificant. The daylight factor level for basic case with standard window reached averagely 3% for both orientations. Subsequently, daylight factor for cases with liquid PCM window are slightly lower – averagely 2.7% and 2.3% for window with PCM layer positioned in the outer and inner cavity respectively. Such level of daylight factors meets the requirements of minimum 2% at the working plane in the office area. Nevertheless, level of daylight factors for cases with solid PCM layer are significantly lower and not complete required level.

## DISCUSSIONS AND CONCLUSIONS

Presented analysis focus on the assessment of daylight availability in a room with triple glazed window integrated with PCM layer. The application of PCM in window increases its thermal capacity but simultaneously decrease the light transmission through the window. Therefore, the analysis of the PCM application in glazing unit need to include the visual

comfort assessment in area connected with modified unit. This topic was studied so far only by Giovannini et al. (2017), analysing impact of double glazed unit with PCM layer in solid phase on the luminous environment and the visual comfort in room under a clear sky and with the façade facing south. Considering different assumptions of presented study and mentioned Giovannini et al. (2017) research, results obtained from them are incomparable.

In presented research the daylighting availability in the office room were presented considering different types of triple glazed window: standard and filled with liquid/solid PCM positioned in interior/exterior cavity. It was observed that application of PCM layer into triple glazed window decrease the daylight transmittance of glazing unit causing reduction in the illuminance and DF in room. For liquid phase of PCM this reduction is small and not influences significantly the daylight distribution in interior. However, PCM in solid phase highly decrease the daylight transmittance and hence the illuminance distribution. Furthermore, analysis of PCM position indicates that position of the PCM layer in the outer cavity for both liquid and solid phase influence higher daylight availability than position of the PCM in inner cavity. In conclusion, application of PCM layer in glazing unit decrease the daylight availability in room equipped with such window. However, PCM window has high potential to improve the thermal capacity properties with insignificant influence on the visual comfort when it will be design to be melted during a day to ensure visual comfort in room.

#### ACKNOWLEDGEMENT

This work was funded in a framework of ERANet-LAC 2<sup>nd</sup> Joint Call on Research and Innovation by NCBiR as part of the project entitled: Solar hybrid translucent component for thermal energy storage in buildings (acronym: SOLTREN).

### ABSTRACT

Smart windows, especially those electric-driven, represent one of the most advanced technologies for controlling solar radiation. For a correct use, it is necessary to understand their real behaviour through in-situ measurements on full-scale application as well as calibrating and validating visual simulation models capable of predicting their performances. In this paper, the preliminary results of current research activities aimed at developing simulation models of electric-driven full-scale glazing are presented. The research activities started with the assessment of the visible solar transmittance as a function of light incident angle through in-situ measurements; different models, with related values, of the visible solar transmittance were considered. For each simulation model, the corresponding transmittance value was set in the RADIANCE “*trans*” material model and the simulated illuminance values, for a defined acquisition point of a test-facility, were then compared with the experimental data. Finally, for each model, indoor luminance distributions were reported considering a typical office seating position. Preliminary results, based on the in-situ measurements approach, highlighted a sufficient accuracy for one of the models adopted; further analyses are needed in order to upgrade the simulation models available and assess the effective performances of these windows.

### KEYWORDS

Electric driven window, Experimental measurements, Visual Comfort, Daylight simulation, Radiance.

### INTRODUCTION

The correct use of daylight allows to reduce energy use for lighting in buildings as well as improve visual comfort (Ciampi et al., 2015a; Ciampi et al., 2015b). In this scenario, smart windows, especially those electrically driven, can play an important role in controlling the visual and thermal conditions inside a room. Differently from conventional windows, these new typologies of glazing allow to vary their visible and thermal characteristics by applying an electric field to active layers. With the aim of controlling solar radiation and improving indoor conditions, more and more new electric-driven types of smart materials and systems are being developed. Nevertheless, for the best use of these new technologies, in-situ assessments on full-scale devices are necessary to understand their real behaviour upon varying internal and external conditions as well as to develop simulation models capable of predicting their performance under different operating conditions. For these reasons, experimental and theoretical studies have been performed to evaluate the visual and thermal

performances of different full-scale devices as: electrochromic windows (Piccolo et al., 2009), Suspended Particle Device (SPD) (Ghosh et al., 2016) or gasochromic windows (Feng et al., 2016). In this paper, the preliminary results of experimental research aimed at evaluating the visual behaviour and developing simulation models of an Electric-Driven (ED) glazing are presented. The analysed electrically driven glazing can be switched from an opaque white (milky) to a transparent (clear) state in the presence of an electric field. A preliminary and simplified optical characterization of the electric-driven glazing was performed to evaluate the visible solar transmittance as a function of sunlight incident angle, through simultaneous on-site measurement of the vertical illuminance values on the external and internal surfaces of the window; the measurements were collected on a full-scale ED device by using a test facility. Experimental data were then used to calibrate and validate simulation models of the two states of the ED glazing using a RADIANCE “trans” material model as first approach; the calibration/validation was carried out by using models of glazing solar transmittance presented in previous researches. Finally, it has been performed a preliminary comparison among different simulation models for ED glasses in terms of illuminance distributions as well as Discomfort Glare Probability (DGP) inside the facility.

### TEST FACILITY AND MEASUREMENTS SET UP

In order to allow for experimental studies to assess the in-situ visual performances of full-scale smart windows, an experimental station was designed and set-up at the Department of Engineering of the University of Sannio (Ascione et al., 2016; Sibilio et al., 2016). The station consists of a steel structure placed on a turntable, with external size of 6.00 m x 6.00 m and height of 5.50 m. The facility is equipped with a double-hang wood frame window with a total size of 2.000 m x 1.200 m, a ratio between glass area and total window area equal to 0.59; each hang has a glazing with size of 0.785 m x 0.900 m. In this paper, the first results of the in-situ visual characterization of the two full-scale double ED glazings, manufactured by Gesimat (GESIMAT), were presented. The ED glazing was composed, from outside to inside, of a 4 mm uncoated float glass, a 16 mm gap filled with Argon and an electric-driven layer between two 4 mm uncoated glasses. According to the technical data declared by the manufacturer, the ED glazing is switched from milky to clear state by applying an electric field of about 115 V, within about 1 s. In the clear state, ED glazing was characterized by a visible solar transmittance ( $\tau_{vis}$ ) equal to 72.5%, a thermal transmittance ( $U_g$ ) equal to 2.5 W/m<sup>2</sup>K, a solar factor (g) equal to 0.72 and a power demand of about 10 W/m<sup>2</sup>. In the milky state, the ED glazing was characterized by a visible solar transmittance ( $\tau_{vis}$ ) equal to 60.7%, a thermal transmittance ( $U_g$ ) equal to 2.5 W/m<sup>2</sup>K and a solar factor (g) equal to 0.67. The in-situ visual characterization was carried out in two steps: (1) evaluation of the visible solar transmittance as a function of light incident angle and (2) evaluation of vertical internal daylight illuminance on a specific measurement point.

#### Evaluation of the visible solar transmittance as a function of light incident angle

The first set-up was realized to evaluate the variations of visible solar transmittance as a function of the sunlight incident angle. With this aim, the vertical illuminance values on the external surface of the window  $E_v^{ext}$  and just behind the internal surface of each ED glazing  $E_v^{int}$  were acquired during different days with completely clear sky conditions. In this step, measurements were performed with i) window west oriented and ii) left ED glazing in clear and right ED glazing in milky state. The illuminance values were acquired every 20 s by three Konica Minolta T-10 (accuracy of  $\pm 2\%$ ) when direct sun light strikes on lux-meters, from around 2 pm (incident angle of direct light about 65°) to the sunset (incident angle about 5°).

Figure 2a shows the experimental visible solar transmittance values, calculated as  $E_v^{int} / E_v^{ext}$  for clear state, while Figure 2b shows those for milky state.

Figure 1. Experimental visible solar transmittance values as a function of the sunlight incident angle for a) clear and b) milky state.

The experimental data were then compared with 3 simulation models:

- 1) **#1 ( $\tau_{maker}$ )**: value of the visible transmittance constant for different sunlight incident angles and equal to the value declared by manufacturer;
- 2) **#2 ( $\tau_{dif-dif,fit}$ )**: value of the visible transmittance constant for different sunlight incident angles and equal to the diffuse-diffuse transmittance  $\tau_{dif-dif,fit}$  of the glazing, defined as

$$\tau_{dif-dif,fit} = \int_0^{\pi/2} \tau_v(\theta) \sin(2\theta) d\theta \quad \text{where } \theta \text{ is the incident angle and } \tau_v(\theta) \text{ is the}$$

empirical angular function  $\tau_v(\theta) = \tau_0 \cdot (1 - \tan^x(\theta/2))$  (Reinhart and Andersen, 2006); these models are reported as dash lines in Figure 2a for clear and Figure 2b for milky state. The calculated values of  $\tau_{dif-dif,fit}$  are equal to 43.8% for clear and 42.7% for milky state;

- 3) **#3 ( $\tau_{fit}$ )**: value of the visible transmittance variable with the sunlight incident angle and equal to value predicted by the empirical angular function  $\tau_v(\theta) = \tau_0 \cdot (1 - \tan^x(\theta/2))$  (dash lines in Figure 2a and Figure 2b).

Figure 2. Curve fitting for a) clear and b) milky state (model #2 and #3).

Later, as first approach, the ED glazing was modelled through the RADIANCE “trans” material. The “trans” material model considers the glass as a perfect Lambertian diffuser and assumes the solar visible transmittance constant for different light incident angles. The two states of ED glasses were simulated setting the amount of light transmitted as totally direct for clear and totally diffuse for milky state.

### Evaluation of vertical internal daylight illuminance on a specific measurement point

The external daylight availability as well as the internal illuminance daylight distributions were acquired at the same time, with the test room south oriented. The measurements were collected on sunny days from 9:00 to 18:00 local time with a time step of 1 hour, on 12<sup>th</sup>, 13<sup>th</sup> and 18<sup>th</sup> July in the milky state and on 11<sup>th</sup>, 15<sup>th</sup> and 16<sup>th</sup> July in the clear state. The external daylight availability was evaluated acquiring the horizontal global and diffuse illuminance values on the roof of the facility, by using two illuminance-meters LP PHOT 03 (DELTA-OHM), with accuracy <4%. For the horizontal diffuse illuminance, a black painted shadow-ring, with a diameter of 0.574 m and thickness equal to 0.052 m were used. The simulation results were compared with the experimental data acquired by an illuminance-meters Konica Minolta T-10 placed in vertical position just behind the glass (V1, as reported in the Figure 3a). Figure 3b shows the window equipped with the ED glasses in the clear (left pane) and milky (right pane) states. In this paper, only the sensor V1 was considered because it was not affected by internal light reflections, allowing to evaluate the behaviour of the glazing alone.

Figure 3. a) Layout of the room with position of the sensor and b) the ED device in the two states.

### RESULTS AND DISCUSSION

Figure 4 the comparison among the experimental illuminance values acquired behind the ED device (measurement point V1), the simulation results obtained setting the visible transmittance equal to  $\tau_{\text{maker}}$ ,  $\tau_{\text{dif-dif,fit}}$  and  $\tau_{\text{fit}}$  as well as the external horizontal global illuminance values. In the figure, the connecting lines between the dots are only guidelines for the eye to connect data points. The values are plotted as a function of both the hour of the day and the light incident angle. The Figure 4 shows that:

- whatever the glazing state is, the simulation performed using  $\tau_{\text{maker}}$  overestimates the experimental data, while  $\tau_{\text{fit}}$  underestimates the experimental data;
- for both the clear and milky state, the simulations performed using  $\tau_{\text{dif-dif,fit}}$  allow to achieve the best prediction of experimental data;
- whatever the glazing state is, the simulation performed using  $\tau_{\text{dif-dif,fit}}$  overestimates the experimental data in the morning, while underestimates the measured values in the afternoon;
- the average relative percentage error values with respect to the measurements are equal to about 73.0% for  $\tau_{\text{maker}}$ , -2.6% for  $\tau_{\text{dif-dif,fit}}$  and -59.0% for  $\tau_{\text{fit}}$  in clear state, while in the milky state are equal to about 59.0%, -2.0% and -52.0%, respectively;
- for  $\tau_{\text{dif-dif,fit}}$  in the clear state, the smallest illuminance difference between the experimental and simulated data is observed on 16<sup>th</sup> July at 16:00 (with values of about 5287 lux and

5243 lux, respectively); in milky state, it is observed on 12<sup>th</sup> July at 17:00, (with values of about 4900 lux and 4861 lux, respectively).

In Figure 5, the simulated luminance distributions inside the facility, using the three simulation models described above, were reported. With the aim of reproducing a typical seating position, the luminance distributions, with associated DGP values, were calculated from a point placed at the eye level of a person considered as seated at the desk, facing and looking at the screen of a notebook computer (Figure 3a). The simulations were carried out at midday of a conventional sunny sky with sun.

Figure 4. Measured and simulated illuminance values on the measuring point V1 for a) clear and b) milky states as well as the external horizontal global illuminance values.

Figure 5. Simulated daylight luminance distributions for a)  $\tau_{\text{maker}}$ , b)  $\tau_{\text{dif-dif,fit}}$  and c)  $\tau_{\text{fit}}$  in clear state as well as d)  $\tau_{\text{maker}}$ , e)  $\tau_{\text{dif-dif,fit}}$  and f)  $\tau_{\text{fit}}$  in milky state.

The preliminary investigation allows to provide some models for the simulation of the ED glasses and define, among them, the more accurate one for utilization within software for indoor daylighting analysis. The research, even if performed with a preliminary approach based upon on-site measures, highlighted differences in outcome among the different considered models of ED windows. In particular it should be noted that the data provided by

the manufacturer do not always provide an accurate assessment of the transmission of sunlight and its value nearby the window. The same results were obtained considering the model  $\tau_{fit}$  that always underestimate experimental data. Through preliminary on-site measurements it was defined a more reliable sunlight visible transmittance factor that took into account the influence of the incidence angle of solar radiation. The availability of models with a good accuracy represent the starting point to perform detailed analyses for evaluating the ability of these ED glasses to reduce energy consumption and improve visual and thermal comfort in comparison with more conventional design solutions. In addition, for these types of glasses there are other issues to consider, such as: (i) the way in which the light is transmitted inside the room and (ii) the fact that the milky state prevents exterior view. An example of these last effects can be viewed in Figure 5, where ED milky state prevents reflections of direct sunlight on internal surfaces but at the same time lead to higher DGP values with respect to the clear state. Finally, it is important to highlight that the progress in the use of innovative materials raises the issue to have reliable simulation models able to correctly describe their behaviour.

## CONCLUSIONS

In this paper, the preliminary results of research activities aimed at calibrating and validating visual simulation models for ED glazing were presented. The RADIANCE “trans” material model was used as a first approach to simulate the behavior of the two states of the ED glazing. Starting from the manufacturer data and in-situ measurements, three different values of the visible solar transmittance, for each ED state, were deduced to be set in the “trans” material model. The results of the three simulation models show that the simulation model #2 is the best way to predict the experimental data, for both the clear and milky states. The results also suggest that internal daylight distribution, in addition to the weather conditions, is strongly correlated to the simulation models applied for the same smart glazing. In the next research step the ability of other simulation models will be considered to provide a suitable tool for predicting the real performance of these systems.

### ABSTRACT

The lighting environment of the shopping malls will greatly influence the customer's visual comfort and product sales. This experiment studied the lighting environment of jewelry stores with the highest lighting energy consumption in shopping malls. The jewelry store scene which was built in the Key Laboratory of Building Environment Simulation had a total of 150 lighting conditions. Then, we measured lighting parameters, and subjective evaluation of lighting quality (including lighting comfort and commodities display effect) with 30 participants were carried out. We analyzed the experimental data to get the influence law of lighting parameters on lighting quality. Finally, this paper introduces an emerging ensemble learning algorithm XGBoost (extreme gradient boosting) to construct evaluation models of multiple lighting parameters for lighting quality in jewelry stores, which were verified to have good accuracy. It is of great significance to save energy on the basis of ensuring the lighting quality of the shopping malls.

### KEYWORDS

Jewellery stores, Lighting quality, Experimental study, XGBoost, Evaluation model

### INTRODUCTION

With the development of economy in China, the increasing number of shopping malls have very high requirements for visual comfort of the indoor light environment, resulting in high energy consumption (Hou et al. 2016). However, visual comfort of shopping malls is poor due to incomplete lighting design standards (MOHURD 2013); lighting in shopping malls accounts for 30%-40% of total energy consumption, so energy conservation has become an urgent problem (Xu et al. 2013; Lowry 2016). Because the establishment of the light environment index system is based on human subjective feelings, the impact mechanism of different spatial and lighting parameters on visual comfort is studied through evaluation experiments and parameter analysis. And to build the lighting evaluation model is the main means to solve the above problems, but there are still some problems in the current studies:

(1) In the aspect of evaluation experiments, there are mainly three kinds of research methods: a) The evaluation experiment in real buildings can not change lighting parameters. Therefore, it is difficult to obtain the influence rules to establish an index system (Jin et al. 2017; Ricciardi and Buratti 2018); b) Constrained by the laboratory environment, evaluation experiments in the laboratories can not study the impact of spatial parameters (Ampenberger et al. 2018); c) There is some controversy over using virtual reality technology to study lighting environment (Heydarian et al. 2015; Natephra et al. 2017). (2) In the aspect of lighting parameters analysis, regression equations were used to fit the visual comfort formula which continuous number could be predicted. However, the sample size was usually limited,

and the existing methods greatly reduced the accuracy of the evaluation formula (Deng et al. 2018; Jin et al. 2017).

In order to solve the above problems, the real store scene was built in the Key Laboratory of Building Environment Simulation to conduct an evaluation experiment; XGBoost (Hassan et al. 2017; Urraca et al. 2017) was used to solve the classification problem of big data. Based on this, the impact of lighting parameters on the lighting quality were studied, and lighting evaluation models were established to ensure visual health, to improve visual comfort, and to save lighting energy consumption, while satisfying the functions of lighting. It has important scientific and practical significance for achieving a healthy, comfortable and energy-saving light environment of shopping malls.

## METHODS

### Experimental setup

We designed and built the Key Laboratory for building light environment simulation in Tianjin University, which is biggest and high performance in Asia (Figure 1). The plan, the height and all the luminaires of the laboratory can be adjusted. Therefore, the light environment of various architectural spaces can be restored and monitored in the laboratory.

Figure 1. Key Laboratory of Building Environment Simulation. a) Exterior, b) Interior.

The jewelry stores with the highest lighting energy consumption in the shopping malls were selected as the research object, and the jewelry store experiment scene was set up in the laboratory (Figures 2). 12 downlights (Dimension:  $\phi 282 \times H130$ ; Beam angle:  $120^\circ$ ; Power: 60w) embedded in the ceiling were as ambient lighting; 12 spotlights (Dimension:  $\phi 158 \times H100\text{mm}$ ; Light source: LED; Beam angle:  $24^\circ$ ; Power: 30w) embedded in the crane span structure and the strip light (Dimension:  $W39 \times H9\text{mm}$ ; Light source: LED (SMT 2835); Beam angle:  $110^\circ$ ; Power: 12w) in the counters were as accent lighting. The luminous flux and CCT (correlated color temperature) of all luminaires can be adjusted intelligently which can constitute a large number of lighting conditions.

Figure 2. The simulated jewelry store. a) Store plan, b) Luminaire plan, c) Elevation, d) Photo.

### Lighting variable setting and measurement methods

According to the standards and the field investigation, we determined the extreme values of the variables of lighting conditions to cover most of actual conditions. In the experiment, all luminaires were intelligently controlled to set up a total of 150 lighting conditions (Table 1).

Using the center-distribution method, measurement points are shown in Figure 3. And the measurement height was 0.75m (SAC 2009). The measurement instrument was CL-500A spectroradiometer. The stores scene without windows avoided the effect of natural light while measuring.

Table 1. Lighting variable setting.

Lighting system	Variable	Number of levels	Value
Ambient lighting	illuminance	3	500 lx, 1000 lx, 1500 lx
			1000 lx, 1500 lx, 2000 lx, 3000 lx, 4000 lx,
Accent lighting	illuminance	10	5500 lx, 7000 lx, 8500 lx, 10000 lx, 12000 lx
	CCT	5	3500 K, 4000 K, 4500 K, 5000 K, 5500 K

Figure 3. Measurement points plan. Figure 4. The process of the experiment.

### Subjective lighting quality assessment

In the experimental scene of jewelry stores, a questionnaire survey (Table 2) was conducted to subjectively evaluate 150 lighting conditions. Thirty research participants who aged 22 to 26 years (15 female and 15 male subjects) were divided into 6 groups to evaluate the randomly disturbed lighting conditions in 5 days. In the experiment scene, participants simulated the shopping process, fully experienced the light environment and then subjectively evaluated the lighting quality. The experimental process is shown in Figure 4. Participants were asked to wear eye masks to avoid interference between two lighting conditions. After evaluating every 10 lighting conditions, participants rested for 20 minutes to eliminate the effect of fatigue experiment on the experiment results.

Table 2. Lighting quality questionnaire.

Lighting condition number	Visual comfort	Very bad			Bad		Good			Excellent	
		1	2	3	4	5	6	7	8	9	10
	Effects of commodities presentation	Very bad			Bad		Good			Excellent	
		1	2	3	4	5	6	7	8	9	10

## RESULTS

Processed experimental data and conducted preliminary analysis. 150 lighting conditions were discussed separately in accordance with three ambient lighting conditions. In each ambient lighting scene, CCT of the accent lighting was set in five levels. But in the actual measurement, CCT changed due to the change of the illumination. In order to analyze the results, the average number of CCT was obtained from the CCT which were set up as same.

### The influence of lighting parameters on lighting quality

Figure 5 describes the influence of illuminance and CCT of accent lighting on visual comfort when ambient CCT is 4000 K which is the most commonly used and ambient illuminance is in three levels. The abscissa is horizontal illuminance of accent lighting, and the ordinate is

the value of visual comfort. The different colored lines represent different CCT of accent lighting. The question of visual comfort had a scale value from 1(very bad) to 10(excellent) which greater values indicated more comfort.

As shown in Figure 5, within the range of experimental values, (1) When the ambient illuminance is different: visual comfort increases with the increased ambient illuminance. With the increase of ambient illuminance, visual comfort increases smaller and smaller with increased accent illuminance. When ambient illuminance increases to more than 8000 lx, visual comfort of some conditions begin to decrease. (2) When the ambient illuminance is the same: visual comfort increases with the increase of illuminance, and the increase tends to be smaller and smaller. When the accent CCT is about 4000K (medium color temperature), the jewelry store has better visual comfort. (3) As shown in Figure 5-c, when the ambient illuminance is 1500 lx, the reason for the special point is: the sequence of lighting conditions to evaluate was random. The lighting condition of special point (Accentuated CCT is 5290.8K, and accent illuminance is 10000 lx) was evaluated after the condition (Ambient illuminance is 500 lx, and the accent illuminance is 576 lx). The difference in illuminance between the two lighting conditions is too large, causing visual discomfort.

Figure 5. Influence of lighting parameters on visual comfort. a) Illuminance of ambient lighting is 500 lx, b) Illuminance of ambient lighting is 1000 lx, c) Illuminance of ambient lighting is 1500 lx.

Fig. 6 describes the lighting parameters on the presentation effect of the commodities when the ambient CCT is 4000K. The abscissa is horizontal illuminance of accent lighting, and the ordinate is effect of commodities presentation. The scale value of presentation effect is from 1(very bad) to 10(excellent), and larger values indicate better presentation.

As shown in Figure 6, within the range of the experiment values, (1) When the ambient illuminance is different: the ambient illuminance has small effect on the presentation effect. (2) When the ambient illuminance is the same: the effect of commodity presentation increases with the increased accent illumination. When the accent illuminance is greater than 10000 lx, the presentation effect decreases or stays the same. When the accent CCT is medium CCT(4000K) or high CCT(4000K-5600K), the presentation effect is better. Accent lighting in low CCT in the jewelry store has poorer presentation effect.

Figure 6. Influence of lighting parameters on effects of commodities presentation. a) Ambient illuminance is 500 lx, b) Ambient illuminance is 1000 lx, b) Ambient illuminance is 1500 lx.

### Evaluation model

XGBoost is an extension of the Gradient Boosting Machine. The Boosting classifier belongs to the ensemble learning model (Hassan et al. 2017; Urraca et al. 2017). XGBoost is widely used in energy consumption prediction (Touzani et al. 2018; Robinson et al. 2017) and power distribution due to its high efficiency and accuracy. This paper introduces XGBoost into the evaluation of lighting quality in shopping malls and establishes a multi-parameter evaluation model.

### Evaluation model of visual comfort in the jewelry store

Data preprocessing was performed, the outliers of visual comfort experiment data were removed by using an interquartile range method, and then the end points of the interval were used as the comfort label values. We obtained the visual comfort distribution of all lighting conditions of the jewelry store.

We used python to build an evaluation model of visual comfort in the jewelry store based on the XGBoost ensemble learning classification algorithm. Experimental data was randomly divided into training sets and test sets in a ratio of 4:1. And we built XGBoost classification models on the training sets and adjusted parameters according to the classification prediction accuracy rate of the test sets. Finally, the optimal combination of parameters are as follows: max\_depth=3, n\_estimators=50, learning\_rate=0.1, subsample=0.95. The prediction accuracy rate of the model on the test sets is 0.9, which shows that the model has good generalization ability, and the accuracy rate of the training sets is 0.942, which can effectively prevent the model from overfitting. According to the weights, the order of features of well-trained XGBoost model is: accent illuminance (0.3483), accent CCT (0.2780), Ra (general color rendering index) of accent lighting (0.2161), ambient illuminance (0.1573) (Figure 7).

### Evaluation model of commodities presentation effect in the jewelry store

Similarly, an evaluation model of product presentation effect in jewelry store was obtained. When ambient CCT is approximately 4000K, the order of the features is: accent illuminance (0.5244), accent CCT (0.2502), Ra of accent lighting (0.1934) and ambient illuminance (0.0319) according to the weights (Figure 8).

Figure 7. Weights of the features that affect visual comfort of the jewelry store. Figure 8. Weights of the features that affect commodity presentation effect of the jewelry store.

### DISCUSSIONS

In the aspect of illuminance, visual comfort and commodity display effect increase with the increase of illuminance, but the increasing trend gradually flattens. And for the effect of commodities display, the accent illuminance has a greater influence, and the influence of the ambient illuminance is smaller (Figure 8). However, when the accent illuminance is greater than 8000 lx, most of the visual comfort and display effect begin to decrease. In the aspect of CCT, when accent CCT is about 4000K, the jewelry store has better visual comfort and product display effect. Store lighting design should consider both sides.

When the ambient CCT is about 4000K, the well-trained XGBoost model can be used to predict the visual comfort and the commodities display effect to guide the lighting design of the jewelry stores. The evaluation model has the following limitation: In order to avoid the fatigue test of participants from affecting the results, the ambient CCT is unified to the

commonly used value (4000 K) according to the field investigation. Therefore, this evaluation model can not evaluate other lighting conditions except that the ambient CCT is 4000K.

## CONCLUSIONS

This study proposes the influence laws of lighting parameters on lighting quality of jewelry stores in shopping malls, and obtains an evaluation model of lighting environment in jewelry stores. Based on advanced machine learning algorithms, the proposed model can predict and evaluate lighting quality (visual comfort and effect of commodity display) through multiple lighting parameters (illuminance of ambient lighting, illuminance of accent lighting, CCT of accent lighting, and Ra of accent lighting). The results show that the model achieves an ideal predicting accuracy. This method can be extended to lighting design in shopping malls to improve lighting quality and to achieve energy saving.

### **ABSTRACT**

This paper reports the results of experimental tests and numerical simulations aimed at evaluating the performance of an electric-driven smart window with respect to solar control in buildings. The experimental performances of the electric-driven smart window were evaluated using a south oriented full scale experimental facility designed and realized. The tests were carried out during the summer under real sky conditions upon varying the state of the electric-driven smart window (clear and milky). In the first part of the paper, the experimental results are discussed in terms of surface temperature of glazings as well as indoor air temperature in order to highlight the potential benefits on thermal comfort associated to the application of electric-driven smart windows. In the second part of this paper, the experimental data are compared to the numerical results generated through a simulation model of the electric-driven smart window in order to assess its reliability under different operating scenarios. Finally, the simulation model is used to quantify the potential cooling load reduction deriving from the integration of electric-driven smart windows in an office façade located in Naples (Italy).

### **INTRODUCTION**

A significant portion of the total worldwide energy demand (around 40%) can be attributed to heating and cooling of the building sector (European Commission, 2015). In this context, the Electric-Driven (ED) smart window technology, especially for the buildings with a large glazed surface, can help to significantly reduce the energy consumption as well as to improve the indoor thermal comfort. Indeed, these new typologies of glazings allow to vary their visible solar transmission and solar factor by applying an electric field. A large number of studies are currently in progress about electric-driven smart windows (Baetens R. et al. 2010, Fernandes et al. 2013, Niklasson and Granqvist 2006, Piccolo 2010, Piccolo et al. 2009, Piccolo and Simone 2009, Sibilio et al. 2017). The literature review reveals the need to perform further experimental analysis to evaluate the on-site performances of these type of smart windows taking into account that: (i) the most analyzed electric-driven smart windows typology has been the electrochromic window, (ii) the visual comfort as well as the electric energy savings for lighting have been the most investigated aspects and (iii) the experimental performances of small-scale smart windows prototypes have been generally investigated. However, it can be noticed that the benefits in terms of reduction of cooling energy demand as well as capability in maintaining the thermal comfort by the application of the smart windows have been rarely investigated.

In this paper, the results of experimental tests and computer simulation modelling aimed at evaluating the thermal performance of a full-scale ED windows with respect to solar control in buildings are reported. The experimental thermal performances of the ED window were evaluated by using a south oriented full-scale experimental station during the summer and under real sky conditions. In the first part of the paper, the experimental results are discussed in terms of surface temperature of glazings as well as indoor air temperature. The ED window is modelled by means of the software (WINDOW 7.5) and then imported into the software (TRNSYS 17). In the second part of the work, the numerical results are compared to the experimental data in order to assess the model reliability. Finally, the ED window model is used to quantify the cooling energy demand reduction deriving from the use of ED windows into an office façade located in Naples (Italy).

### FULL-SCALE TEST-ROOM

The experimental facility is a full-scale outdoor test-room (Ascione F. et al. 2016) designed and set-up at the Department of Engineering of the University of Sannio, Benevento (latitude:  $41^{\circ}7' N$ ; longitude:  $14^{\circ}47' E$ ). The test room has a floor area of  $36.0 \text{ m}^2$  ( $6.0 \text{ m} \times 6.0 \text{ m}$ ) with a height of  $5.5 \text{ m}$ . The test-room is able to rotate  $360^{\circ}$  on the horizontal thanks to a motorized steel support that allows to modify the orientation. The envelope of the experimental station consists of three removable vertical test walls ( $U=0.43 \text{ W/m}^2$ ), one unremovable vertical technical wall ( $U=0.05 \text{ W/m}^2$ ), a floor ( $U=0.05 \text{ W/m}^2$ ) and a roof ( $U=0.06 \text{ W/m}^2$ ) (Ascione F. et al. 2016). The total size of the window is  $2.00 \text{ m} \times 1.20 \text{ m}$ ; two ED double glazings (each with size of  $0.785 \text{ m} \times 0.900 \text{ m}$ ), produced by (GESIMAT), were installed. This typology of electric-driven smart window consists of three layers as reported in Figure 1a. In particular, the ED glazing is a polymer with dispersed Liquid Crystal (LC) between two float glass substrates. This third layer allows the ED window to switch quickly (1 second) from transparent to opaque state, and vice versa. The switching is possible thanks to a potential difference across the glazing; in particular, when the voltage is equal to  $0 \text{ V}$  the smart window is opaque (milky), while when the voltage is equal to  $115 \text{ V}$  the ED window is transparent (clear). Figure 1b reports an indoor view of the ED window installed in the test-room with the left window pane in the clear state and the one on the right in the milky state.

Figure 1. a) Schematic layout of the ED double glazed unit, b) indoor view of the ED window installed in the test-room.

In clear state, ED glazing is characterized by a visible solar transmittance ( $\tau_{vis}$ ) equal to 72.5%, a thermal transmittance ( $U_g$ ) equal to  $2.5 \text{ W/m}^2\text{K}$ , a solar factor ( $g$ ) equal to 0.72 and a power demand of about  $10 \text{ W/m}^2$ . In milk state, the ED glazing is characterized by  $\tau_{vis}$  equal to 60.7%,  $U_g$  equal to  $2.5 \text{ W/m}^2\text{K}$  and  $g$  equal to 0.67.

The outdoor boundary conditions were monitored by means of a weather station. In particular, the test-room is well equipped (Ascione F. et al. 2016) in order to measure the following parameters: air temperature, relative humidity, rainfall, wind-speed, wind-direction, diffuse and global solar radiations. The technical specifications of the outdoor sensors are reported in (Ascione F. et al. 2016). In addition, external daylight availability is evaluated by measuring the horizontal global and diffuse illuminance values on the roof of the test-room by means of two illuminance-meters LP PHOT 03 of (DELTA-OHM) and with an accuracy  $< 4\%$ . In order to highlight the potential benefit on thermal comfort associated to the use of the ED windows, the surface temperature of glazings as well as the indoor air temperature are also measured. The temperatures are monitored by using a resistance thermometer Pt100 with a range of  $-40\div 80\text{ }^{\circ}\text{C}$  and an accuracy equal to  $\pm 0.1\text{ }^{\circ}\text{C}$  at  $0\text{ }^{\circ}\text{C}$ . The sensors on the surface of glazings are installed with appropriate shielding to consider the effect of direct solar radiation. Each parameter is logged every 10 seconds by means of a Fluke NetDAQ Data Logger.

### **SIMULATION MODELS**

The whole ED window was modelled by means of the software WINDOW 7.5, considering the schematic layout of the ED double glazed unit reported in Figure 1a. In particular, two different window models were realized, one for the ED window in the clear state and another one for the ED window in the milky state. The output file of the software WINDOW 7.5 was then used in software platform TRNSYS 17 by means of the Type 56 to compare the experimental thermal performances with those obtained through simulations. However, in order to take into account the thermo-physical characteristics of the building envelope of the facility (Ascione F. et al. 2016), the test-room was firstly modelled in TRNSYS 17.

A simulation time step equal to 10 seconds was used. During the simulations, the same outdoor boundary conditions measured during the experimental tests were considered.

Finally, the two simulation models of ED window were used to quantify the cooling energy demand reduction associated to a typical office building located in Naples by replacing the conventional double-glazing windows with the same thermal transmittance.

### **RESULTS AND DISCUSSION**

#### **Experimental results**

Measurements were carried out for about 1 month during the summer of 2017 from 29<sup>th</sup> June up to 20<sup>th</sup> July (for a total of 22 days) from 9:00 up to 18:00 by using the above-described facility located in Benevento (latitude:  $41^{\circ}7' \text{ N}$ ; longitude:  $14^{\circ}47' \text{ E}$ ). The experimental tests were carried out under real sky conditions with the ED window south orientated. The ED window was manually switched from clear to milky state and vice versa. During the experimental tests the indoor air temperature was monitored, but not controlled, in order to estimate the influence of solar gains upon varying the state of the ED window. Taking into account that only one test-room was available, a first comparison between the boundary conditions during the days with the ED window in clear state and those with the ED window in milky state was carried out. This comparison is mandatory, in order to verify that the experimental tests for both states were conducted in the same outdoor condition. This comparison was performed in terms of percentage difference of external air temperature ( $\Delta T_{\text{amb}}$ ), percentage difference of global solar radiation on the horizontal ( $\Delta I$ ) and wind velocity. The comparative test was considered acceptable in the cases of the difference in the outdoor environmental variables never exceeded 5%. Figure 2a reports the values of  $\Delta T_{\text{amb}}$  and  $\Delta I$  as a function of the hour of the day for July 8<sup>th</sup> (clear ED window) versus July 12<sup>th</sup> (milky ED window). No significant differences in terms of wind velocity were observed for this two days. This figure highlights how the values of both  $\Delta T_{\text{amb}}$  and  $\Delta I_{\text{mean}}$  never exceeded

5%; in particular,  $\Delta T_{\text{amb}}$  ranges between -1.77% and 4.58%, while the values of  $\Delta I$  range from a minimum of 0.46% up to a maximum of 4.41%. This means that the same outdoor conditions for both July 8<sup>th</sup> and July 12<sup>th</sup> can be assumed. With respect to these two days, the measured values of the internal surface temperature of the glazing ( $T_{\text{int}}$ ) and the measured values of the indoor air temperature ( $T_{\text{indoor}}$ ) are reported in Figure 2b. In particular, Figure 2b shows, on left axis, the difference between the internal surface temperature of the glazing with the ED transparent window ( $T_{\text{int,clear}}$ ) and the internal surface temperature of the glazing with the ED opaque window ( $T_{\text{int,milky}}$ ) and, on right axis, the difference between the measured values of the indoor air temperature with the ED transparent window ( $T_{\text{indoor,clear}}$ ) and the measured values of the indoor air temperature with the ED opaque window ( $T_{\text{indoor,milky}}$ ), both as a function of the time. This figure highlights how the differences are always positive: this means that (i) the values of the internal surface temperature of the glazing associated to the clear window are greater than those of the milky window and (ii) using the ED window in the clear state, the indoor air temperature is greater than that one of the ED window in the milky state. In particular it can be noticed how using the ED window in the milky state during the summer the indoor air temperature can be reduced by a value between 0.65°C and 1.10°C.

Figure 2. a) Values of  $\Delta T_{\text{amb}}$  and  $\Delta I$ , b) differences between  $T_{\text{int,clear}}$  and  $T_{\text{int,milky}}$  as well as between  $T_{\text{indoor,clear}}$  and  $T_{\text{indoor,milky}}$  as a function of the time.

### Numerical results

The simulation results were compared to the experimental data in order to assess the model reliability. The comparison was performed in terms of internal surface temperature of the glazing as well as indoor air temperature for both July 8<sup>th</sup> (ED window in clear state) as well as July 12<sup>th</sup> (ED window in milky state). In order to verify the accuracy of the modelled ED window, the following percentage differences were calculated:

$$\Delta T_{\text{int}} = \frac{T_{\text{int,exp}} - T_{\text{int,sim}}}{T_{\text{int,exp}}} \quad (1)$$

$$\Delta T_{\text{indoor}} = \frac{T_{\text{indoor,exp}} - T_{\text{indoor,sim}}}{T_{\text{indoor,exp}}} \quad (2)$$

where  $T_{\text{int,exp}}$  and  $T_{\text{int,sim}}$  are the experimental and simulated internal surface temperature of the glazing, respectively;  $T_{\text{indoor,exp}}$  and  $T_{\text{indoor,sim}}$  are the experimental and simulated indoor air temperature of the test-room, respectively.

Figures 3a and 3b compare the simulation results with the experimental data in terms of  $T_{int}$  and  $T_{indoor}$  as a function of the time for the clear state (July 8<sup>th</sup>). These figures highlight how the modelled clear ED window predicts quite well the measured values. In particular, the values of  $\Delta T_{int}$  range from -1.13% to 4.14%, while the values  $\Delta T_{indoor}$  during July 8<sup>th</sup> range from -3.67% to 0.82%. Figures 4a and 4b compare the simulation results with the experimental data in terms of  $T_{int}$  and  $T_{indoor}$  as a function of the time for the milky state (July 12<sup>th</sup>). These figures highlight a good model reliability. In particular, the values of  $\Delta T_{int}$  range from -1.79% to 2.19%, while the values of  $\Delta T_{indoor}$  range between -4.14% and 1.08%.

Figure 3. Comparison between simulation results and experimental data in terms of: a) internal surface temperature of the glazing, b) indoor air temperature.

Figure 4. Comparison between simulation results and experimental data in terms of: a) internal surface temperature of the glazing, b) indoor air temperature.

Finally, the two simulation models of ED window were used to quantify the cooling energy demand reduction associated to a typical office building located in Naples (latitude = 40°51'46"80 N; longitude = 14°16'36"12 E) by replacing the conventional double-glazing windows with the same thermal transmittance. In particular, an office building with 200 m<sup>2</sup> as floor area and 600 m<sup>3</sup> as volume with a total window area ( $A_{w,total}$ ) of 36.02 m<sup>2</sup> ( $A_{w,South}$ =27.02 m<sup>2</sup>,  $A_{w,East}$ = 4.5 m<sup>2</sup>,  $A_{w,West}$ = 4.5 m<sup>2</sup>) was modelled in TRNSYS 17 by means of the Type 56. Thermal transmittance of the building envelope has been equated to the threshold values specified by the Italian Law (Italian Decree 2015). A preliminary ON/OFF control logic for the ED window was used; in particular two hours before and two hours after the maximum

global solar radiation on the horizontal (from 10:00 up to 14:00) the ED window was switched in milky state, while it was switched in clear state in the rest part of the day. The cooling plant was considered ON from 8:00–18:00 in weekdays with an indoor target temperature equal to 26°C. Performing a simulation during the summer time (from June 1<sup>st</sup> to August 31<sup>st</sup>) with a simulation time step equal to 1 minute, a cooling energy demand reduction of about 26% was achieved.

## CONCLUSIONS

In this paper the results of experimental tests and computer simulation modelling aimed at evaluating the thermal performance of a full-scale ED window with respect to solar control in buildings were reported. The experimental analysis showed how switching the ED window to the milky state can reduce the indoor air temperature of about 1°C. The ED window was modelled by means of the software WINDOW 7.5 and the comparison between numerical and experimental data showed a good reliability of the developed ED model.

Finally, a cooling energy demand reduction deriving from the integration of ED windows in a typical office façade located in Naples of about 26% was assessed by means of the software TRNSYS 17. In future works, the modelled ED smart window will be used to study and predict the performance of these windows under different operating scenarios.

## **A Novel Approach to Near-Real Time Monitoring of Ventilation Rate and Indoor Air Quality in Residential Houses**

Achalu Tirfe<sup>\*1</sup>, and Jianshun Zhang<sup>1</sup>

<sup>1</sup>Syracuse University, Syracuse, USA

*\*Corresponding email: Achalu.Tirfe@gmail.com*

### **ABSTRACT**

Physics-based infiltration models, like Lawrence Berkeley Laboratory (LBL) and Alberta Infiltration Model (AIM-2), have been used to predict infiltration rate in near-real time. These models are derived from the driving forces of wind and temperature difference across the building enclosure system, both of which cause pressure differences across the enclosure system for infiltration. The model incorporates other major factors like building leakage characteristics, distributions of openings, microenvironment conditions around the building enclosure as affected by building shields, topography and building shape. The accuracy of the models depends on getting these factors right. However, these factors are specific for individual buildings and measuring these factors in occupied buildings is difficult. In theory, these can be determined by using generalized table and blower door test but it requires heavy equipment and skilled work force, which is difficult to implement in occupied houses.

In this paper, a methodology is developed to determine the air change rate (ACH) and Indoor air quality (IAQ) in near-real time by combining a physics-based infiltration model with a tracer gas decay test method. The methodology is applicable to naturally ventilated houses. Existing infiltration models are modified explicitly to include the impact of the wind direction. The input data for the models also include indoor air temperature and weather data. Tracer gas method is used to determine the infiltration model parameters using multi variable nonlinear regression. Once these parameters are obtained, it is able to predict the ACH with 10% and 16% error for AIM-2 and LBL models, respectively

### **KEYWORDS**

Infiltration, ACH, AIM2 model, LBL Model, Tracer Gas method

### **INTRODUCTION**

For many residential houses in the U.S, infiltration is the main source of ventilation. Airtight buildings raise concern in indoor air quality (IAQ) unless mechanical ventilation is used (Skon et al., 2011). It requires measuring or predicting the ACH in better accuracy. The two standard methods to measure ACH are the building pressurization method and tracer gas method (ASTM E779-10, 2010; ASTM E741-11, 2011). Building pressurization method uses to compare infiltration between buildings and to measure building leakage characteristic. However, it is not applicable to near-real time infiltration measurement. Tracer gas method is the most accurate infiltration measurement near-real time. The choices of the tracer gas are limited. The presence of the occupant in test site could affect the measurement for tracer gas like carbon dioxide. Therefore, tracer gas methods are also not applicable at occupant presence.

Infiltration models are an alternative way to determine the infiltration rate in the building. The most common infiltration models are Reduction Pressurization Test, Regression Technique, ASHRAE Model, Building Research Establishment (BRE) model, Lawrence Berkley

Laboratory (LBL) model, and Alberta Infiltration model (AIM-2) (Awbi, 2003). All the infiltration models required blower door test to determine building leakage characteristics. Physics based models, LBL and AIM-2, gives a better prediction than the other models. These models derives base on the infiltration driving forces: wind and stack effect induced pressure differences across the building enclosure. They also include all of the important parameters like neutral pressure level, wind shield effect and building leakage characteristics. The accuracy of these models heavily depends on quantifying these factors. However, these factors are specific to individual buildings.

The objective of this paper is to combine the infiltration model, LBL or AIM-2, with tracer gas decay method to predict the ACH in near-real time for occupied naturally ventilated houses with a better accuracy.

## METHODS

A methodology is developed to combine infiltration model (AIM-2 or LBL) with tracer gas method. As it is shown in Figure 1 below, the methodology has two parts: building calibration and monitoring. Steps only needed for building calibration are indicated by dotted line.

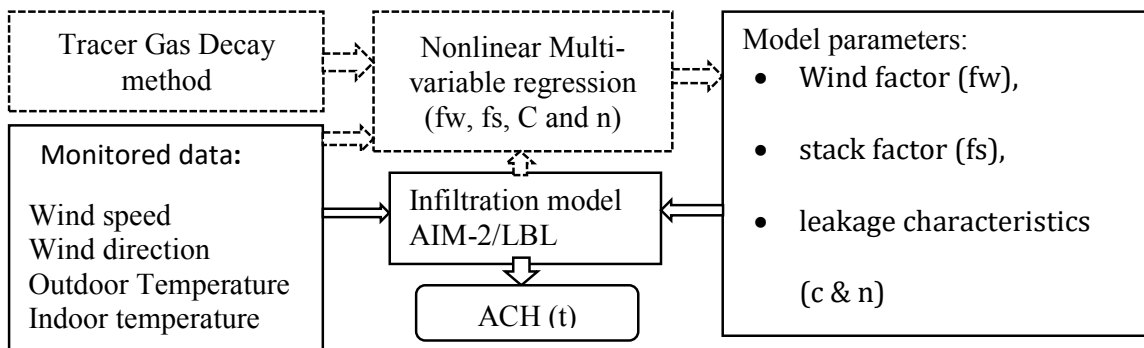

Figure 1. Methodology to determine ACH near-real time using tracer gas and weather data in the infiltration model

To determine the infiltration model parameter, preparing the house for a tracer gas decay test is the starting point. The calibration should be done in the absence of occupants. All door and windows should be closed. The indoor air temperature is set to 75°F and measured every minute. The weather data (temperature, wind speed and wind direction) for every minute is obtained from the nearby weather station. For this study, the National Oceanic and Atmospheric Administration (NOAA) weather data collected at Syracuse airport was used. A well mix condition is created inside the house by running the circulation fan continuously. The next step is to apply tracer gas method to determine the infiltration rate. The detail of the tracer gas technique was described in detail in (Sherman, M.H. 1990). CO<sub>2</sub> is injected until it reaches 1200 ppm. Occupant generated CO<sub>2</sub> can be used as the tracer gas for easier implementation of the method. This tracer gas concentration limit is set based on CO<sub>2</sub> sensor capacity. It can be injected in the return duct or after the circulation fan. The CO<sub>2</sub> concentration is measured in every minute. For leaky house the infiltration rate is higher. The tracer gas decays faster and reaches the outdoor CO<sub>2</sub> concentration before collecting enough data to do the regression. For this kind of situation, the tracer gas is injected again when the room CO<sub>2</sub> level reaches 600 ppm. The data collected from the BEST laboratory indicates that the outdoor CO<sub>2</sub> concentration is between 360 to 380 ppm. It is important to note that the presence of CO<sub>2</sub> in

the background would affect the ACH measurement. From the CO<sub>2</sub> concentration data, ACH is determined for every minute.

Once the weather data, the infiltration rate and the room temperature are known for every minute, nonlinear multi-variable regression technique is used to determine the infiltration model parameters. The regression variables, which are also the infiltration model parameters, are building leakage characteristics, building leakage exponent, wind factor and stack factor. To get valid results from the regression test, it is important to use the following the reasonable constraints:

1. Building exponent is between 0.5 and 1.
2. The building leakage coefficient is always greater than 0.
3. The combined shield and wind factor is between 0 and 1.
4. The stack factor is between 0 and 1.

Once the infiltration model parameters are determined from the regression, the infiltration of the house is calculated more accurately from the monitored wind speed, wind direction, the indoor temperature and the outdoor temperature.

### Modified Infiltration Models

AIM-2 and LBL models are discussed in detail in (Walker and Wilson 1990) and (Sherman and Grimsrud, 1980) respectively.

In this paper, a discrete function is used to determine the wind factor and to capture the effect of the terrain and building microclimate as a function of wind direction. The wind factor function is given as:

$$f_w = \begin{cases} f1 & \text{where } 0 \leq \phi < 30 \\ f2 & \text{where } 30 \leq \phi < 60 \\ f3 & \text{where } 60 \leq \phi < 90 \\ \vdots & \\ \vdots & \\ f_{12} & \text{where } 330 \leq \phi < 360 \end{cases} \quad (1)$$

where  $f_w$  is the wind factor and  $\phi$  is the wind direction. Wind angles 0, 90, 180 and 270 indicate wind blows from north, east, south and west respectively.

### Error calculation

The absolute percentage error was used to compare the AIM2-Regression and LBL-Regression results. The error is calculated using the following equation:

$$|Error\%| = \frac{|(ACH_{measured} - ACH_{predicted})|}{ACH_{measured}} * 100 \quad (2)$$

where  $|Error\%|$  is the percentage error,  $ACH_{measured}$  is the air change rate measured using tracer gas method, and  $ACH_{predicted}$  is the air change rate calculated using AIM-2 or LBL model.

### Test House and location

The experiment was performed in Building Enclosure System Technology (BEST) laboratory located at Sky top Rd, Syracuse NY. The BEST laboratory is a two story building constructed in 2009 with the collaboration of Oakridge National Lab, Air Barrier Association of America, NYSERDA, and Syracuse University. The building has 41ft length, 33ft width and 21ft height. It has no internal partitions. The first story and the second story of the building are connected with a stairway opening. The building has central air system to cool and heat the house. The circulation system fan can set to run continuously. The building is also equipped with blower door test equipment. INNOVA gas monitoring system is used for tracer gas methods. The building east side is shielded by trees. An office building is located in the west side the test house. The south side has no shield. There is a hill on the south west side of the BEST laboratory building. The elevation difference is around 120 feet.

Figure 2. BEST lab equipment and arrangement

### RESULTS

A non-linear multi-variable regression was used to determine the model parameters for both AIM2 and LBL models with a ten day data. Figure 3 presents the comparison between the measured and predicted ACH for AIM-2-Regression and LBL-Regression models respectively.

Figure 3. Comparison between measured and predicted ACH results. a) AIM-2 model, b) LBL model

Table 1 indicates the AIM2 regression result has average error of 9.7 % with the standard deviation of 9.2%. On other hand LBL regression result indicates an average error of 15.6% with a standard deviation of 14.1%.

Table 1: Average error in percent for LBL and AIM2 model

	AIM2-Regression	LBL-Regression
<b> Error% </b>	9.7%	15.6%
<b>Standard deviation</b>	9.2%	14.1%

AIM-2 regression model captures the entire measured infiltration spectrum better than LBL-Regression model. LBL-Regression tends to underestimate the infiltration rate due to the wind effect and overestimate infiltration rate cause by stack effect. The main difference between the AIM-2 regression and LBL regression equation that AIM-2 model considers the interaction between the wind effect and the stack effect. It is also important to notice that the wind effect of the AIM-2 model is as a function of wind velocity square.

Table 2: Comparison of AIM-2 regression with AIM 2 model done in other studies

	AIM2-Regression (BEST Lab)	Standard AIM2 model prediction (BEST Lab)			Francisco and Palmiter, 1996		Wang et al., 2009
Leakage Distribution  Error %	Not Applicable 9.7	X=R =0.6 17.3	X=R= 0.5 24	X=R=0 .37 35	X=R 16.2	X=0 & R=0.5 46	X=0 & R=0.5 19
Standard Deviation (%)	9.2	12.7	18.6	22.6			16

Table 2 shows the percentage error of AIM2 model for BEST laboratory and work done in previous studies. We can see that the AIM-2-Regression is the only method able to predict the ACH with an average absolute value error less than 10 %.

## DISCUSSIONS

The AIM-2 Regression and LBL Regression model wind factor was expressed in a discrete function. This capture the impact of the building shape and the building surrounding to improve the accuracy of the model. The model parameters are unique for each building and its surrounding. The nonlinear multivariable regression for each building give a better result.

The author likes to mention the following two assumptions were validated. First a wel-mix condition was maintained when the circulation fan was running continuously. Second, Decay tracer gas method can be used to estimate near-real time ACH, if the decay process is capture in a minute interval and the CO<sub>2</sub> level is high enough from the background level. The minimum CO<sub>2</sub> level for decay test was set to 600 while the background level was around 360ppm.

## CONCLUSIONS

The findings are summarized as followed:

- Weather data, IAQ monitoring and decay method can be used to predict the building leakage characterizes wind factor and stack factor.
- AIM2-Regression method predicts ACH better than LBL-Regression
- The accuracy of the new methodology is depending on the number of records obtained for regression.
- AIM-2-Regression predicts the ACH with an average absolute value error less than 10 %.

### **ABSTRACT**

To achieve stringent energy objectives, new dwellings are subject to energy conservation measures including low air permeability and high levels of insulation. Mechanical Ventilation with Heat Recovery (MVHR) can be used to control the balance between energy efficiency and Indoor Air Quality (IAQ) in these buildings. This paper evaluates the effectiveness of the design and operational strategies adopted in a new development comprising two apartment blocks in East London. The findings point to significant gaps in operational energy use compared against design projections, and high concentrations in benzene and formaldehyde three years after construction. It is suggested that a combination of internal source control measures at design stage and building fine-tuning in early stages of post-occupancy is necessary to close the performance gap in energy and IAQ.

### **KEYWORDS**

Low-energy dwellings, IAQ, MVHR, Performance gap

### **INTRODUCTION**

In pursuing energy objectives such as the nearly zero-energy target in Europe, the existing standards for building air tightness and fabric heat loss are reaching their technical and economic limits. There is thus a risk that the focus may be shifting to save energy by reducing ventilation demand with potential adverse impacts on health and wellbeing. Annex 68 of the Energy in Buildings and Communities Programme of the International Energy Agency (IEA EBC Annex 68) aims to address this issue by finding design solutions and operational strategies that help achieve low energy and good IAQ in new dwellings. A review of empirical evidence carried out as part of the on-going activities in IEA EBC Annex 68 found that concentrations of pollutants such as toluene, ethylbenzene, trichloroethylene and styrene in new low energy dwellings were up to 10 times higher than in old dwellings (Salis, et al., 2017). Another driver for a focus on IAQ is heavy traffic and high outdoor pollution (e.g. micro particles and NO<sub>2</sub>) in cities such as London and Beijing (Walton, et al., 2015).

The work presented in this paper is part of a wider research programme entitled ‘Total Operational Performance of Low Carbon Buildings in China and the UK (TOP)’, which covers the energy and environmental performance of a large cross section of non-domestic buildings and apartment blocks. The aim of this paper is to evaluate the Energy and IAQ performance of a new residential development. The specific objectives are to: 1) compare operational energy against design projections, 2) monitor the concentration level of major outdoor and indoor driven air-borne pollutants, and 3) identify the improvement opportunities to close the performance gaps in energy and IAQ in the context of the case study, and more generally suggest improvements for future projects.

## OVERVIEW OF THE CASE STUDY

To investigate IAQ in low energy residential buildings, two recently built apartment blocks constructed as part of a regeneration scheme in East London were selected as a case study.

Apartment blocks A and B were completed in December 2014 and January 2015 respectively. Block A is a 13-storey building; Block B has 9 floors. They are located next to each other and close to two main roads in the London Borough of Tower Hamlets in East London. There are 97 flats and maisonettes (two-storey apartments) in these blocks. Building fabric U values are around 40% better than the limits prescribed by the 2013 edition of the Building Regulations. The buildings were also designed with target air permeability of 2-3 m<sup>3</sup>/hr./m<sup>2</sup> at 50 Pa pressure difference which is significantly lower than 10 m<sup>3</sup>/hr./m<sup>2</sup> limit set out in the Building Regulations (HM Government, 2013). Consequently, mechanical ventilation with heat recovery (MVHR) was specified to ensure adequate background ventilation is provided to these apartments. Heating is provided by a community heating scheme that is currently gas fired with provisions for integration of a combined heat and power (CHP) plant in future. There is no mechanical cooling. Table 1 provides background information about the sample apartments included in this study. The air permeabilities reported are based on pressure test results carried out on these apartments after building completion.

Table 1. Background information about sample apartments

Dwelling	Type	Gross Floor Area (m <sup>2</sup> )	Floor level	Orientation	Bedroom no.	Occupant no. (steady mode)	Air tightness (m <sup>3</sup> /hr./m <sup>2</sup> @ 50 Pa)
Apt. 1	Flat	100	Block A, 7 <sup>th</sup> floor	South/West	3	3	3.3
Apt. 2	Flat	100	Block A, 8 <sup>th</sup> floor	South/West	3	5	2.2
Apt. 3	Flat	100	Block A, 9 <sup>th</sup> floor	North/West	3	5	2.0
Apt. 4	Maisonette	127	Block B, Ground floor	South/East	5	7	3.8
Apt. 5	Maisonette	106	Block B, 8 <sup>th</sup> floor	East	3	4	2.9

## METHOD

The following activities were planned with relevant methods adopted:

- 1) **Energy monitoring:** A review of the annual energy performance of the apartments that were fully occupied during the monitoring period and had reliable energy data was carried out. Heating demands of these apartments were compared against the projections made in the respective Energy Performance Certificates produced after completion in accordance with the Standard Assessment Procedure (BRE, 2012). Available data for the community heating scheme serving the blocks were sourced from its Energy Service Company (ESCO) to evaluate the supply side. Electricity use of five sample apartments sourced from the electrical meters were also compared against the benchmarks.
- 2) **Active monitoring of IAQ:** Five sample apartments were selected for detailed analysis of IAQ to meet the minimum sampling requirement of 5% of zones in large buildings in BS EN 15251 (BSI, 2007). IAQ sensors were installed to measure the concentration levels of CO<sub>2</sub>, PM<sub>2.5</sub> and NO<sub>2</sub> in living rooms and kitchens of the apartments during typical weeks

in the heating season (February-March 2018) with 5-minute frequency.<sup>1</sup> CO<sub>2</sub> levels were also monitored in one bedroom. CO<sub>2</sub> concentrations are often used as a proxy for IAQ in the UK construction sector. PM<sub>2.5</sub> and NO<sub>2</sub> were identified as pollutants with risk of high concentration in new low energy buildings in the IEA EBC Annex 68 programme with significant health impacts, and are also of great interest in London due to major outdoor sources for these pollutants. Concentrations of these pollutants were compared against the recommended limits provided in BS EN 15251 and WHO guidelines (WHO, 2006).

- 3) **Passive Sampling for IAQ:** the diffusive sampling method, in accordance with ISO 16017, was used to measure the average concentrations of volatile organic compounds (VOCs) with risk of concentrations higher than long-term/chronic exposure limit values (ELVs) in new low energy dwellings (Salis, et al., 2017). Concentration levels of benzene, formaldehyde, trichloroethylene, styrene, naphthalene, toluene, and tetrachloroethylene were measured in living room, kitchen and one bedroom of the sample apartments during the same weeks active monitoring took place. Passive tubes and absorbent pads were also installed outdoors to identify the indoor/outdoor trends and sources.

Finally, to give context to IAQ monitoring results, a perfluorocarbon tracer (PFT) gas method (Persily, 2016) was used to infer the average air exchange rates in the monitored zones of the sample apartment.

## RESULTS

**Energy:** Figure 1 compares the actual heating demand of 40 apartments in the case study against the design projections. Actual heating demand in 30 apartments is higher than expected and in the worst case is around three times more than the design performance. Figure 1 also shows a snapshot of a thermographic survey of the case study which did not reveal any significant defects or thermal bridges within the external envelope. These observations, combined with the variation in heating demand across different apartments, suggests the overall increase in heating demand is predominantly driven by occupant behaviour (e.g. heating set points and heating schedules), and is reminiscent of the rebound effect seen in new dwellings built to meet energy efficiency requirements (Kelly, 2011).

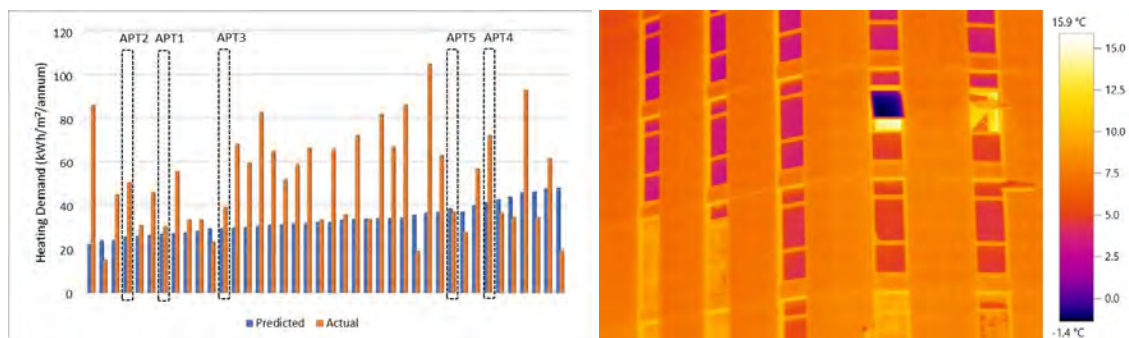

Figure 1. Actual vs. design heating demand, and external envelope thermographic survey

The annual gas use data and the data for delivered heat to the apartments released by the ESCO running the community heating scheme show an average annual heating efficiency of 50%, significantly lower than the design specification of 87%. This exacerbates the performance gap between actual operation and design intent.

<sup>1</sup> Measurement accuracies: CO<sub>2</sub>:  $\pm 50$  ppm, PM<sub>2.5</sub>: 0.84 coincidence probability at 10<sup>6</sup> particles/L; 0.24 coincidence probability at 500 particles/L, NO<sub>2</sub>:  $< \pm 0.5$  ppm

Annual electricity use of all sample dwelling is higher than design intent with a maximum 53% deviation in Apartment 3.

**Active monitoring of IAQ:** Figure 2 shows the boxplots for indoor concentration levels of CO<sub>2</sub>, and indoor and outdoor concentrations of PM<sub>2.5</sub>, and NO<sub>2</sub>.<sup>2</sup>

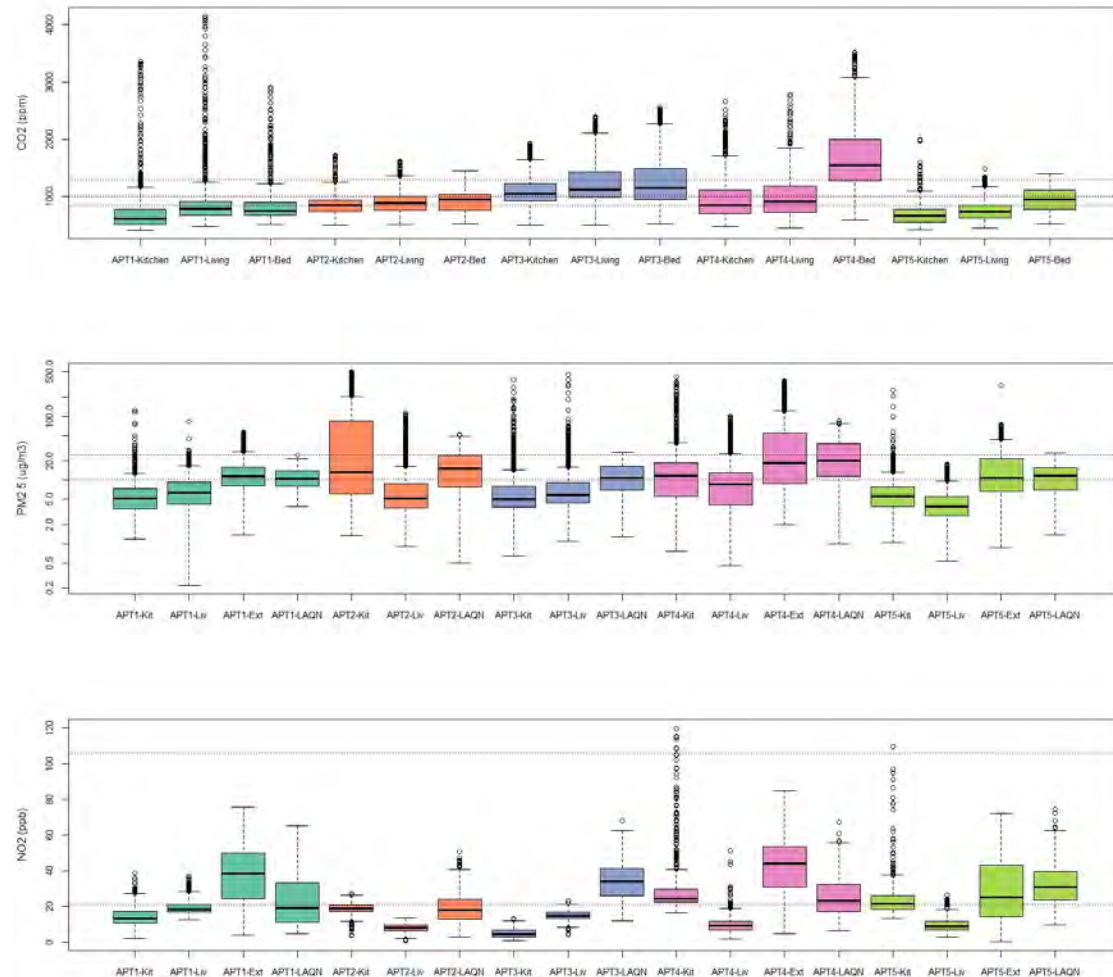

Figure 2. Concentrations of CO<sub>2</sub>, PM<sub>2.5</sub>, and NO<sub>2</sub> during typical weeks in heating season

The dotted horizontal lines on the CO<sub>2</sub> graph represent 350, 500, and 800 ppm above external CO<sub>2</sub> concentrations in keeping with the classification provided in BS EN 15251. Apartments 3 and 4 show CO<sub>2</sub> concentration levels above the other apartments and the most lenient guideline limit, which could be indicative of inadequate ventilation. The guideline limits for PM<sub>2.5</sub> are the WHO annual and daily means of 10 µg/m³ and 25 µg/m³ respectively. It is notable that the outdoor PM<sub>2.5</sub> levels are often higher than WHO guideline for annual mean. However, indoor concentrations in most spaces are kept below the guideline limit most of the time, which could be indicative of the effectiveness of the air filtration installed in the MVHR system. Whilst outdoor levels are again often higher than the WHO annual mean (40 µg/m³, 21 ppb), indoor NO<sub>2</sub> levels are generally lower than this limit, except in the kitchens of Apartments 4 and 5. Indoor NO<sub>2</sub> levels are generally well below the WHO hourly guideline

<sup>2</sup> Ext: external air quality kit installed onsite, LAQN: closest weather station to the site

limit of 200  $\mu\text{g}/\text{m}^3$  (105 ppb). In addition to the effect of outdoor sources,  $\text{PM}_{2.5}$  and  $\text{NO}_2$  levels in apartments could be increased by internal sources especially in the kitchens.

**Passive Sampling for IAQ:** Table 2 reports the results of passive sampling for Apartments 3 and 4. These apartments were selected for reporting in this paper as the active monitoring results pointed to potential ventilation issues in these apartments. Furthermore, this selection allows a cross comparison of the dispersion of pollutants in the lowest (ground floor) and highest (9<sup>th</sup> floor) height in the sample and between different building orientations.

Table 2. Passive sampling results for Apartments 3 and 4 (typical weeks in heating season)

VOC concentration ( $\mu\text{g}/\text{m}^3$ ) & Air Change rates per Hour for each zone	APT. 3 (Block A, 9th Floor)			APT. 4 (Block B, Ground Floor)			IEA EBC Annex 68 Long Term ELV
	Living room	Kitchen	Sample bedroom	Living room	Kitchen	Sample bedroom	
<b>Benzene</b>	<b>1.3</b>	<b>1.0</b>	<b>1.2</b>	<b>1.5</b>	<b>2.1</b>	<b>1.6</b>	0.2
<b>Formaldehyde</b>	<b>29.25</b>	<b>26.87</b>	<b>29.53</b>	<b>21.23</b>	<b>31.35</b>	<b>27.44</b>	9
Trichloroethylene	<0.5	<0.5	<0.5	<0.5	<0.5	<0.5	2
Styrene	1.5	2.2	3.0	0.8	0.7	1.7	30
<b>Naphthalene</b>	<b>5.4</b>	<b>5.4</b>	<b>5.0</b>	0.9	0.9	1.3	2
Toluene	2.7	2.9	3.1	2.2	2.6	2.4	250
Tetrachloroethylene	0.6	<0.6	<0.6	1.5	1.2	1.8	100
ACH (PFT measurements)	0.50	0.52	0.76	1.02	1.14	0.6	n/a

The VOCs with concentration levels higher than the recommended long-term ELVs are highlighted in bold. While high concentrations of Naphthalene could be a specific problem in Apartment 3 related to occupant behaviour (e.g. smoking or use of chemical insecticides/pest control), concentrations of Benzene and Formaldehyde in both apartments are significantly higher than the respective ELVs. Measurement of outdoor concentrations confirm benzene is driven by outdoor sources, whereas formaldehyde levels are driven by internal sources.

## DISCUSSION

The outcomes of this study point to the challenge of achieving a ‘low energy’ building in practice. People’s expectation of comfort in new dwellings may be different than their previous older accommodation. This case study represented a social housing scheme. An appropriate system of incentives and effective behavioural strategies may be developed in parallel with design processes and implemented post-occupancy to address potential rebound effects. From a supply point of view, the existing operational efficiency of the community heating scheme is a key driver of the performance gap. This is however not a unique case. Detailed studies of community heating schemes have found operational efficiencies as low as 37% (Wingfield, et al., 2013). The existing plant room in the case study is currently not running at full capacity, as the second phase of the development has not yet been completed and part load performance compromises efficiency. Distribution losses are also a major issue and significantly higher than the default factor of 5% assumed for new developments in the Standard Assessment Procedure (BRE, 2012). Better understanding of inefficiencies in energy generation and distribution can help narrow the energy performance gap. If the operational issues are addressed, a community heating scheme provides ample opportunities for further improvements including decarbonisation by integrating CHP plant with other technologies. Air filtration in the installed MVHR units appear to be effective. The ventilation rates inferred from PFT measurements are also generally consistent with the minimum ventilation

requirements set out in the UK Building Regulations (HM Government, 2010), although the MVHR system is only partially responsible for air exchange, and other factors such as natural ventilation (via window opening) are also effective. Enhanced ventilation beyond the regulatory requirements by adjusting the fan speed in the MVHR to its boost or maximum flow rate can help reduce formaldehyde levels, although this can also increase the concentrations of outdoor driven pollutants such as benzene as well as energy use. A trade-off based on an assessment of health impact of these pollutants may inform the ventilation strategy. However, a more fundamental solution in future projects is to improve source control of materials used in the building and furniture to keep formaldehyde levels below the limits. The fact that after three years of building handover formaldehyde levels are higher than three times the chronic ELV points to significant IAQ issues and potential health impacts. This problem can be addressed by a combination of source control and enhanced/boost ventilation in the early stages of post-occupancy with seasonal commissioning to reduce fan speed after the off-gassing period and when measurements confirm concentrations of formaldehyde and other critical pollutants are acceptable.

## CONCLUSIONS

This study uncovered significant gaps in energy performance and concentration levels of benzene and formaldehyde in dwellings more than 3 years after construction. The gap between actual building performance and design intents is currently not adequately addressed in energy efficiency policies. The intricate relation between energy efficiency requirements and IAQ may also lead to unintended consequences for IAQ where sources of pollution are not effectively controlled and ventilation is not adequate. Building performance evaluation and fine-tuning in the early stages of post-occupancy should be an integral part of building procurement process to ensure low energy and good levels of IAQ are delivered in practice.

## ACKNOWLEDGEMENT

The authors wish to thank building occupants for their support and participation in research. This research was funded by the EPSRC ('TOP' project, Grant Code: EP/N009703/1).

## Effects of Semi-Open Space on Micro-Environmental Control

Meng Kong<sup>1,\*</sup> and Jianshun Zhang<sup>1</sup>

<sup>1</sup>Department of Mechanical and Aerospace Engineering, Syracuse University, NY, USA

### ABSTRACT

Semi-open space (SOS) is defined as a space semi-confined by partitions in an open space environment. Most of the previous indoor environmental researches were focused on the open space environment, while only a few of them looked into the performance of the SOS. The existence of the SOS is for providing a certain level of privacy to the occupant, but it has been reported that it significantly affects the room air distribution, hence the thermal environment and indoor air quality. The micro-environment control system is defined as a system which provides heating, cooling or ventilation to the occupant locally. In this study, we evaluated the performance of a cubicle, as an SOS in the office, with different configurations, including opening size and orientation, and the combination of the micro-environmental control system and SOS in providing improved indoor air quality. The work included the computational fluid dynamics (CFD) simulation representing a typical office space with one cubicle. The results showed that the cubicle “protects” the occupants from background air flow but this protection may not always be favored, and the location of the pollutant source significantly influenced the performance of the cubicle. The combination of the micro-environmental control system helped create an independent micro-environment as well as offset the effect of the cubicle.

### KEYWORDS

Semi-open space, micro-environmental control system, air quality, computational fluid dynamics, cubicle.

### INTRODUCTION

Semi-open Space (SOS) is defined as a subspace created by semi-enclosed partitions in a larger open space. A semi-open space, on the one hand, is a partially open space with connections between one SOS and the others as well as the outside space. On the other hand, SOS also provides a relatively independent space. So far most of the ventilation studies are focused on the air distribution in open spaces.

Only a few studies have been conducted to investigate the performance of SOS (Zhang et al. 2007; Demetriou et al. 2008). Jiang et al. (1997) numerically studied two kinds of office configurations with five ventilation strategies and found that the use of partitions significantly affects the uniformity of the supply air distribution. Bauman (Bauman et al. 1991; Bauman et al. 1992) did a very comprehensive work to look into the influence of a series of partition configurations and environmental parameters in a ceiling-ventilated room regarding the thermal environment and ventilation efficiency. After this study, another work (Shaw et al. 1993; Shaw et al. 1993) investigated the effect of the cubicle partition on the air quality. It was concluded that the existence of a cubicle could cause a dead air space inside the cubicle and, hence, an increase of mean age of air. Nevertheless, due to the non-uniformity of the mixing ventilation, different configurations of the workstation and different air supply conditions, the effects of the partitions cannot be generalized.

The micro-environment control system ( $\mu$ X) or personal environmental control (PEC) system is defined as a system which provides heating, cooling or ventilation to the occupant locally. Integrated with an SOS, the  $\mu$ X has a big potential of saving energy while improving thermal comfort level and air quality around occupants as well as providing sound, light, and spatial privacy. This study is focused on investigating how the Semi-Open Space, equipped with or without a  $\mu$ X, would affect the air quality by using the Computational Fluid Dynamics (CFD) model.

## METHODS

A CFD model based on the guidelines given by Russo's validated CFD case (Russo, 2011) was developed and further validated by the experimental work (Kong et al. 2017). A 1.8 m  $\times$  1.8 m cubicle placed in a typical office space was built in the CFD model (Figure 1). The air quality in all regions in the room was compared for scenarios with and without a cubicle. The effect of the openness of the cubicle was also investigated as well as the opening direction. This work also included the studies on the effects of the cubicle as an SOS in combination with a  $\mu$ X with local air purification.

Figure 1 Computational domain and cubicle opening condition

The room modeled is the same as those used in the previous work (Kong et al. 2017). The cubicle was created symmetrically around the desk and seated occupant. The height of the cubicle partition was 1.8 m. All the four sides of the cubicle could be half or fully opened. The boundary condition of each segment of the manikin was set to be constant heat flux. The heat flux value came from the experimental results. The room wall was set to be the same with the indoor temperature set-point (return air temperature) – 26.1 °C for the cases with the  $\mu$ X (because the  $\mu$ X was designed to provide local cooling for elevated room temperature) and 23.9 °C for the case without the  $\mu$ X. The supply air temperature from the  $\mu$ X was set to be 23.0 °C at a flow rate of 0.014 m<sup>3</sup>/s. Since this work focuses on how the cubicle configuration, as well as the  $\mu$ X, affects the indoor air quality instead of the actual distribution of specific contaminant, a tracer gas (sulfur hexafluoride, SF<sub>6</sub>) was used to represent the pollutant emission. Two emission sources, the wall, and the desk, were simulated in this work (Figure 1). The emission from the wall is used to present the case in which pollutant sources are outside the cubicle and that from the desk to represent the sources inside the cubicle. The  $\mu$ X placed under the table has a supply duct attached to the bottom side of the table and two

suction openings on both sides of the box (Kong et al. 2017). When the  $\mu X$  is on, the air purification starts to work by taking in contaminated air and supplying clean air.

In the current work, the Contaminant Removal Efficiency (also called Ventilation Efficiency,  $\epsilon$ ) and Blocking Coefficient ( $\beta$ ), were used to quantify the performance of the ventilation strategies and SOS. The Contaminant Removal Efficiency or Ventilation Efficiency was calculated using Eqn. 1 where  $C_e$  is the pollutant concentration in the exhaust,  $C_s$  is the pollutant concentration in the supply and  $C_p$  is the pollutant concentration in the breathing zone, which is conventionally defined as the zone within a 0.3 m radius of a worker's nose and mouth (OJIMA 2012). Blocking Coefficient was calculated using Eqn. 2 where  $C_{SOS}$  is represented by the volume averaged SF6 concentration in the cubicle.

$$e = \frac{C_e - C_s}{C_p - C_s} \quad (1)$$

$$\beta = \frac{C_e - C_s}{C_{SOS} - C_s} \quad (2)$$

## RESULTS AND DISCUSSIONS

The partitions around the workstation changes the airflow pattern around it, hence the contaminant distribution. However, the performance of the cubicle is dependent on many factors, including the opening direction and size, the location of the contaminant source, as well as whether the  $\mu X$  is on or off.

### Pollutant mass fraction level in the breathing zone

Pollutant mass fraction in the occupied space is a direct indication of the air quality. Figure 2a shows the mass fraction level of the SF6 when the pollutant was emitted from the desk. When the  $\mu X$  is off, FC gave the highest pollutant mass fraction in the breathing zone, and the pollutant concentration in the breathing zone was reduced with opened cubicles. After turning on the  $\mu X$ , the effect of the local purification was obvious regardless whether there was a cubicle even though the clean air was not supplied to the breathing zone directly. Figure 2b shows the mass fraction level of the SF6 in the breathing zone when the pollutant was emitted from the wall. Different from the cases of desk source, the pollutant mass fraction in the breathing zone was quite close to each other among the cases without local purification. This is because when the emission was from the walls, the distribution of the pollutant was very uniform, and the air was well mixed before it entered the cubicle. When the  $\mu X$  was turned on with local purification, regardless how the cubicle was arranged, the mass fraction was reduced by almost the same amount.

### Contaminant Removal Efficiency

In order to examine the performance of the ventilation system under different configurations of the cubicle, Contaminant Removal Efficiency ( $e$ ) was calculated in the breathing zone (Figure 3). The results show that when the pollutant was emitted from the desk, the air quality in the breathing zone was not better than the well-mixed condition for any of the cases with or without the  $\mu X$ . The worst efficiency was given by the FC case. The use of the  $\mu X$  could improve the efficiency by more than 20 percent when there was a fully closed cubicle or no cubicle at all. When the cubicle was opened partially the advantage of using the  $\mu X$  became unclear and sometimes negative. This means that when the cubicle was partially opened, adding a local purification in the  $\mu X$  is not necessarily better than adding purification process in the background mixing ventilation. When the pollutant was emitted from the wall, as

mentioned before, a well-mixed condition was established in the room including the cubicle, so the  $e$  in the breathing zone of any cases was around 100%. However, different from the case of the desk source, the use of the  $\mu$ X with local purification always brought an improvement of the air quality in the breathing zone.

Figure 2 SF6 mass fraction in the breathing zone (a. desk emission; b. wall emission)

Figure 3 Contaminant Removal Efficiency in the breathing zone

Figure 4a shows the Contaminant Removal Efficiency contours for the cases with desk emission. It was demonstrated that the pollutant distribution in the cubicle was highly non-uniform, especially in the region close to the desk. The dirty air carrying the pollutant from the desk was mixed with the surrounding air in the cubicle and then was pulled out of the cubicle due to the entrainment of the supply jet of the background mixing ventilation. The make-up air entered the cubicle in different ways depending on the opening direction and size and diluted the air in the breathing zone. A local jet of clean air was observed when the  $\mu$ X was turned on. However, since the local supply air was maintained at a lower temperature than the ambient room air, most of the local clean air, instead of entered the breathing zone, was transported downward to the lower region and mixed with the dirty air carrying the pollutant from the bottom side of the desk. This should be the reason why the  $\mu$ X brought little improvement of the contaminant removal efficiency in the breathing zone. Figure 4b shows the Contaminant Removal Efficiency contours for the cases with wall emission. Different from the cases of desk emission, the pollutant distribution of the wall emission cases was much more uniform and well-mixed. When the  $\mu$ X was turned on, a clean jet, as well as a clean region, showed up around the occupant. This clean region effectively reduced pollutant concentration in the breathing zone and increased the contaminant removal efficiency. Comparing these cases with the cases of desk emission, the reason why the  $\mu$ X could improve the air quality more effectively is that in the lower region of the cubicle there was no pollutant

source and therefore the cooler clean air remained clean before it was taken by the thermal plume to the breathing zone.

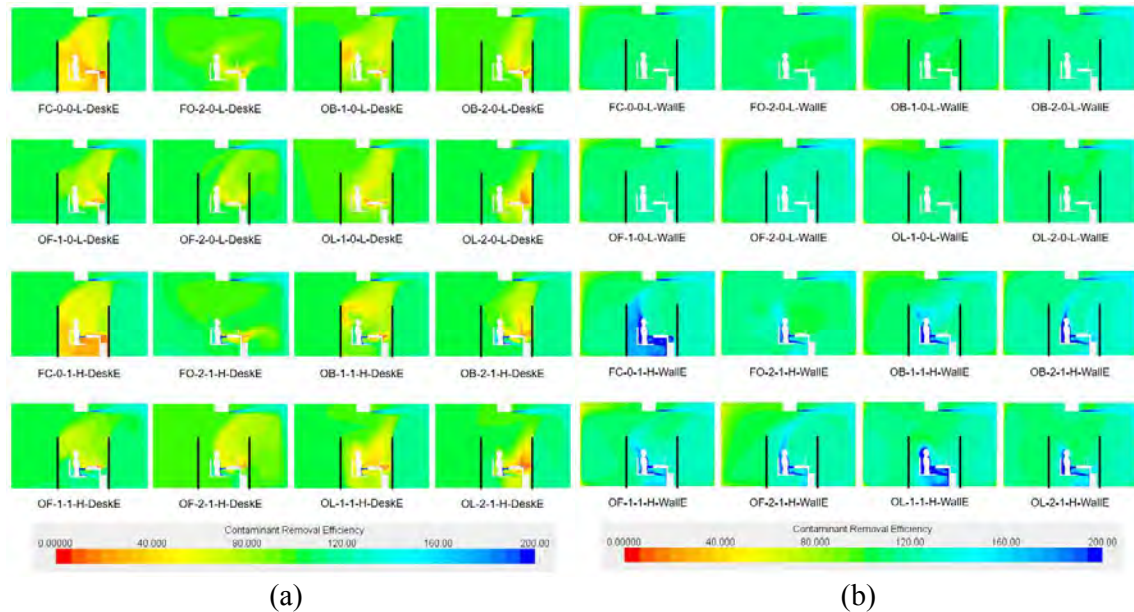

Figure 4 Contaminant Removal Efficiency (a. desk emission; b. wall emission)

### Blocking Coefficient

Blocking Coefficient ( $\beta$ ) is an index to quantify the performance of the SOS. It is a ratio between the exhaust pollutant concentration and the pollutant concentration in the SOS. Figure 5 illustrates the blocking coefficient of the cubicle. When there was no cubicle, the blocking coefficient was around 100% regardless where the emission source was. When the pollutant was emitted from the desk,  $\beta$  was always less than 100%. A fully closed cubicle (FC) gave a blocking coefficient less than 40%, and a partially opened cubicle gave a blocking coefficient between 60% and 80%. In this case, the  $\mu$ X did not make a big difference because it reduced the pollutant level in the cubicle as well as the pollutant level in the exhaust. When the pollutant was emitted from the wall, the  $\beta$  was always higher than 100%. Without the  $\mu$ X,  $\beta$  was a little higher than 100% with a maximum of around 120%. Turning on the  $\mu$ X could significantly improve the blocking coefficient, and the most improvement was given by the fully closed cubicle in which the blocking coefficient was increased by 30%. This is because the fully closed cubicle could hold most of the clean air made by the  $\mu$ X inside the cubicle.

Figure 5 Blocking Coefficient of the cubicle

## CONCLUSIONS

The effects of the cubicle and the combination of the  $\mu$ X with air purification in the cubicle on the air quality were evaluated using CFD simulation. The results indicate that the performance of the cubicle that defines the semi-open space was highly sensitive to the location of the emission location and it should be used and designed with caution. When the pollutant was emitted inside the cubicle, the use of the cubicle was unfavoured since it prevented the contaminant from being diluted by the mixing ventilation. However, when the pollutant was emitted from outside cubicle, the use of it should be encouraged since it helps prevent the contaminant from entering the cubicle. The use of the  $\mu$ X with local air purification could always improve the air quality in the breathing zone, and especially when the emission source was outside the cubicle, it demonstrated a big advantage. However, this combination might not be more efficient than adding the same amount of purified return air to the background mixing ventilation system when the emission source was inside the cubicle. In general, the use of the  $\mu$ X with local air purification is beneficial for improving the air quality in the breathing zone and the cubicle, reducing the pollutant concentrations by 10 to 44%.

### **ABSTRACT**

The need to meet requirements, both in terms of ventilation and thermal comfort in modern buildings, has led to the development of different concepts for ventilation, among which the so-called Diffuse Ceiling Ventilation (DCV). This system makes use of the space between the ceiling slabs and the suspended ceiling as a plenum for fresh air, while the suspended ceiling itself becomes an air diffuser element. If compared to traditional solutions, this allows a higher amount of ventilation air to be injected in the room at lower speed, and a more even distribution of the fresh air within the room. Furthermore, it allows an easy integration with sound-absorbing perforated ceiling panels, since their typical design makes them particularly fit to be used as air diffusers.

This paper builds upon a previous work by the authors where CFD simulations were used to optimise the dimension and the distribution of the perforation pattern in the panels to achieve an even air speed distribution. In this work, the performance of the perforated ceiling is investigated in a more comprehensive way, evaluating the thermal comfort in the room when varying the outdoor temperature. This solution is in fact meant to work in combination with natural or hybrid ventilation strategies, where the fresh air flow is supplied from the façade.

Numerical simulations were performed on a typical office room, considering both the winter and the summer season, for different inlet air temperatures. This solution demonstrated a positive impact on the indoor conditions and on the thermal comfort inside the room in most of the cases but the most extreme ones. The thermal stratification in the room demonstrated to remain within a satisfactory level.

### **INTRODUCTION**

Diffuse Ceiling Ventilation (DCV) is a novel air distribution concept for ventilation in low and plus energy buildings. The volume between the ceiling slabs and the suspended ceiling constitutes a plenum where the ventilation air is injected, and the dropped ceiling acts as an air diffuser. This way a large amount of ventilation air can be provided to the room at lower speed, and with a more even distribution compared to conventional inlet solutions realized through ceiling/wall/duct diffusers. According to previous researches, this concept provides several advantages, such as a low pressure loss, low investment cost and higher thermal comfort if compared to traditional ventilation systems (Zhang et al. 2016).

First proposed in livestock buildings (Van Wagenberg and Smolders 2002), it was presented as a suitable solution to improve the air quality in classrooms by Jacobs et al. (2008). Several scholars investigated the effect of the suspended ceiling characteristics on the ventilation quality (Fan, et al. 2013; Petersen et al. 2014). Zhang et al. (2015) performed hot-box

measurements to evaluate the possibility to couple the DCV with water based thermal elements in the plenum while Hviid and Svendsen (2013) evaluated the performances and excluded DCV as source of possible thermal discomfort by means of experiments in a real size test chamber. The last two works both considered the dropped ceiling as realised with sound-absorbing perforated panel. The presence of these panels is quite common, especially in office buildings, and their constructive characteristics make them particularly fit to act as air diffuser without particular design modification, even if their use as air diffuser could slightly affect the sound absorbing capacity – an aspect not herewith investigated, though.

One of the known limitation of the DCV concerns the possible unevenness in the air distribution in the room. In fact, the injection of air ventilation in the plenum typically takes place through a surface of the plenum or via duct works. This creates an uneven pressure distribution in the plenum, therefore the air exiting the diffuser will present a highly non-uniform velocity profile. A proper design of the suspended ceiling considering the use of different panels perforation size and rate in different zones, could partially solve this issue.

In the last years, CFD as a tool to evaluate the performance of DCV appeared in research works (Mikeska and Fan 2015; Zhang et al. 2017). In those cases, the perforated panels were modeled as porous media, not focusing on the different influence that different perforation patterns can have on the fluid dynamics of the ventilation and the air circulation in the room.

In Figure 1, a comparison between injecting the air directly through the façade ((a) and (b)) or through the dropped ceiling plenum is shown. This first illustration previews how a direct inlet leads to potential discomfort (a) due to low air temperature (below 10 °C in most of the room) and an uneven distribution of the fresh air (b), especially if compared to a solution where the air is (much more evenly) distributed through the plenum of the dropped ceiling (c). The present investigation builds up on a previous work by the authors (Nocente et al. 2018) in which CFD calculations were used to evaluate an optimal panel distribution for a typical office room which ensures a more even velocity distribution out of the perforated ceiling. The previous work focused only on the fluid-mechanical aspects, but neglected the thermal domain of the problem.

The objective of the analysis presented in this paper is instead to take into consideration the thermal environment derived by the direct injection of ventilation air from the façade through the dropped ceiling. For this reason, simulations have been carried out parametrizing the inlet temperature (and the airflow rate) with the aim of assessing the performance of DCV in a more comprehensive way, and evaluating the risk of incurring in thermal discomfort conditions in the room under different outdoor air temperature conditions.

The investigation is however limited by the fact that the entire thermal balance of the room is not considered, i.e. the effect of the ventilation air on the heating and cooling load of the room is not assessed in this work.

## METHODS

### Numerical Model

In a previous work (Nocente et al. 2018) three models (with different perforation size and distribution) of commercially available sound-absorbing panels were taken into account for the suspended ceiling. Two optimal combination were found in that study, and one of those was chosen to realise the numerical analysis presented in this work.

The computational domain, in order to reduce the simulation time, is a room section, which is representative of the entire room geometry. The width is that of one dropped ceiling panel (0.6 m), while all other dimensions are typical of an office room: length 3.6 m and height 3.0 m. The height of the plenum is 0.35 m. The air inlet is the whole surface of the plenum directed towards the façade, while the outlet is placed on the opposite surface and it is modelled as a rectangular opening with dimensions (WxH) 0.6 m x 0.05 m.

The computational mesh is structured hexahedral and counts 22 million cells. The high number of cells was necessary to calculate with sufficient precision the flow conditions past the panel perforation. This also required a high computational effort, which was reduced considering a section of the room, and by setting a non-conformal mesh interface between the suspended ceiling and the room volume. The commercial code Ansys Fluent was used, especially because of the ease of handling of non-conformal interfaces.

### Boundary Conditions

Two typical seasonal conditions were taken into account. In both cases the temperature of the plenum ceiling, room floor, and the vertical wall which contains the ventilation outlet, were set constant at the internal room temperature. The wall below the ceiling inlet was considered part of the façade. Therefore, the wall temperature was calculated considering an ideal thermal transmittance in steady state conditions for the façade equal to  $0.8 \text{ W/m}^2\text{K}$ . Both the side walls ( $3.6 \times 3.0 \text{ m}$ ) are treated as internal air and not as walls.

The calculations were performed in steady state imposing atmospheric pressure at the room outlet and a constant velocity at the plenum inlet. Two conditions were tested, calculated to provide an amount of ventilation air of  $1.2 \text{ m}^3/\text{h}$  and of  $2.7 \text{ m}^3/\text{h}$  per square meter of room floor area. The lowest value is meant to represent a baseline ventilation, while the highest one is representative of a fresh airflow that satisfies the requirements for ventilation in a low-polluting office, reaching an IEQ category III.

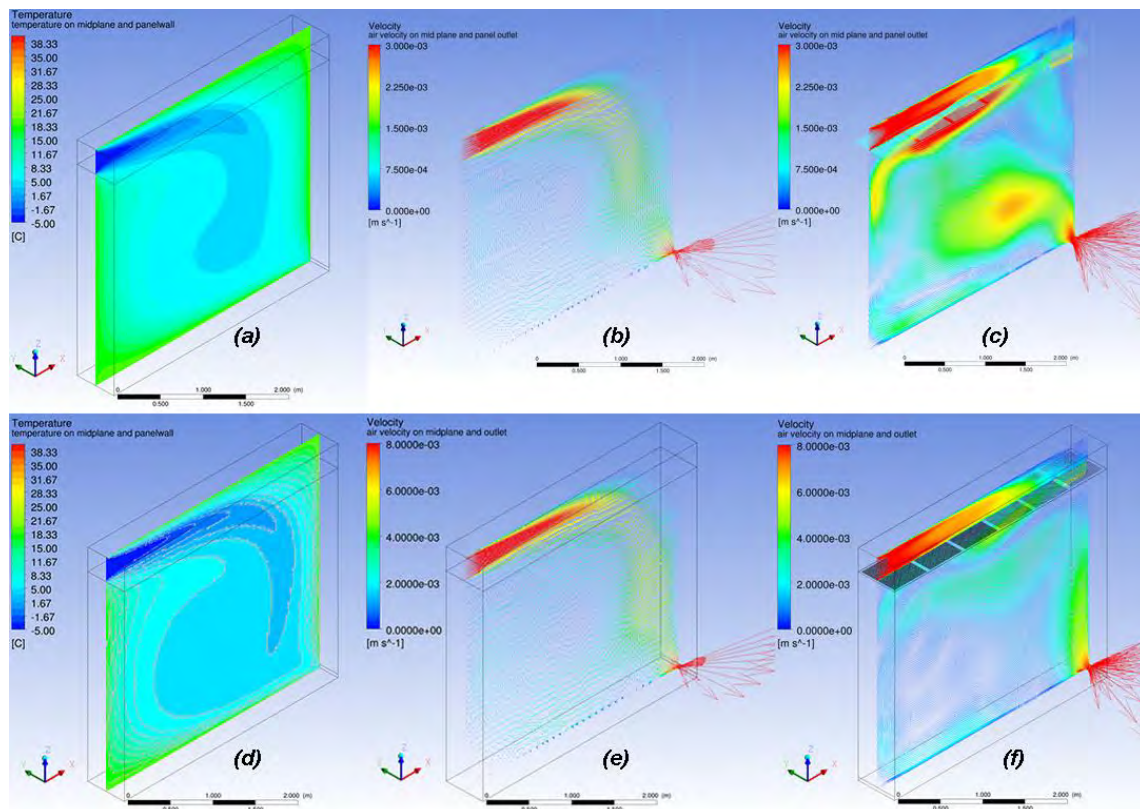

Figure 1. Comparison between inlet design without (a, b and d, e) and with (c, d) a dropped ceiling. (a) temperature profile with inlet temperature equal to  $-5 \text{ }^{\circ}\text{C}$ , airflow:  $1.2 \text{ m}^3/\text{h m}^2$ ; (b) velocity field with airflow:  $1.2 \text{ m}^3/\text{h m}^2$ ; (c) velocity field with airflow:  $1.2 \text{ m}^3/\text{h m}^2$ ; (d) temperature profile with inlet temperature equal to  $-5 \text{ }^{\circ}\text{C}$ , airflow:  $2.7 \text{ m}^3/\text{h m}^2$ ; (e) velocity field with airflow:  $2.7 \text{ m}^3/\text{h m}^2$ ; (f) velocity field with airflow:  $2.7 \text{ m}^3/\text{h m}^2$ .

## RESULTS

### Winter case

For the winter case, the temperature of the room surfaces (with the exception of the façade and of the dropped ceiling) was considered 20 °C. The outdoor air temperature was set as a variable, and a parametric analysis was carried out to assess the impact of this variable on the system's performance. Simulations were repeated for the following values of the outdoor air temperature: -5, 0, 5 and 10 °C. The ventilation air enters the plenum with conditions equal to that of the outdoor air temperature. Figure 2 reports the temperature distribution in the plenum, the room and the ceiling panel surface for the most extreme cases (-5 °C and 0 °C). In the cases where the inlet temperature is greater than case 0 °C, the injection of air at outdoor temperature does not cause a substantial deviation from the comfort temperature except for

the part of volume directly in contact with the ceiling and the façade. Conversely, the internal comfort can be affected in case of an outdoor temperature  $\leq -5$  °C.

### Summer case

In the summer case, the temperature of the room surfaces (with the exception of the façade and of the dropped ceiling) was set at 26 °C. The outdoor air temperature was imposed at 15 °C, 20 °C, 30 °C and 35 °C. The case with outdoor temperature 25°C was not investigated since, as obvious, it does not lead to any significant variation to the internal temperature field being the difference only 1°C.

The case with outdoor air temperature equal to 15°C was instead selected to represent early morning situation with an outdoor air temperature relatively low. The temperature distribution on the mid-plane and the suspended ceiling surface for the summer case is reported in Fig.3, for the most extreme conditions (cold and warm air). Here it is possible to verify that only under the most extreme conditions (inlet air temperature of 35°C, Fig. 3 b)), the indoor air in the room is outside the comfort range.

### DISCUSSION

In both winter and summer situation, the use of a DCV coupled with natural or hybrid ventilation, does not entail particular problems for the thermal comfort, both in terms of temperature and air velocity, with the exception of the most extreme conditions.

Under the most extreme (investigated) winter conditions (namely, case (a)), the indoor air reaches a too low temperature in the volume immediately close to the dropped ceiling – i.e. a volume of air that is not usually occupied by the user. However, even under these conditions, the performance of the system is better than a competing solution where the air intake is performed directly through the façade (see Fig. 1). The temperature of the dropped ceiling surface is also low, and this might negatively affect the indoor environment, even if problems related to radiant asymmetry discomfort are probably avoided due to the very small surface at low temperature. The lack of surface condensation was also verified (with the assumption of a relative humidity of the air immediately closed to the surface of 90%).

Under the most extreme (investigated) summer conditions (namely, case (d)), the indoor air reaches a too high temperature in the entire room volume. However, a similar condition would occur also with direct inlet through the façade without the dropped ceiling plenum.

In both the extreme winter and summer conditions, a strategy to minimize discomfort is by locally treating the ventilation air right before it enters the room. An interesting solution could be the use of the dropped ceiling as the terminal of a water based cooling/heating system. Two simulations to assess the performance under this configurations were performed, imposing a constant heat flux of 10 W/m<sup>2</sup> in winter (Fig. 2 c) and of -10 W/m<sup>2</sup> in summer (Fig. 3 c), to the entire dropped ceiling, thus turning it into an active conditioning surface.

The temperature of the suspended ceiling shows in both cases a non-uniform distribution, and this is due both to the temperature distribution in the plenum and the different air velocity through the perforation. In the winter situation, the solution seems to accomplish the objective with no particular problems. In the back section of the dropped ceiling may reach surface temperatures as high as 30 °C, which is still an acceptable surface temperature, even if in the proximity with the head of the users.

In the summer case instead, a more evident thermal stratification in the room is shown, and the temperature of the section of the suspended ceiling at the rear of the room (far away from the façade) reaches values as low as in the range 15-16 °C. Limiting the area of the dropped ceiling's panels equipped with hydronic system to the first two panels next to the façade would probably assure a suitable air temperature and an optimal surface temperature of the dropped ceiling.

## CONCLUSIONS

The DCV ventilation system, object of the present work, demonstrates to have a positive impact on the comfort inside a typical office room. A sufficient amount of ventilation air is provided at low velocity and ensuring the absence of draft according to the values recommended by ISO 7730(7730:2005). In case of coupling between DCV and natural and hybrid ventilation, the system ensures the thermal comfort except in case of extremely high or low outdoor temperature. The use of the suspended ceiling as terminal of a water based heating/cooling system can be taken into account. According to preliminary simulations, the water based system should be capable of proving a thermal flux of  $\pm 10 \text{ W/m}^2$ , depending on the seasons. This eventuality demonstrated both in the winter and in the summer case a good influence on the comfort conditions. The portion of the dropped ceiling to be equipped with a water based heating/cooling system could be limited to the area closest to the façade and provide an adequate surface temperature of the DCV while conditioning the airflow under the most critical boundary conditions.

### ABSTRACT

The indoor temperature measured by the sensor is an important basis of air conditioner control strategy. Accordingly, the position of the sensor influences power consumption and the stability of indoor temperature control. This paper aims to study the influence of different sensor positions on air conditioner power consumption and indoor temperature stability. An experiment is conducted, which has 20-position circumstances, including different height, horizontal distance, and vertical distance from the air conditioner. Furthermore, Fluent is used to simulate the situation that sensor is in rooms with different sizes and air conditioner direction. An optimal sensor position searching model is developed, and an ideal position is proposed. A correction parameter is presented to adjust the sensor in original position. This study provides theoretical and practical support for improvement of the operation of air conditioners.

### KEYWORDS

Air conditioner; Thermal comfort; Indoor temperature; Temperature sensor

### INTRODUCTION

With the advancement of science and technology, the living condition of people is becoming increasingly comfortable, and the air conditioner plays an important role in creating such a comfortable condition. As the demand for indoor comfort continues to increase, higher requirements have been placed on the air conditioner (Jani et al. 2017). Moreover, efficient operation of an air conditioner is necessary under the energy conservation trend.

One study focuses on the heat pump inside the air conditioner (Waheed et al. 2014). However, as a key input for the operation of the air conditioner, the temperature measured by temperature sensor cannot be neglected. The temperature of the sensor position directly affects the air conditioner start-stop control, which eventually affects energy consumption and indoor temperature. If comfort and efficiency can be improved by optimizing this input, then low-cost optimization can be achieved. The conventional air conditioner contains a temperature sensor positioned on the return air grill, which measures the temperature of the return air. This is due to the closed control link of the air conditioner. However, as technology advances, information interconnection makes it possible for an open control link of the air conditioner operation. The temperature data from other sensors, and even the humidity and velocity, could be the input of the air conditioner. When the sensor position is not confined inside the air conditioner, it is necessary to study the ideal position of the sensor. In this paper, cool mode, rather than dehumidification mode or others, will be focused on, thus only temperature would be used as an input.

Yang (2009) put forward a method to find a proper position that can represent the sectional environment of the air conditioner. Liu et al. (2013) studied the influence of three different sensor positions on an indoor PMV. These studies focus on the indoor average temperature, which is affected by the average temperature of the position of the sensor. But the initiative of

people could eliminate the bias of the average temperature because people can change the target temperature of the air conditioner. Meanwhile, Nevins (1971) found that people are sensitive to the fluctuation of temperature, and the fluctuation cannot be directly controlled by changing the target temperature.

In this article, the domestic air conditioner is chosen as the experiment object, and the stability of indoor temperature and power consumption are the criteria to evaluate the air conditioner operation. By analyzing the characteristic of the temperature of different position using clustering and classification method, an ideal measurement position could be indicated.

## METHODS

### Experiment

The experiment is in a 5 m x 3.5 m room on the fourth floor of a six-story residential building in Tianjin, China (as shown in Figure 1). The air conditioner is located 2.7 m high at the southwest corner, which faces east. The temperature monitor device is a HOBO thermocouple data logger. Several pre-experiments are conducted and show that when the distance between two HOBO loggers is bigger than 1.5 m, the measurement error would be insignificant.

The measurement positions fill the room with a 1.5 m interval distance, and there are 20 measurement positions in total, including one at the return air grill. Except for the return air position, all 19 positions are distributed in a grid that has 2 layers (0.3 m high and 1.8 m high), 3 rows with a 1.5 m interval in an east–west direction, and 4 columns with a 1.5 m interval in a north–south direction. In the grid, 5 positions in a 0.3 m high layer are unreachable because of furniture and thus are ignored. HOBO loggers are placed at all 20 positions to monitor the temperature change (as shown in Figure 2).

There is only one adjacent room with an exterior wall, which is installed using a smart heater to be constant 30° C, according to the local summer outdoor design temperature. The air conditioner mode is cool, and the target temperature is set at 24° C, which is accordant with the adjacent room to avoid external factors. Other settings are set at default. By modifying the circuit, the sensor inside air conditioner is extended to reach all the positions. During the experiment, the sensor will be at one of the 20 positions, and the air conditioner will operate using the temperature of that position. The moving of the air conditioner temperature sensor only happens during the stopped period of the air conditioner's intermittent operation.

Figure 1. Experiment environment

Figure 2. Measurement positions

### Data analysis outline

The 20-position temperature is clustered using two key factors, and the influence of sensors located at positions of different cluster is analyzed. Thus, the clustering result and the cluster to which the ideal sensor measurement position belongs are obtained. The clustering result would be used to train a classifier. Afterwards, ANSYS is used to simulate the indoor temperature of rooms with different parameters, and the trained classifier is used to classify the temperature. Then, the recommended measurement position for rooms with different

parameters could be drawn. In this project, clustering and classification algorithms run in the Ubuntu operating system, and the algorithm program is written in Python.

### Simulation

ANSYS is used to simulate three different conditions, including a verification condition and two generalization conditions (GCs). In the verification condition, all parameters are accordant with the experiment to verify. In GC I, the room is changed to 10 m x 7 m. In GC II, the room is changed to 10 m x 7 m, and the air conditioner direction is changed to northeast. DesignModeler is used to build models, and ICEM-CFD is used to generate the mesh. Fluent is used to perform the transient simulation calculation, and the time step is set to 2 s.

### Data analysis method

Min–Max Normalization is used before the analysis algorithm to normalize the data with different ranges or units. The clustering method is K-means, which has better performance (Milligan and Cooper, 1980), and the silhouette coefficient is used to select the clustering number. The Bayesian classifier is used for classification, which is not sensitive to data deficiency. The temperature of the 20 positions is recorded using a time–domain curve, which is not compatible with the clustering or classification methods. Therefore, two key factors—temperature fluctuation amplitude and delay—are extracted from the original data to represent the characteristic of the temperature curve. Because the average indoor temperature is not the evaluation quota, the average temperature is not chosen to be the key factor.

## RESULTS

### Experiment and clustering result

Figure 3 show a 20-position temperature curve controlled by the air conditioner from one day of the experiment. It is obvious that the temperature of every position fluctuates together but has different amplitudes. For the following discussion, a position named  $\alpha$  position is defined as the position that is 2 m high, along the same wall as the air conditioner but 1 m away from the air conditioner. In the experiment,  $\alpha$  position is position 2. The experiment lasted for 19 days, and all the data is used for following analysis. When the clustering number is 3, the silhouette coefficient reaches best, which indicates the proper clustering number. By using amplitude and delay, the clustering result could be calculated (as shown in the Table 1).

Figure 3. 20-position temperature

Figure 4. Typical curves

Table 1. Clustering result: experiment

Cluster	Measurement Position
Cluster 1	5, 9, 10, 13, 20
Cluster 2	4, 7, 8, 12, 14, 17, 19
Cluster 3	1, 2( $\alpha$ ), 3, 6, 11, 15, 16, 18

### Difference between clusters

The typical temperature curves of three clusters are shown in Figure 4. It is obvious that the temperature of positions in cluster 1 fluctuates significantly, of which the amplitude is the

largest. In cluster 2, it fluctuates softly with an obvious delay. Cluster 3 performances between two other clusters. The average parameter of three clusters is shown in Table 2.

Table 2. Parameter of three clusters

Cluster	Average Temperature (℃ )	Amplitude (℃ )	Delay (s)
Cluster 1	23.54	2.43	32
Cluster 2	23.93	1.13	81
Cluster 3	23.79	1.6	55

### Runtime difference

The temperature of the different clusters behaves variously, which will cause diversity in the air conditioner operation if the sensor is placed at positions of different clusters. When the sensor is changed from one cluster to another one, the air conditioner will perform differently, which leads to the change of both indoor temperature and power consumption. By using 20-position temperature to represent the indoor temperature, the alteration is clear. It can be seen in Figure 5 that when the sensor is changed to the position in cluster 1, the indoor temperature fluctuates gently and is more agglomerative. The period of air conditioner operation shortens obviously but the temperature changes as almost straight lines. In Figure 6, compared with that of cluster 3, the period is stretched and the temperature in cluster 2 changes in a bent way.

Figure 5. Cluster 3 to 1

Figure 6. Cluster 3 to 2

Three parameters are used to evaluate the air conditioner operation caused by different sensor position. Temperature fluctuation variance is the temporal variance. Temperature distribution variance is the spatial variance. Power consumption is the electricity used in a unit time. The former two represent the stability of indoor temperature, which is directly related to indoor comfort. For better comparison, three parameters are converted to three indexes: temperature fluctuation variance index (TTVI), temperature distribution variance index (TDVI), and power consumption index (PCI). These three indexes are three parameters divided by the respective average value. For example, the TTVI is the temperature fluctuation variance divided by the 20-position average value. A comparison is shown in Table 3.

Table 3. Run-time difference of the three clusters.

Cluster	TTVI	TDVI	PCI
Cluster 1	0.88	0.93	1.14
Cluster 2	1.37	1.19	0.81
Cluster 3	0.99	1.02	0.98

### Simulation

Figure 7 is the temperature distribution of a 2 m high layer in vilification condition; the general boundary of three clusters at 2 m high is also shown by blue lines: the left part is cluster 2, the middle part is cluster 3, and the right part is cluster 1. In Figure 8, the normalized value of the temperature fluctuation amplitude is shown, where the average

temperature is 23.8° C, and the min/max value of temperature fluctuation is 0.9/2.6° C. In verification condition, though there is a visible bias from position 13 to position 19, which is because of the unconsidered furniture in simulation, the simulation result shows a high accordance with the experiment. In two GCs, by using the classifier trained by the clustering result, the positions could be classified as the previous three clusters according to their temperature amplitude and delay. The classification result is shown in Table 4. As the size of room becomes larger, the airflow has a weaker return trend, which leads to a weak response for every position. Because the characteristic of positions changes, the clustering result alters.

Figure 7. Temperature distribution

Figure 8. Verification

Table 4. Clustering result: simulation.

Cluster	Measurement Position-GC 1	Measurement Position-GC 2
Cluster 1	1, 5, 20	5, 20
Cluster 2	3, 4, 6, 7, 8, 11, 12, 14, 15, 16, 17, 18, 19	3, 4, 7, 8, 10, 11, 12, 14, 15, 16, 17, 18, 19
Cluster 3	2( $\alpha$ ), 9, 10, 13	1, 2( $\alpha$ ), 6, 9, 13

## DISCUSSIONS

### Evaluation index

To compare the performance of the air conditioner operation, an evaluation index (EI), as a comprehensive consideration of indoor comfort and power consumption, is defined as:

$$EI = \frac{2}{\frac{2}{TTVI + TDVI} + \frac{1}{PCI}} \quad (1)$$

where *TTVI* is the temperature fluctuation variance index, *TDVI* is the temperature distribution variance index, and *PCI* is the power consumption index. A lower EI is better. As shown in Table 5, cluster 3 shows a better performance than the two other clusters.

Table 5. EI of three clusters

Cluster	EI (lower is better)
Cluster 1	0.981
Cluster 2	0.986
Cluster 3	0.973

### Suggested position

After analyzing the characteristics of the three clusters, it can be drawn that three clusters can be named as Direct Zone, Inert Zone, and Reasonable Zone, respectively.

Direct Zone: The positions are close to the air conditioner, and are directly blown by the air conditioner, so the temperature fluctuates greatly; the response is quick; and the feedback to

the air conditioner is intense. In general, this zone is within 3.2 m of the wind path of the air conditioner, and the boundary varies around 3 m when the wind speed or room size changes.

**Inert Zone:** The positions are located far away from the air conditioner or in the corner of the room. Obviously, due to the stagnant airflow, the temperature fluctuation is weak, and the feedback to the air conditioner is weak. The boundary of this zone varies significantly.

**Reasonable Zone:** The measurement points in this cluster are in the middle of two other clusters. They are in a relatively open position with moderate temperature fluctuations. The reasonable zone is an ideal choice of air conditioner sensor measurement position, which considers both indoor comfort and energy conservation. The clustering stability, the accordance in different condition clustering, of the position should also be considered. The distance from the center of the cluster represents the clustering stability, and positions that are closer to the center would be clustered in the same cluster and perform more like the expect performance. The location of air conditioner temperature sensor recommended in this paper is position  $\alpha$ , defined previously as located on the same wall as the air conditioner, 1.8 m high and 1 m away from the air conditioner. This measurement position is not only good in theoretical performance but also in application because it is located on the wall surface, which is convenient for placement. It is not in the center of the room or in the place where people pass by, which is less influenced by human activities, ensuring stable and efficient operation.

#### **Sensor correction**

The original position of the temperature sensor is at the return air grill, which belongs to the Direct Zone. By analyzing and comparing the characteristic of the temperature curve of the recommended measuring position and that of the original position, which is the fluctuation amplitude and delay, it can be found that the delay is 25 s shorter and the fluctuation amplitude is 35% higher. It can be adjusted simply by adding an RC circuit.

#### **CONCLUSIONS**

This paper proposes the following method to find the ideal air conditioner sensor position of different parameters of the room: by clustering and classification after simulation to obtain the proper and stable position. This method does not require the actual measurement of different rooms, as different circumstances can be achieved through simulation. Therefore, it is applicable not only to the actual construction but also to the design stage. Meanwhile, this article gives the recommended air conditioner temperature sensor position,  $\alpha$  position, which can make the air conditioner run at the balance point of energy-saving and indoor comfort.

More kinds of room conditions, including different return air forms and room shapes, may produce different ideal measuring positions, which could be studied in the future. Moreover, due to the distance between measuring points, the precise  $\alpha$  position needs further study.

### **ABSTRACT**

The indoor environmental quality and energy performance of two modern secondary schools in the UK which have fundamentally different environmental strategies were investigated during building performance evaluations. The performances of these buildings against the projected weather data for future were also analysed. The results point to significant risk of future overheating as a result of climate change in the naturally ventilated building with passive measures that go well beyond the existing guidelines for schools. The other school with mechanical ventilation shows resilience to future overheating. However, shortcomings in building procurement and operation have severely compromised its energy performance. It is suggested to carry out integrated life-cycle assessment of energy performance and overheating resilience in the context of climate change during design stages and identify the corresponding risks and mitigation measures required to ensure design intents will be met in practice.

### **KEYWORDS**

Overheating, Energy Performance, Climate Change, Schools, UK

### **INTRODUCTION**

Average global temperatures are rising due to climate change. This has serious repercussions for the risk of overheating in buildings. Our understanding of human response to high ambient temperatures is also evolving and has led to adaptive overheating criteria for free-running buildings and overheating thresholds for mechanically conditioned buildings defined in BS EN 15251 (BSI, 2007) and CIBSE TM52 (CIBSE, 2013). This necessitates revisiting the performance of the existing buildings that were designed in accordance with different sets of overheating criteria and climatic conditions. Furthermore, while resilience against overheating is a key objective in climate change adaptation, improving the energy performance of buildings is also significantly important in the context of climate change mitigation to limit the increase in average global temperatures. Reconciling these competing objectives is therefore essential. This paper adopts a case study approach to investigate how energy efficiency and overheating control measures are being implemented in the UK construction industry. Two educational buildings have been selected for this purpose. Both buildings were constructed in England over the period 2008-2010 under the Building Schools for the Future (BSF) programme, which led to renewal or replacement of one fifth of English secondary schools. These buildings represent fundamentally different environmental strategies and were subject to post-occupancy investigations as part of a wider programme of building performance evaluation (BPE) instigated by the Innovate UK, the UK government innovation agency. The BPE programme, however, was focused on the current performance, and did not consider the potential response of these cases to future climate change. The aim of this paper is thus to adopt a long-term perspective in the context of a changing climate. The key

objectives are: 1) to review the performance of the case studies against outdoor temperatures experienced during monitoring along with their energy use, 2) investigate the likely response of the existing design strategies and operational regime to future climate change, and 3) review the potential measures to enhance buildings' resilience against future climate change and the implications of the research for wider building stock.

## OVERVIEW OF THE CASE STUDIES

**School A:** School A is a secondary school in London that was completed in 2010. Total useful floor area of the building is around 14,600 square meters. It was designed as a 2,000-pupil facility. The building is predominantly naturally ventilated and mechanical ventilation is only provided to the core spaces that do not have access to external facades and the ICT enhanced spaces with high internal gain. In total, around 80% of the building area is naturally ventilated. The external skin is formed from pre-cast concrete panels finished with brick tiles to achieve air permeability less than  $5 \text{ m}^3/(\text{m}^2.\text{hr})$  at 50 Pa. The reported air permeability following the pressure test on completion of the building was  $4.36 \text{ m}^3/(\text{m}^2.\text{hr})$ . The main facades of the building are east and west oriented. Previous studies found the risks of such a layout for overheating (Pegg, 2007). The design team specified several measures to mitigate overheating: 1) vertical fins are positioned on east and west elevations to provide solar shading; 2) Glazing g values are relatively low between 0.45-0.5; 3) typical classrooms have opening areas at around 7% of the floor area for single-sided ventilation. This is significantly higher than the existing guideline for opening area required for single-sided ventilation in schools which is 5% (DfES, 2006); 4) the facility for cross or stack ventilation has been provided for most classrooms by means of motorised vents controlled by the building management system (BMS). These vents are meant to open in response to poor indoor air quality or high temperatures. 5) the exposed thermal mass of the building can help regulate indoor temperatures; 6) Secure louvered windows facilitate night-time ventilation in summer.

**School B:** School B is located in Greater Manchester and was completed in 2008. Total useful floor area of the building is around 10,400 square meters. It was designed as a 1,150-pupil facility. The school is a steel frame building with brick facades and cavity wall insulation that was designed to comply with the regulatory air tightness requirement of  $10 \text{ m}^3/(\text{m}^2.\text{hr})$  at 50 Pa. The building is located under the flight path of Manchester airport. Therefore, mechanical ventilation strategy was adopted to meet acoustic requirements. Classrooms facing external facades have at least one operable top-hung window. Glazing g values are between 0.68-0.75, reduced to 0.36 on the south, southeast and southwest elevations by applying solar film after completion. A Ground Sourced Heat Pump (GSHP) system is installed as the lead heating system and is also capable of providing cooling to ICT enhanced spaces of the school that have chilled beams installed for cooling. Other classrooms do not have cooling terminals. However, the main air handling units (AHUs) serving classrooms and labs have cooling coils that are fed by the GSHP system. While the building is not fully air-conditioned, the GSHP system and AHU cooling coils can provide limited cooling when outdoor temperatures are high.

**Figure 1** shows the external views of the case studies.

Figure 1. External view from the courtyard of School A (left), and southside of School B

## METHODS

**Occupants' perception of the current conditions:** The Building Use Studies (BUS) questionnaire survey (Leaman & Bordass, 2001) was used to assess the satisfaction of teaching and support staff with the current performance. The response rate in both schools was 75%. The results for comfort variables are presented in this paper.

**Overheating analysis and simulation under current climate conditions:** Calibrated Type T copper-constantan thermocouple data loggers were used to record air temperatures every 10 minutes for one full year (measurement accuracy:  $\pm 0.35$  °C). At least 10% of teaching zones, representatively chosen, were covered. The results were compared against the overheating criteria for schools which were prevalent at the time the buildings were designed (DfES, 2006). Actual measurements were also compared with the outcomes of building simulations carried out with IES software (using current Test Reference Year weather file for London) to ensure a reasonable base model is available for future climate scenario analysis.

**Energy Performance:** the actual annual energy performances of the schools were established through regular recording of all main meters and submeters. Annual energy performances were then compared against the median of secondary schools in the UK to evaluate the success of energy efficiency measures adopted.

**Projections for performance under future climate scenarios:** The IES models developed based on the current performance were used to investigate the effects of the expected changes in weather conditions in future. It is envisaged that the buildings will be subject to major refurbishment within the next 20-30 years, the usual life-expectancy of most building services. This sets out a reasonable time horizon for investigating the effects of future climate change (CIBSE, 2014). Prometheus weather files developed by the Exeter University were used for this investigation. The current Design Summer Year (DSY), and the central estimate (50th percentile) for the effects of the medium carbon emissions scenarios in 2030 and 2050 were used to consider the effect of current climate change mitigation policies. The results for two classrooms in each school, which according to the technical measurements are prone to high temperatures, are presented against the new overheating assessment criteria set out in CIBSE TM52. Where a classroom fails 2 criteria (i.e. is overheated according to CIBSE TM52 criteria), the findings of building performance evaluations are used to identify improvement opportunities within the existing environmental strategies or suggest low cost interventions that may be used to improve overheating resilience.

## RESULTS

Figure 2 shows the BUS survey comfort variables generally score higher than the median benchmarks which represent the results of the last 50 survey in the database. However, the score for temperature in summer is the lowest among variables for both case studies and the benchmark. This is indicative of challenges of achieving occupant satisfaction in summer.

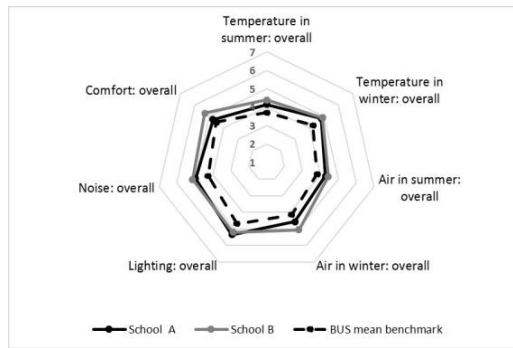

Figure 2. BUS results for comfort variables in the case studies

Figure 3 shows the measured and simulated air temperatures under ambient conditions close to Test Reference Years which are representative of the current climatic conditions. All sample classrooms comply with the overheating criteria prevalent at the time of design (DfES, 2006). Uncertainties in occupancy pattern, internal heat gains, and window positions can explain the discrepancies observed between measured data and simulation. Overall, the models appear to be reasonable representations of the thermal performance of the schools to be used for future climate scenario analysis. Classrooms with significant discrepancies between measurement and simulation were discounted from future climate analysis.

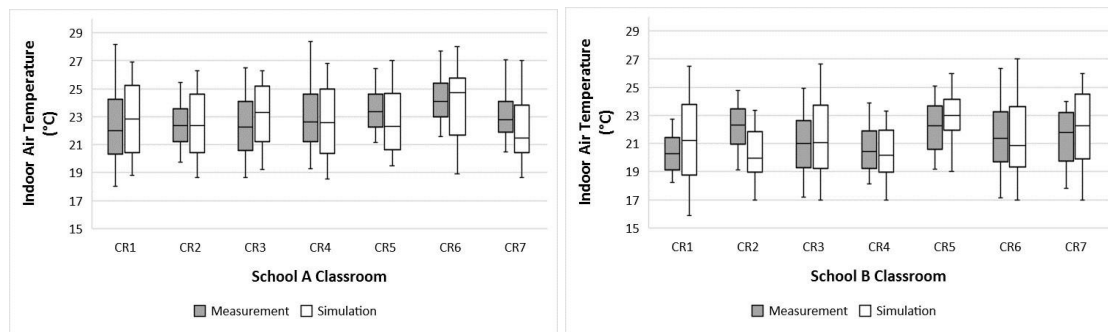

Figure 3. Whisker plots of current summertime air temperatures (May-September, 9:00-15:30)

Figure 4 compares the CO<sub>2</sub> emissions associated with operational energy use in these schools against the median stock (typical benchmark for schools in the UK).

Figure 4. Carbon dioxide emissions associated with operational energy use

Table 1 reports the results of future climate change analysis (grey color indicates failure to meet the overheating criterion). The following additional passive measures were considered for School A that showed risk of overheating with the existing environmental strategies: 1) increasing the window opening from the design value of 250 mm to 400 mm, 2) applying solar films to glazing to reduce the g value to 0.15.

Table 1. Overheating risk assessment (CIBSE TM52/ BS EN 15251 method)

School Classroom /	Internal gain of people, lighting, and small power (W/m <sup>2</sup> )	Simulation scenario	Current Design Summer Years (DSY): more extreme dataset than TRY			2030 DSY for medium emissions scenario (50 <sup>th</sup> percentile)			2050 DSY for medium emissions scenario (50 <sup>th</sup> percentile)

	Max: 43	Existing building	0	0	0	0.2	0	0	0.4	0	0

## DISCUSSION

Both case studies had been designed to comply with the requirements set out in the Schools Building Bulletin 101 (DfES, 2006) when exposed to a weather file representative of

‘average’ weather conditions. Applying the new overheating criteria and the more stringent DSY weather conditions (representative of ‘extremes’ for overheating analysis) shows the resilience of the environmental strategies adopted for these buildings to more extreme conditions. School A would comply with the overheating criteria under the current DSY conditions if the design strategy is followed in practice. However, a number of interventions would be required to mitigate the risk of overheating over the coming years. Table 1 shows that overheating is not merely a result of exceeding certain threshold temperature (Exceedance criterion), but the severity of it also exceeds the 6 degree-hours limit set out by CIBSE TM52. School B, on the other hand, is quite resilient to the current and future weather conditions even under the new overheating criteria set out for mechanically conditioned buildings that specify fixed threshold and upper limit temperatures lower than Building Bulletin 101. Figure 4 shows that this resilience comes at a huge price in terms of energy use and specifically auxiliary energy that includes the energy used by air handling units. However, building performance evaluations revealed significant shortcomings in the procurement of School B that compromised its operational energy, notably failure of demand-controlled ventilation and specific fan powers being much worse than the design intents.

## CONCLUSIONS

The future overheating risk in new school buildings in the UK is currently not adequately addressed at design stage. This can have implications for capital expenditure on the necessary interventions across the school estate in future that are not quite transparent.

This study found that a naturally ventilated school with several measures to protect the building against overheating in current climate will almost certainly experience severe overheating during teaching hours over the expected life cycle of its environmental strategy unless additional measures are specified to enhance its resilience. Mechanical measures to improve overheating resilience, on the other hand, can increase energy use and carbon emissions of schools. It is therefore recommended to carry out integrated life-cycle assessment for both energy performance and overheating resilience at design stage and identify major risks and mitigation measures to ensure design intents will be met in practice.

### **ABSTRACT**

The purpose of this study is to investigate the main influential factors of the subway Particulate Matter (PM) pollutants under the air-conditioning condition and ventilation condition, by an on-site field measurement in a subway station in Shanghai. It is found that the dust accumulation at fresh air shaft was the secondary dusting action under the influence of fresh air flow, leading to a higher concentration of the PM in the subway station than in the outdoor air even when the outdoor air quality was good. In addition, in the morning rush hour the PM 2.5 value near the platform screen door our is highest of the day.

### **KEYWORDS**

Subway platform, PM 2.5 concentration, air-conditioning conditions, ventilation conditions

### **INTRODUCTION**

The air quality of the subway station such as the PM concentration affects the health and comfort of a larger number of passengers and staffs. On the one hand, the friction on the rails during the operation of the train generates a large number of particles (Wen Zhengjiang et al.2012), on the other hand, ventilation shafts bring the outdoor particles into the tunnels, leading to the higher PM concentration in the tunnels. Furthermore, the suspended particles caused by the trains' operation may cause the increasing of the PM concentration on the platform during the opening of the platform screen door (Chang Jingjing and Sun Jian, 2014). Therefore, The variation of the PM concentration on the platform is relevant to the health of the passengers and staffs and arouses extensive attention from the researchers.

At present, researches on pollutants' control of the subway platform are mostly conducted through on-site measurements. For example, Zhao et al. used this method to study the concentration of particulates in subway platforms and train compartments, and observed their changes with the subway operation (Zhao et al., 2016). Kim et al. found that the concentration of PM<sub>10</sub> and PM<sub>2.5</sub> in the passenger compartment of the subway was lower than that in the station (Kim et al., 2010). Liu et al. measured and analyzed the concentration of the PM in the subway station and obtained a clear spatial-temporal distribution of the PM concentration in each area. It was found the concentration of the PM in the transition zone of the station was significantly higher than that of the PM on the platform and in ticket hall (Lu et al., 2015). There is no research or analysis on the influential factors of the PM<sub>2.5</sub> on subway station platform and its significance. Therefore, the research on the influential factors of the PM<sub>2.5</sub> on the station platform is urgently needed.

In this work, the dynamic PM 2.5 concentration on the subway platforms was measured on-site under the real-time inspection, aiming at finding the influential factors of the PM 2.5 on the platform.

### Methods and Methodology

Characteristics of the PM<sub>2.5</sub> concentration on the platform were measured at varied locations during several periods of the day with systematical field-monitoring of the carbon dioxide concentration, air temperature, and humidity. The measurement was conducted under the ventilation condition and air-conditioning condition. The pollutants' distribution characteristics were analyzed regarding the concentration and the heat pressure differences between the tunnel and the station platform during the opening process of the screen doors.

The field-measurements were conducted in the Caobao Road station of Shanghai Metro Line 12 on September 27th, 2017. The ventilation condition was from the starting points of train's operation in the morning to the noon, and the air-conditioning condition was from the noon to the midnight. In order to avoid interfering with the subway operation, two types of on-site measurement methods were developed including long-term and short-term monitoring. During the long-term monitoring, the equipment was fixed for a whole day, recording the data once a minute; during the short-term monitoring, the removable cart is utilized to collect the data at 1.5 m height dynamically.

The traditional ventilation and air conditioning system is used in Caobao Road subway station with the supply air pipe and the return air pipe on the two sides of the platforms (Figure 1). The platform is about 120 m long. Both the supply air pipe and the return air pipe are extended from the two ends to the middle of the platform. The locations of measuring points are shown in Figure 1 with the detailed descriptions in Table 1. The key parameters of the instruments used in the field-measurements are shown in Table 2. Figure 2 presents the photos of the measurement sites.

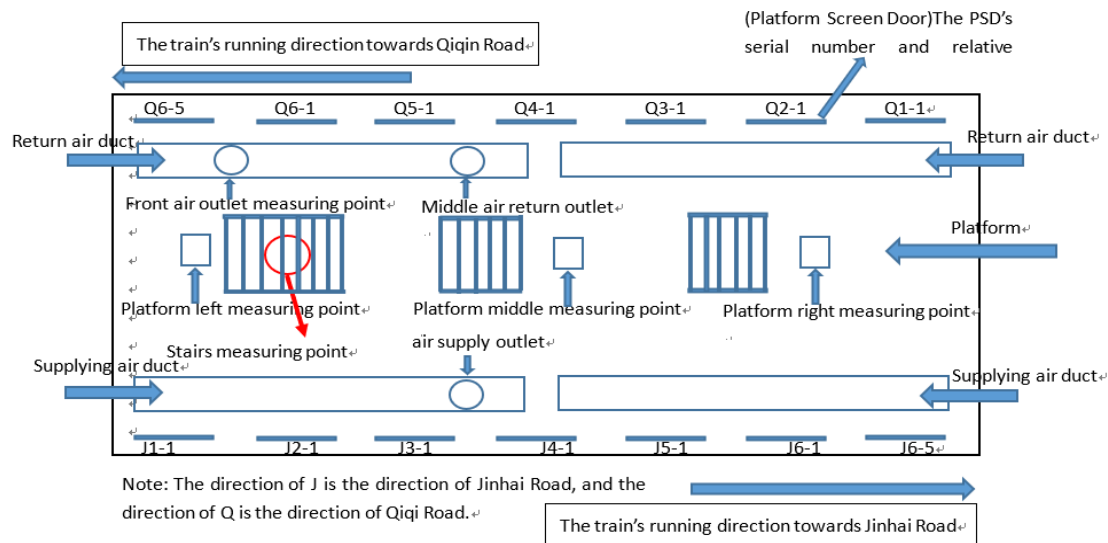

Figure 1 The locations of measuring points

## RESULTS

### Dynamic variation of PM<sub>2.5</sub> concentration on the platform and related influential factors under air-conditioning condition

Figure 3 shows the dynamic monitoring results of the PM<sub>2.5</sub> concentration in the supply air and return air vents, fresh air shaft, and outdoor air during the long-term monitoring. The PM<sub>2.5</sub> concentration in the supply air was affected by both the concentrations in both the fresh air and return air. The supplying air parameters are relevant to those of the fresh air shaft and the outdoor environment.

Figure 3 Monitoring results of the PM<sub>2.5</sub> concentration in the supply air and return air vents, fresh air shaft, and outdoor air during the long-term monitoring

It can be seen from Figure 3 that the PM<sub>2.5</sub> concentration in the return air vents was lower and correlated with the one in the supply air vents. The return air seemed not the main reason for the high PM concentration in the supply air under the air-conditioning condition. However, the fresh air was likely to contribute to the peaks of PM concentration in the supply. The PM level of the outdoor air was the lowest and much lower than that in the fresh air shafts. One explanation is that there was lots of dust accumulated in the fresh air shaft. It can be concluded that the secondary dusting action by the fresh air shaft led to the higher PM concentration in the fresh air intake even though the outdoor air was fairly clean. The PM concentration in the supply air was lower than that in the fresh air shaft and return air during most of the time, demonstrating that the filtration equipment in the air-conditioning system of the subway station did provide certain purification.

#### Dynamic variation of PM value on the platform under ventilation condition

Figure 4 shows the dynamic monitored PM<sub>2.5</sub> concentration in the supply air, fresh air shaft and outdoor air under the ventilation condition. As shown in Figure 4, the PM<sub>2.5</sub> concentration in the fresh air shaft was higher than that in the outdoor air, confirming that the dusting action in the air shaft was the main reason for the high PM<sub>2.5</sub> concentration in the supply air. To avoid that, the supply air shaft of the subway station needs to be maintained and cleaned. On the other hand, the filtration system is critical for maintaining the PM concentration in the subway.

Figure 4 Variation of PM2.5 Concentration in Ventilation, New Ventilation Well, Outdoor Air under air conditioning condition and all-fresh-air condition

#### Dynamic characteristics of PM2.5 on the platform, return air and influential factors

Figure 5 shows the relationship between the concentration of PM2.5 in the return air and that of some typical locations on the station platform under both ventilation condition (from morning to noon) and air-conditioning condition (from noon to evening). The PM2.5 concentration in the return air correlated with the concentrations on the platform. The PM level both on the platform and in the return air vent reached the peak of the day during the rush hour in the morning. It can be concluded that the accumulation dust in the tunnel and in the fresh air shaft at night are secondary-dusting generated by the trains' operation during the rush hour in the morning. Besides, the PM levels of the typical locations and in the return air vent were also high from the evening rush hour to the end of the day. It can be attributed to the PM continuously escaping from the tunnel through platform screen doors (PSDs) during the operation hour, with the help of the passengers' movement on the platform.

Figure 5 Variation of PM2.5 at different locations over time

#### The variation of the PM concentration near the platform

Figure 6 shows the data at the two typical measurement locations at 1.5m height on the platform, as well as the average values near the PSDs obtained during the rush hour in the morning, off-peak periods and rush hour in the evening. It can be seen that the PM2.5 concentration near the PSDs during the rush hour in the morning was significantly higher than

that on the platform. Besides during the non-rush and rush hour in the evening, the PM<sub>2.5</sub> concentration during the door opening process was slightly higher than that of the typical locations on the platform.

Figure 6 Comparison between PM<sub>2.5</sub> concentration on the platform and near the PSDs

## CONCLUSIONS

The conclusions of this current work are as follows:

1. The dusting action in the fresh air shaft led to the higher PM<sub>2.5</sub> concentration in the fresh air vents even though the outdoor air was fairly clean.
2. The PM<sub>2.5</sub> concentration in the return air correlated with the ones on the platform.
3. The PM<sub>2.5</sub> concentrations during the rush hour in the morning were obviously higher than that of the off-peak hour and the rush hour in the evening.
4. The dusting action in the tunnel caused by the train in the morning is remarkable, resulting in that the PM<sub>2.5</sub> concentrations on the platform near PSDs were always higher than that on the platform.
5. In order to avoid the dusting action in the fresh air, the fresh air shafts should be cleaned in a regular schedule.

### ABSTRACT

Volatile organic compounds (VOCs) are considered a major group of indoor air contaminants with several proven adverse health effects. Ultraviolet photocatalytic oxidation process (UV-PCO) is a promising technology for the removal of VOC contaminants in indoor air environments. In addition, adequate efficiency of PCO has been proven in laboratory conditions. However, when PCO is scaled up and applied in real conditions, there are some limitations that need to be addressed. Several factors are involved in the efficiency of the PCO process such as humidity, flow rate (residence time), inlet of contaminant concentration, light source, etc. To the best of our knowledge, most of the research conducted in this area has been performed in a bench-scale reactor with long residence times of several minutes and at high VOCs concentrations (hundreds ppm level), which are far from being real indoor conditions. The main objective of this research is to study the scaling effect on isobutanol removal efficiency under the conditions relevant to real indoor applications. For this purpose, full-scale (0.6 m × 0.6 m), pilot-scale (four parallel ducts, 0.3 m × 0.3 m each) and bench-scale (9 cm × 7 cm) test set-ups were used to study the VOCs removal efficiencies via PCO in the gas phase. First, three experimental set-ups for testing TiO<sub>2</sub> photocatalyst are described. Then, the isobutanol removal efficiency is evaluated in the condition, which is close to the real application, considering the low-level contaminant concentration and high flow rate. The relative humidity in this study is kept in the comfort zone (RH ~ 50±5 %). The performance of UVC-PCO of the three scales is compared and discussed. For isobutanol with 0.003 mg/m<sup>3</sup> inlet contaminant concentration, around 24%, 56%, and 68% removal efficiencies were achieved in the full, pilot, and bench-scale systems, respectively.

Photocatalytic oxidation (PCO), Volatile organic compound, Indoor air quality, Scale-up, Titanium dioxide (TiO<sub>2</sub>)

### INTRODUCTION

Volatile organic compounds (VOCs) are considered major contributors to air pollution and a cause of adverse health effects in humans. VOCs are found in the indoor air of residential and commercial buildings; they are released from building materials, consumer products, and occupant-related activity (Vildozo et al. 2011, Weon et al. 2017). Various techniques have been studied to remove VOCs, including adsorption, non-thermal plasma, catalytic oxidation, etc. (Huang et al. 2017a). However, these methods may have several drawbacks, such as generation of secondary pollutants, high energy consumption and high cost, which are obstacles when dealing with low VOCs concentration ranges (Ji et al. 2017).

Photocatalytic oxidation (PCO) is a promising technique, which can degrade various types of VOCs at low concentration levels (Huang et al. 2017b, Lyulyukin et al. 2018). Among different photocatalysts,  $\text{TiO}_2$  is considered as one of the most efficient, because of its low cost, abundance, strong photo-oxidation power, and high chemical and photochemical stability (Ji et al. 2017, Weon et al. 2018). Our previous work summarized the PCO of several types of contaminants on  $\text{TiO}_2$  photocatalyst surface (Shayegan et al. 2018). Accordingly, most of the published papers are based on bench-scale applications in laboratory conditions, whereas there is limited research on pilot or full-scale, which are applicable to real indoor application (Zhong et al. 2013). Small-scale investigations have often considered a high level of contaminant concentration and a low amount of flow rate with long residence time. Their results are not suitable for scaling up since they do not resemble real indoor air conditions (Shu et al. 2018).

This paper focuses on the effects of scaling up on the PCO process of a commercial filter. PCO of isobutanol at three different scales—including bench, pilot, and full-scale set-ups—are studied to determine the possible obstacles in scaling up the air purification process.

## METHODS

### Materials

In this study isobutanol (99.9%, ACS grade, Fisher Scientific, Canada) was used as the target contaminant. A commercial PCO filter was purchased from Saint Gobain Quartz Company. The 2,4-dinitro-phenylhydrazine (DNPH) cartridge and acetonitrile (HPLC grade) were purchased from Sigma Aldrich and Fisher Scientific, respectively for HPLC analysis.

### Experimental set-ups

In this work, three experimental set-ups are used to investigate the effect of scaling up on the removal efficiency of the PCO process. Table 1 shows the operational parameters of these set-ups.

**Bench-scale.** The first experiment was carried out using a bench-scale duct. Fig. 1a shows the schematic diagram of the bench-scale set-up. The apparatus was made from an aluminum duct which had been anodized to have the highest reflectance to UV, with 7 cm  $\times$  9 cm cross-sectional area, 100 cm length, and  $6.3 \times 10^{-3} \text{ m}^3$  volume. All the fitting and tubing used in the system were stainless steel or PTFE. For this set-up, two separate compressed air streams were used as the carrier gas and passed through the mass flow controller (MFC, OMEGA, FMA5442ST). The total flow rate of the duct was adjusted at 1.8  $\text{m}^3/\text{h}$ . Relative humidity of the system was controlled by passing one of the air streams through a vessel of distilled water. The second air stream was used to adjust the specific flow rate. The specified amount of isobutanol (see Table 1) was automatically injected by a syringe pump (KD Scientific, KDS-210, USA) into the duct. GC/MS (Agilent) and HPLC (Perkin Elmer) were used to analyze the contaminant concentration. Accordingly, GC and HPLC samples were collected to measure the isobutanol concentrations at the points upstream and downstream of the duct.

**Pilot-scale.** The second test apparatus used in this work is made of four parallel aluminum ducts, each with a 31 cm  $\times$  31 cm inner cross-sectional area. Fig. 1b depicts the schematic diagram of the test rig. As shown, the dimension of the closed part of the set-up is 3.6 m long and 1.2 m wide, with a total volume of 1.7  $\text{m}^3$ . The length of each duct is long enough to assume the air is following the ideal plug flow pattern. By using a radial fan, the system was able to control the speed of air and provide the flow rates up to 340  $\text{m}^3/\text{h}$  (200 cfm). Due to the size of the set-up, the laboratory air was used as the carrier air. The laboratory air, which

had passed through the filter, mixed with the air containing the evaporated isobutanol, was introduced into the system. The experimental set-up is an open duct system; therefore three humidifiers were used near the entrance of set-up to keep the relative humidity at a specified amount. The relative humidity and temperature at upstream and downstream of each duct were monitored by sensors (HMT 100, Vaisala) and recorded. The sensors were installed in two locations: at the center for upstream and past each duct's reactor sections for downstream. The cross-shaped sampling tubes were mounted at the beginning and at the end of the reactors to collect the upstream and downstream samples. GC and HPLC samples were collected to analyze the isobutanol concentrations at the upstream and downstream of each duct. Two pressure taps were installed, at the beginning and at the end of the PCO reactors for each duct. All of the probes and tubing used in the system were stainless steel or PTFE. The reactor was designed to be able to accommodate the various geometric shapes of the in-duct UV-PCO filters available on the market. Moreover, the design of these reactors allow for the changing of the number of lamps and catalysts. In this study, two layers of PCO filters and two UVC lamps were installed. The distance between the surfaces of catalyst and UV lamps was approximately 5 cm. In addition, the distance between each of the two lamps and the distance from each lamp to the reactor's wall were 13.3 cm and 8.6 cm, respectively. At the end of each duct, the clean-up section containing activated carbon, activated aluminum, and MnO<sub>2</sub> scrubbing filters was installed to capture the residual VOCs and any potentially generated by-products. The adequate numbers of MnO<sub>2</sub> layer post-filters were installed to control the exhaust ozone concentrations, less than 50 ppb.

**Full-scale.** The third set of experiments was carried out with a full-scale set-up, as presented in Fig. 1c. The duct was designed based on the ASHRAE standard 145.2 (ASHRAE 2016). The full-scale set-up has a 61 cm by 61 cm cross-sectional area, 11.5 m length, and 10 m<sup>3</sup> volume. It is constructed of stainless steel with a smooth interior finish to minimize the absorption of contaminants on the internal surface of the duct. The design of the reactor offers the ability to test different types and sizes of air cleaning systems. As depicted in Fig. 1c, a radial fan with speed control (Rosenburg America, DKNB-355) is utilized which can provide an airflow rate up to 3400 m<sup>3</sup>/h (2000 cfm). A clean-up bed followed by a HEPA filter are installed, just past the fan, to filter out the possible particulate matter and aerosol from the carrier air. To reduce air leakage through the inlet or outlet dampers, ultra-low leakage positive pressure dampers (M&I Air Systems Engineering) were utilized in the system. The final clean-up bed was installed to adsorb possible by-products or unreacted contaminants before the exhaust is directly vented through the laboratory exhaust duct (Bastani et al. 2010).

Table 1: The operating parameters in the bench, pilot, and full-scale set-ups.

Parameter	Value		
	Bench-scale	Pilot-scale	Full-scale
Temperature	23.5 ± 0.5 °C	21 ± 0.5 °C	23.5 ± 1 °C
Relative humidity	50 ± 1 %	47 ± 3 %	48 ± 2 %
Air velocity	0.5 and 1.25 m/s	0.5 m/s	1.25 m/s
Inlet concentration	0.003 and 3.03 mg/m <sup>3</sup>	0.003 and 3.03 mg/m <sup>3</sup>	0.003 and 3.03 mg/m <sup>3</sup>

## RESULTS

The performance of commercial PCO filter for isobutanol degradation was evaluated under UV irradiation. The experimental data obtained from upstream and downstream of each set-up is employed to calculate the removal efficiency,  $\eta$  (%), as follow:

$$\eta(\%) = \frac{(C_{up} - C_{down})}{C_{up}} \times 100 \quad (1)$$

where  $\eta(\%)$  is the single-pass removal efficiency and  $C_{up}$  and  $C_{down}$  ( $\text{mg}/\text{m}^3$ ) are the contaminant concentrations at upstream and downstream of each set-up.

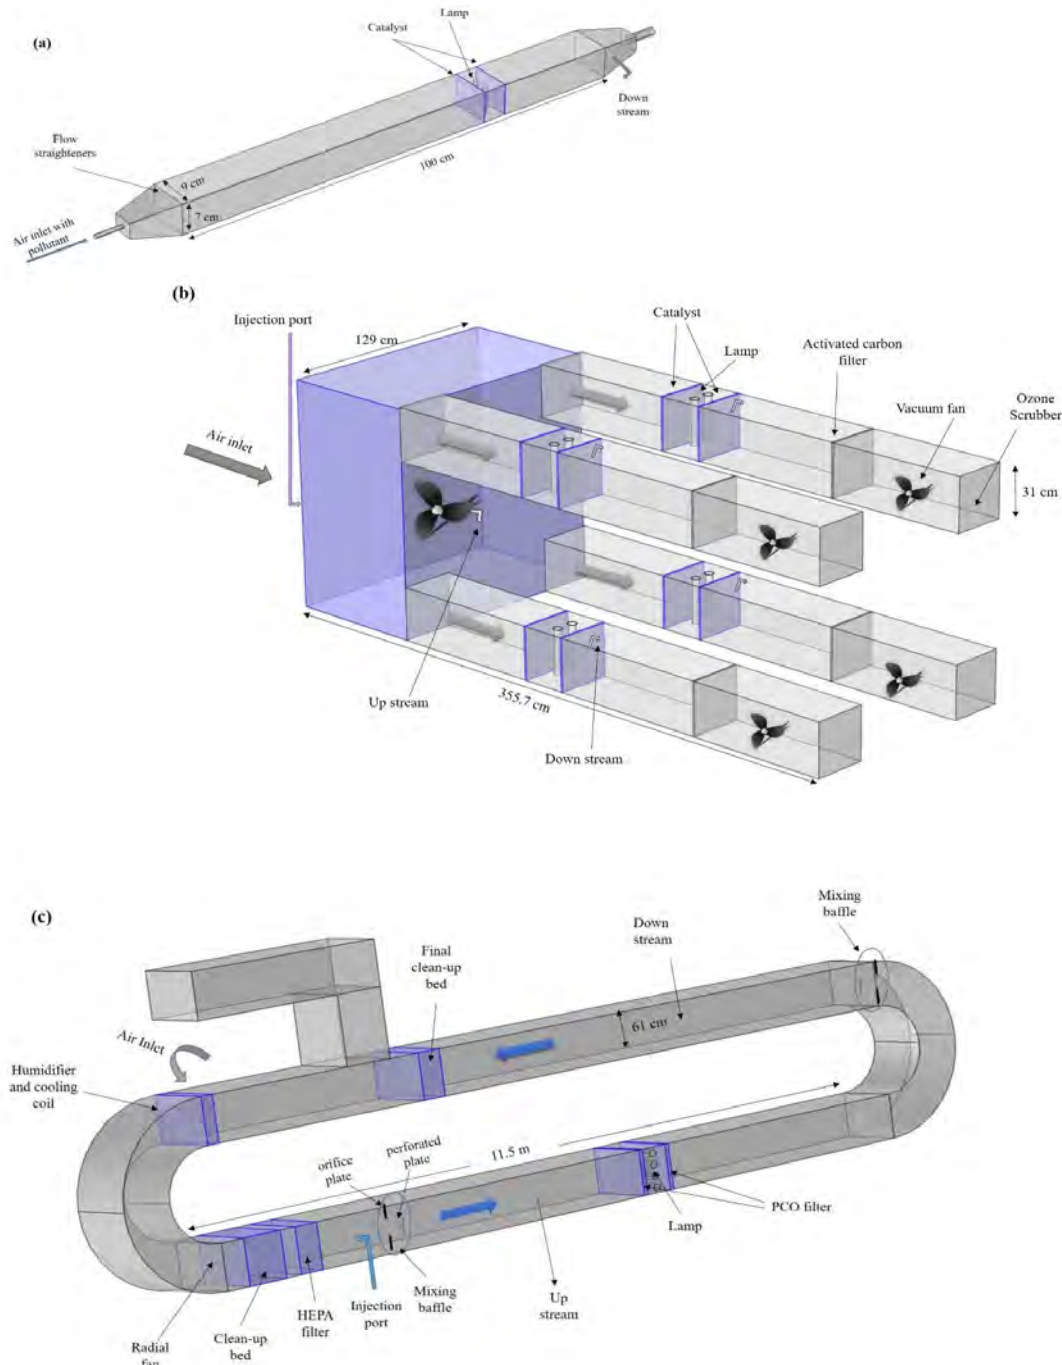

Figure 1. Schematic diagram of a) bench-scale, b) pilot-scale, c) full-scale set-ups.

Fig. 2a and b depict the removal efficiency of isobutanol at  $0.003 \text{ mg/m}^3$  and  $3.03 \text{ mg/m}^3$ , respectively, for bench, pilot, and full-scale set-ups. The velocity of air flow for pilot and full-scale was adjusted at  $0.5 \text{ m/s}$  and  $1.25 \text{ m/s}$ , respectively. In order to compare the results with bench-scale, two sets of experiments were conducted at  $0.5 \text{ m/s}$  and  $1.25 \text{ m/s}$ . As presented in Fig. 2a and b, the removal efficiency of isobutanol in low concentration is higher than in high concentration. Moreover, the removal efficiency of isobutanol decreased as the scale of set-up increased. The difference in results between setups of the same velocity may be a result of the effect of the light source. It is also observed that by increasing the air velocity, the removal efficiency was decreased, either in comparing two sets of bench-scale results or by comparing the pilot and full-scale ones. This is a result of the high air velocity, whereby the residence time is decreased and contaminant molecules have less chance to decompose in the shorter reaction time.

Figure 2. Removal efficiency of isobutanol a)  $0.003 \text{ mg/m}^3$ , b)  $3.03 \text{ mg/m}^3$  at three scale of set-ups.

## DISCUSSIONS

The main problem in scaling up the photocatalytic reactor in large-scale applications is in having a uniform distribution of light irradiation for the entire photocatalyst's surface. The evaluation of light distribution inside the reactor is crucial for the extrapolation of laboratory scale results to pilot or full-scale operations. As mentioned in the results section, the lower inlet contaminant concentration showed higher removal efficiency. This occurs because the fixed active sites of the catalyst have limited adsorption capacity. Moreover, at high inlet concentration, the surface of the photocatalyst becomes saturated and quantum yield decreases due to the shielding effect of contaminants on the catalyst surface. In addition, increasing the airflow rate velocity causes a) the reduction in residence time of PCO process followed by decrease of removal efficiency, b) the increase of the mass transfer rate of contaminants to the surface of the catalysts, improving the PCO removal efficiency. It is obvious that laboratory-scale results are not sufficiently accurate and reliable for use in designing the UV-PCO system for indoor contaminants on a large-scale. Further studies need to be conducted to evaluate the effects of scaling up combined with indoor real conditions (e.g. multi-component mixtures) on by-product generation and catalyst deactivation.

## CONCLUSIONS

Three scales of experimental set-ups were designed and constructed to study the UV-PCO performance of the commercial filter. In order to compare pilot and bench-scale set-ups, the experiments in bench-scale were conducted at  $0.5 \text{ m/s}$  velocity. The results showed that the removal efficiency in the bench-scale setup was higher than that of the pilot in both considered inlet concentrations. Additional experiments were performed at  $1.25 \text{ m/s}$  in bench-

scale in order to compare the results of the bench with full-scale. It is concluded that by increasing the air velocity and the size of the system, the removal efficiency of isobutanol was decreased.

### **ABSTRACT**

Well-mixed assumption normally has flaws in the space with continuous-releasing particle sources. For transient point or puff sources, however, particle concentration might vary differently among locations during emission periods and afterwards. This study measures whether and how rapidly ventilation systems can distribute particles emitted from puff-like sources in an indoor space. The impact of ventilation pattern (over-head mixing ventilation and displacement ventilation), particle size (0.77, 2.5 and 7  $\mu\text{m}$ ) and source location are also examined. The results show that particles with sizes of 0.77  $\mu\text{m}$  and 2.5  $\mu\text{m}$  can be distributed uniformly by both mixing ventilation and displace ventilation shortly (within a few minutes) after particle injection is terminated, regardless of particle source locations with the absence of obstructed airflow. This paper validates the well-mixed assumption when assessing long-term human exposure to puff-generated particles in the indoor environment. With regard to puff sources, the spatial concentration enhancement in human microenvironment/breathing zone might not be as significant as continuous-releasing particle sources.

### **KEYWORDS**

well-mixed assumption, puff, mixing time, displacement ventilation (DV), mixing ventilation (MV)

### **INTRODUCTION**

The assessment of human exposure to indoor particles relies on the information of particle concentration and spatial distribution. The well-mixed assumption is a convenient approximation in the human exposure analysis (Mosley et al., 2001). In many situations, however, particle size and source location affect indoor fate and lead to spatial variability of particle concentration (Bouilly et al., 2005). Rim and Novoselac (2009) found that thermal plume of a sedentary manikin caused up to four times higher concentration in the breathing zone than room concentration with stratified airflow patterns in the room. Air distribution patterns or ventilation systems also cause inhomogeneity of spatial distribution (Zhao and Wu, 2009). These findings on the inadequacy of the well-mixed assumption presume that indoor particles are released from stationary and continuous injecting sources.

Indoor particle sources are often transient, mobile, and in the form of puff-dispersion. Intermittent human activities such as folding clothing, walking around and sitting on upholstered furniture resuspend substantial particles smaller than 5  $\mu\text{m}$  (Ferro et al., 2004). During particle releasing, spatial concentration is greater near the source than other regions. The non-uniformity decays after the particle releasing finishes. The well-mixed condition can be achieved when the standard deviation of the concentration at all locations to be within 10% of the spatial average (Gadgil et al., 2003).

Since human activities release substantial indoor particles near a human body, this study investigates the fate of particles (0.77, 2.5 and 7  $\mu\text{m}$ ) released from a puff-like source in the feet region of an occupant, which simulates particle resuspended from the floor or shed from clothing (pants). Injecting a blast puff of particles in the supply air, we also examine the influence of source location on the mixing time of indoor particles.

The primary objective of this study is to re-visit the well-mixed assumption for indoor particles released from puff-like sources. In addition, this study aims to investigate particle mixing time when considering different indoor ventilation systems (overhead mixing and displacement ventilation), particle sizes and source locations.

## METHODS

### Test chamber and setups

The test chamber for all particle experiments consisted of a precisely controlled HVAC system and a water-heating wall. The chamber had a geometry of 6 m  $\times$  4.5 m  $\times$  2.7 m. It is able to create displacement ventilation and mixing ventilation by using different air diffusers (Figure 1). Both overhead mixing ventilation (MV) and displacement ventilation (DV) provided an air change rate per hour (ACH) of 3.2 hr<sup>-1</sup> that represented a typical office environment. The supply air temperature and turbulence intensities were approximately 17.4 °C and 5%, respectively, which were measured by a hot sphere anemometer (HT-400, SENSOR) with a sampling frequency of 0.5 Hz. This study considered a relatively low-occupation-density office that consisted of two thermal dummies (90W each), two table-boxes (0 W) and one heated wall (320W) representing warm windows or façade in the summer time (Figure 1). An embedded HEPA (high-efficiency particulate arrestment) filter in the HVAC system enabled background particle concentration without indoor sources three order of magnitudes lower than that with such sources.

Figure 1. Schematic of experimental setups. Left) displacement ventilation, Middle) mixing ventilation, Right) particle sampling positions.

### Particle seeding and measurements

Outdoor particles and indoor human activities contribute to indoor particles. Particle sources described in Figure 1 represents resuspended particles (Source 1) from the floor or shed particles from clothing because of human activities and unfiltered outdoor particles entering indoors via supply air (Source 2). We tracked the fates of particles with three different sizes, 0.77, 2.5 and 7  $\mu\text{m}$  considering particle and airflow dynamics (Liu and Novoselac, 2014).

For both DV and MV, particles were released close to body proximity (Source1) (0.02 m from a dummy and 0.3 m above the floor) or in the duct before diffusers (Source 2). Coarse particles (7  $\mu\text{m}$ ) were released only in the duct due to the strong flow disturbance of the generator. The generation period was 100 seconds for 0.77 and 2.5  $\mu\text{m}$  particles, while 30 seconds for 7  $\mu\text{m}$

particles. We measured particle time-serial concentration at five locations (Figure 1) for 1200 seconds across the chamber using Optical Particle Counters (Aerotraks 9306, TSI, Inc). All experiments were repeated three times and measurements uncertainty is represented by standard deviation among the three repeats in this study.

In order to facilitate concentration comparison at the different sampling locations, this study normalized particle concentration by a reference value. For 0.77 and 2.5  $\mu\text{m}$  particles, we used the average concentration over the entire sampling period (1200 seconds) at the chamber exhaust (P2 in Figure 1) as the reference ( $C_{ref}$ ). Nevertheless, particle deposition loss becomes significant for 7  $\mu\text{m}$  particles. As such, we normalized particle concentration for 7  $\mu\text{m}$  based on the instantaneous average concentration over the five sampling locations,  $C_{ref}^*$ . This study focuses on the instantaneous comparison of particle concentration at different locations. The reference value does not affect the comparison of spatial concentration.

## RESULTS

### Mixing ventilation

Supply air diffusers for MV typically create high-momentum jets that entrain air and particles from surroundings and blend them inside the whole room. The concentration of submicron particles that transport similarly to gaseous pollutants tends to be uniformly distributed in the room with MV. Figure 2 shows the measured time-serial concentration of particles (0.77, 2.5 and 7  $\mu\text{m}$ ) released from two sources. When the particle source (Source1) resides in the vicinity of thermal dummy B, convective boundary flow of the thermal dummy spreads particles during the injection period. In Figure 2, the concentration right above the particle source (P4) is approximately two orders of magnitude higher than at other locations for 0.77 and 2.5  $\mu\text{m}$  particles during injection. Nevertheless, this difference disappears a few minutes after particle injection finishes, rendering all concentration curves collapsing onto one. When particles were released into supply duct (Source 2), on the other hand, the concentrations at five locations show a very similar trend for both 0.77 and 2.5  $\mu\text{m}$  particles. With regard to 7  $\mu\text{m}$  particles, the gravitational force becomes competing with drag force, leading to increased deposition loss and decayed concentration with height.

The results for MV indicate that particle source locations only affect  $\text{PM}_{2.5}$  transport during the injection period and the relatively short period (**2 min**) afterward. The well-mixed assumption concentration is valid for transient puff-like particle sources in the typical office environments when considering particle distribution and human exposure for a long term. However, the assumption does not hold for coarse (e.g. 7  $\mu\text{m}$ ) particles.

### Displacement ventilation

Particles take a longer time to transport across the chamber with DV than MV, because DV supplies air at the floor level at a low air speed. In Figure 2, particles (0.77 and 2.5  $\mu\text{m}$ ) emitted at the feet region (Source 1) of the thermal dummy B are transported by the plume to the breathing zone of thermal dummy A (P4) where concentration is one order of magnitude greater than that at room exhaust during particle injection. Compared to the concentration at P4 for MV, DV reduces considerably the peak concentration in the breathing zone. This reduction is attributed to the enhanced airflow disturbance on Source 1 (feet region) when supply air is provided at the floor level.

When outdoor or room-recirculated particles enter the room with DV via supply air diffusers (Source 2), particles transport along the floor and then upwards with thermal plumes when encountering heat sources. Figure 2 shows that particle concentration in the locations close to

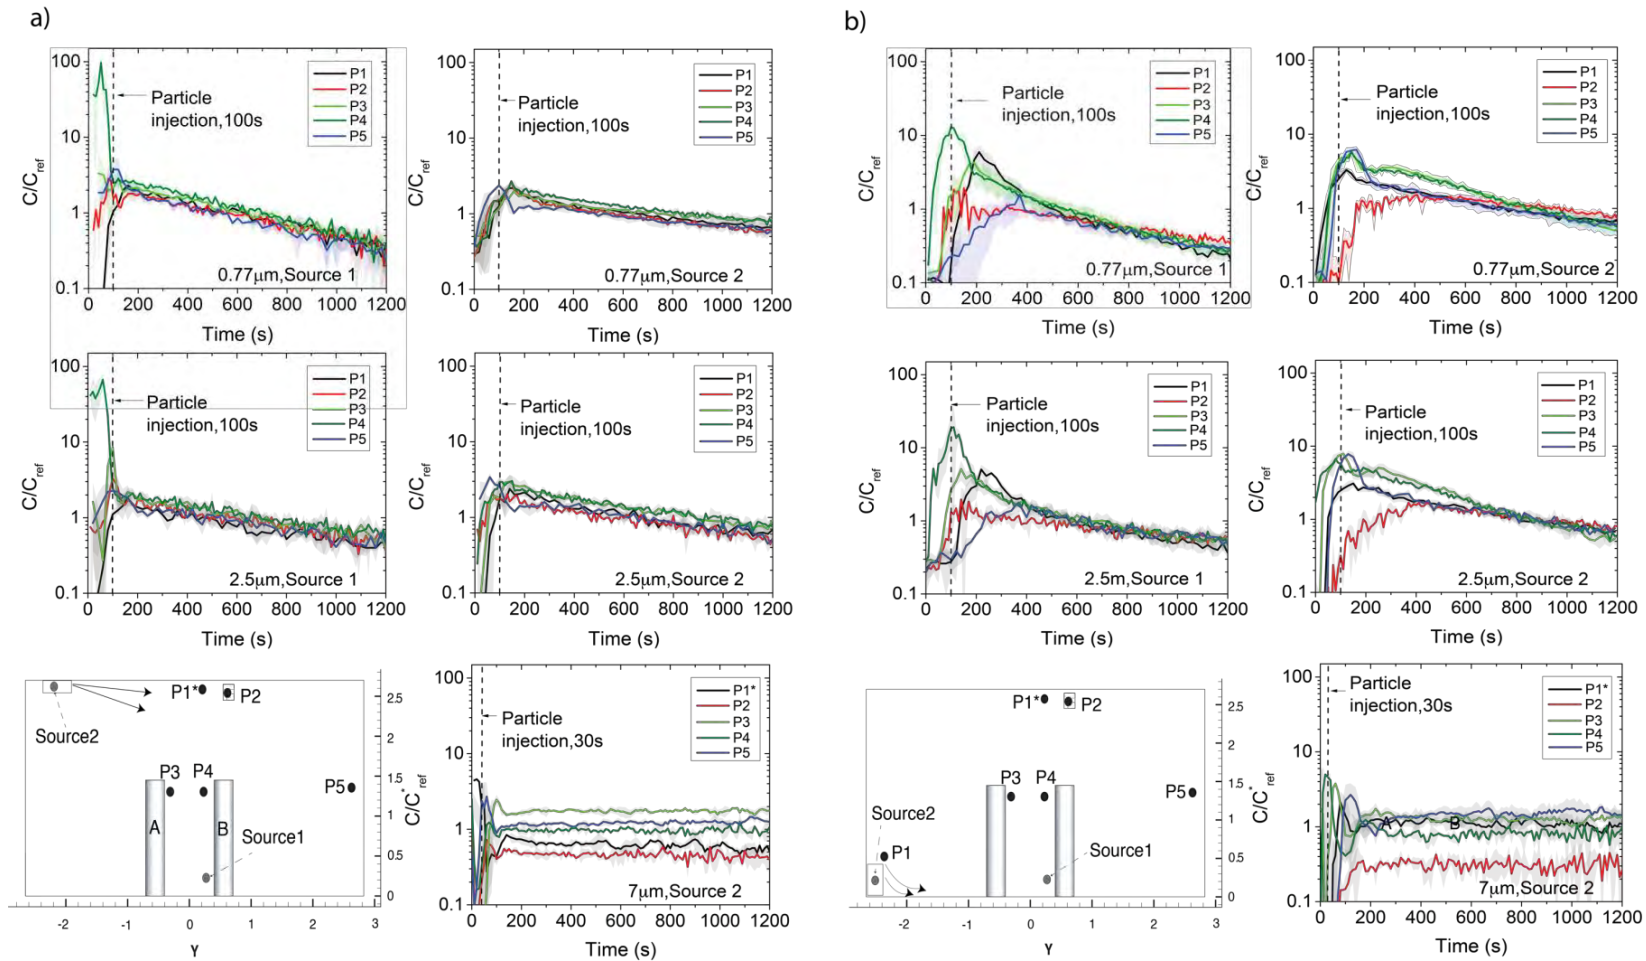

Figure 2. The variation of particle concentration in the room. a) mixing ventilation, b) displace ventilation (cooling condition, ACH=3.2 hr<sup>-1</sup>, exhaust: P2; curve shades represent uncertainty). Note: P2 is the exhaust on a chamber wall, and all other locations are at the central plane of the room

thermal plume such as P3, P4, and P5 are higher than other measured locations during and in the short period after particle injection finishes.

Unlike creating thermal stratification, DV fails to generate stratified concentration for 0.77 and 2.5  $\mu\text{m}$  particles. It is observed in Figure 2 that particle concentrations for the two sizes at all the measured locations decay to the same level in 10 min after particle injection ends. The results suggest that puff-like sources transport  $\text{PM}_{2.5}$  uniformly across a typical office environment shortly after the particle-releasing period, even for thermally stratified systems. Source locations have little effect on the well-mixed assumption for  $\text{PM}_{2.5}$ .

We also measured particle concentration at P1\* that is near the room ceiling and right above the breathing zone (P4) of thermal dummy B. Figure 2 shows that particle (7 $\mu\text{m}$ ) concentration at P1\* is at the same magnitude of that at breathing zones (P3 and P4). The observation implies human thermal plume is able to transport coarse particles (7  $\mu\text{m}$ ) from the floor up to the ceiling level. Again, coarse particles (7  $\mu\text{m}$ ) settle down easily in the indoor environment, and well-mixed assumption is unjustified.

## DISCUSSIONS

Airflow in a typical office with MV distributes uniformly  $\text{PM}_{2.5}$  that constitutes most indoor particles shortly (2 min) after particle injection period. As a stratified system, DV spreads particles generated by puff-like sources and is able to homogenize particle distribution in 10 min after particle generation finishes. The location of particle sources has insignificant influence on the mixing time. However, such phenomena are not observed in the similar indoor environments for continuously releasing sources. For instance, when particles are continuously released in the vicinity of a human manikin, exposure increases significantly compared to other particle sources (Rim and Novoselac, 2009, 2010; Salmanzadeh et al., 2012). These findings assuming continuous particle sources propose a scrutinized investigation in the spatial difference of particle concentration for further exposure analysis. In a real office environment, however, intermittent and short-term puff-like sources, such as walking, body shedding and printing, are much more common than stationary continuous particle sources. The findings from this study imply that  $\text{PM}_{2.5}$  is likely to be uniformly distributed if considering long-term exposure. The findings for  $\text{PM}_{2.5}$  also justify the well-mixed assumption shortly after particle injection ends, regardless of particle location.

In addition, spatial variability of particle concentration occurs during particle injection and only a few minutes afterwards. Such short period makes source-localization that applies inverse tracking techniques more challenging to identify puff-like sources of  $\text{PM}_{2.5}$  or gaseous pollutants (Zhang et al., 2012).

We measured particle transport in a test chamber where interior surfaces might be different in surface roughness and area from offices in reality (Thatcher et al., 2002). In addition, the study considered no furnishing obstructing airflow around particle sources. The findings from this study might be generalized to other short-term puff-like particles sources, such as coughing and sneezing rather than intermittent repeatable sources including breathing and chatting. Other factors such as air change rate per hour, heating source intensity and the number of particle sources might affect particle fate. These factors should be investigated in future.

## CONCLUSIONS

We investigated the fate of particles generated by transient puff-like sources in a test chamber that simulated a typical office environment. We also examined how ventilation pattern, particle size and source location affected particle transport across the room.

This study concludes that both MV and DV can distribute uniformly PM<sub>2.5</sub> released by a puff-like source in the entire room shortly after particle generation finishes. In specific, particle concentration varies insignificantly among different locations in 2 min and 10 min after particle source terminated for MV and DV, respectively. However, gravitational settling generates concentration stratification for coarse particles (7 µm) in the room.

The study justifies the well-mixed assumption for PM<sub>2.5</sub> related to puff-like sources in the indoor environment if considering long-term exposure. In such conditions, long-term human exposure in the microenvironment might not be significantly different from other room space.

## Radon levels in rented accommodation

Torben Valdbjørn Rasmussen<sup>1,\*</sup>

<sup>1</sup> Danish Building Research Institute at Aalborg University, Denmark

### ABSTRACT

Indoor radon levels were measured in 221 homes located in 53 buildings, including 28 multi-occupant houses and 25 single-family terraced houses. The homes consisted of rented accommodation located in buildings recorded as being constructed before 2010 and after the year 1850. In addition, the radon level was measured in the basement in 9 of the buildings.

The mean year value of the indoor radon level was 30.7 (1–250) Bq/m<sup>3</sup>. The indoor radon level exceeded 100 Bq/m<sup>3</sup> in 5.9% of the homes, all located in single-family terraced houses. The variable single-family terraced houses explained 5.9% of the variation in indoor radon levels, and although associations were positive, none of these, besides homes in single-family terraced houses, were statistically significant. Approx. 75% of homes exceeding 100 Bq/m<sup>3</sup> indoor radon level had levels between 100 and 200 Bq/m<sup>3</sup> and 25% had indoor radon levels exceeding 200 Bq/m<sup>3</sup>. Significant differences in indoor radon levels were found in homes located in multi-occupant houses. Additionally, the risk of indoor radon levels exceeding 100 Bq/m<sup>3</sup> in homes in multi-occupant houses was found to be very low, but the risk was highest on the ground floor in a building constructed with slab on ground.

Radon, measurements, homes, rented accommodation, mean year value.

### INTRODUCTION

Radon-222 develops from the radioactive decay of radium-226 and has a half-life of 3.8 days. This noble gas seeps through soil into buildings, and if it is not evacuated, there can be much higher exposure levels indoors than outdoors (Nazaroff, 1992), which is where human exposure occurs (Brunekreef and Holgate, 2002). In this way, radon affects occupants through the indoor climate.

The World Health Organization recommends states to introduce requirements for the maximum concentration of radiation from natural sources in the indoor air. These recommendations are the result of the World Health Organization's evaluation of radon as being responsible for 3-14% of lung cancer incidents, depending on the average radon exposure in different countries (Zeeb and Shannoun, 2009). Results show radon to be the second-largest cause of lung cancer (tobacco smoking is still the primary cause). Radon exposure must be taken seriously in the struggle against radon-induced lung cancer due to the large number of people who are exposed daily in buildings and especially in residential buildings (Zeeb and Shannoun, 2009). If people spend their whole life in a house with an average radon concentration in the indoor air that exceeds 200 Bq/m<sup>3</sup>, their risk of getting lung cancer is higher than 1%. This is far too high and higher than what in other contexts is acceptable for a single-factor risk (Andersen et al., 1997). Therefore, it is crucial to ensure a low radon level in the indoor air and to prevent radon from infiltrating into buildings.

Since 2010, Danish buildings must be constructed so as to ensure indoor radon levels below  $100 \text{ Bq/m}^3$  as the mean year value (Danish Enterprise and Construction Authority, 2010). For all other buildings including homes it is recommended that the mean year value for the indoor radon levels should be below  $100 \text{ Bq/m}^3$ .

In this study, radon levels in rented accommodation were measured in the winter of 2013/14 and again in the winter of 2014/15. The paper shows how well 221 homes for rented accommodation perform, with respect to the Danish Building Regulations for homes constructed after 2010 and with respect to the recommendations for older homes, with regard to radon and to identifying the association between indoor radon in these homes and floor level, multi-occupant houses, single-family terraced houses, and basements. The number of homes with radon levels exceeding 100 and  $200 \text{ Bq/m}^3$  was determined.

## MEASUREMENTS

Measurements were carried out in 221 homes for rented accommodation and in 9 basements. Families and building owners were invited to participate in a radon monitoring programme. The programme took place in the heating periods of 2013/2014 and 2014/2015 between November and May. 196 homes were located in 28 multi-occupant houses and 25 homes were located in single-family terraced houses. Homes were selected from regions where other studies have shown a 1-30% chance of finding detached single-family houses with radon levels exceeding  $200 \text{ Bq/m}^3$ , (Andersen et al., 2001a). Three detectors were distributed to each participant by mail in sealed aluminum-coated envelopes and returned after the integration period in a pre-stamped envelope. Each participant was asked to fill in a questionnaire regarding the date when exposure started and ended, as well as type of room in which the detector was placed. Participants were instructed regarding placement of the detectors ( $>25 \text{ cm}$  from a wall and away from strong draughts and heat) and also instructed to clean and ventilate their homes as they usually would, so that representative levels were obtained. Information regarding year of construction, basement, crawl space, and building and roof materials was gathered from the Danish Building and Housing Register (Christensen, 2011). Information gathered from the Danish Building and Housing Register was used to make sure that homes represented typical rented accommodation in Denmark. In accordance with Danish recommendations for radon measurements in private homes, the simplest assessment of radon concentrations is based on direct integrated measurements (Rasmussen and Wraber, 2011a, Wraber and Rasmussen, 2011b), thus no indirect measurements (geological samples, soil gas measurements, external gamma radiation, etc.) were performed in this study.

## DWELLINGS

Homes were either rented accommodation located in buildings privately owned by landlords or social housing owned by the Danish association of non-profit rented accommodation. Buildings were multi-occupant houses and single-family terraced houses. The buildings represented the building technique and commonly used building materials used in Denmark from 1850 until today. Buildings from this period can be grouped into three types:

- Multi-occupant house built between 1850 and 1920. The buildings were constructed with a solid brick wall founded on masonry foundations. Sometimes single natural stones might be included in the foundations and outer walls. Suspended floors were timber floor constructions. Suspended floors were horizontal partitions and included timber beams. They were traditionally constructed from the top with floor boards, clay infill, wooden boards, empty space, wooden boards and a layer of plaster on straw. The timber beams were usually of good quality with the dimensions approximately

200 mm by 200 mm, see Figure 1. Solid floor against the ground were made of concrete, asphalt or soil.

Figure 1. Suspended floors include from top floor boards, clay infill, wooden boards, empty space, wooden boards and a layer of plaster on straw.

- Multi-occupant house built between 1920 and 1960. The buildings were constructed with solid brick walls or cavity walls founded on cast-on-site concrete foundations. Suspended floors were timber floor constructions, see Figure 1 or reinforced concrete suspended floors cast on site. Solid floors against the ground were made of concrete.
- Multi-occupant house or single-family terraced house built in the period from 1960. The buildings were constructed with load-bearing concrete constructions as prefabricated elements above the ground. Foundations and load-bearing basement walls were made of concrete cast on site. Suspended floors were made of reinforced concrete usually as prefabricated concrete elements. Solid floors against the ground were of concrete cast on site.

## EQUIPMENT

The detectors used were closed passive etched track detectors, made from CR39 plastic film placed inside an antistatic holder. Analysis were carried out by an ISO 17025 and ISO 14001 certified as well as EMAS (European Eco-Management and Audit Scheme) registered laboratory. Measurement methods are accredited according to standards of SWEDAC (Swedish board of Accreditation and Conformity Assessment) and accepted in 18 European countries by the European Cooperation for Accreditation of Laboratories (EAL).

## RESULTS

Radon was measured for a median duration of 90 days (min–max: 60 – 194 days). A single representative indoor radon concentration for each home was calculated as the arithmetic average of the three measurements and used in all statistical analyses.

Table 1 shows the distribution of the determined mean year values of the radon concentration grouped according to floor level in intervals of  $50 \text{ Bq/m}^3$ . The minimum value was  $1 \text{ Bq/m}^3$ , the maximum value was  $250 \text{ Bq/m}^3$ . The standard variation was  $38.3 \text{ Bq/m}^3$ , the median value was  $18 \text{ Bq/m}^3$  and the mean value was  $30.7 \text{ Bq/m}^3$ . The ratio of homes with a mean year value of the radon concentration ranging between  $100 \text{ Bq/m}^3$  and  $200 \text{ Bq/m}^3$  was 4.5%. The ratio of homes with a mean year value of the radon concentration exceeding  $200 \text{ Bq/m}^3$  was 1.4%. The ratio of homes with a mean year value of the radon concentration exceeding  $100 \text{ Bq/m}^3$  was 5.9%.

Table 2 shows the distribution of the determined mean year value of the radon concentration in homes, with a basement or a crawlspace as the lowest level facing the ground, grouped by floor level and in intervals of  $50 \text{ Bq/m}^3$ . The minimum value was  $1 \text{ Bq/m}^3$ , the maximum

value was 206 Bq/m<sup>3</sup>, the standard variation was 32.3 Bq/m<sup>3</sup>, the median value was 17 Bq/m<sup>3</sup> and the mean value was 26.2 Bq/m<sup>3</sup>.

Table 1. The number of homes grouped according to the determined mean year values of the radon concentration is shown by their location, as the floor number, and in intervals of 50 Bq/m<sup>3</sup>.

	0-50	51-100	101-150	151-200	>200	Number of homes
Ground floor	58	18	7	3	3	88
1st Floor	50	0	0	0	0	51
2nd Floor	38	0	0	0	0	38
3rd Floor	30	0	0	0	0	30
4th Floor	6	0	0	0	0	6
5th Floor	8	0	0	0	0	8
Number of homes	190	18	7	3	3	221
Ratio in %	86.0	8.1	3.1	1.4	1.4	100

Table 2. The number of homes, grouped by the determined mean year value of the radon concentration shown by their location and in intervals of 50 Bq/m<sup>3</sup>, in a building with a basement or a crawlspace at the lowest level facing the ground.

Location (floor number)	0-50	51-100	101-150	151-200	>200	Number of homes
Ground floor	42	9	6	2	1	60
1st Floor	43	0	0	0	0	43
2nd Floor	34	0	0	0	0	34
3rd Floor	28	0	0	0	0	28
4th Floor	5	0	0	0	0	5
5th Floor	6	0	0	0	0	6
Number of homes	158	9	6	2	1	176
Ratio in %	89.8	5.1	3.4	1.1	0.6	100

For homes in a building with a slab on ground in the accommodation on the lowest level facing the ground, the minimum value was 10 Bq/m<sup>3</sup>, the maximum value was 250 Bq/m<sup>3</sup>, the standard variation was 53 Bq/m<sup>3</sup>, the median value was 33 Bq/m<sup>3</sup> and the mean value was 50 Bq/m<sup>3</sup>.

Table 3 shows the distribution of the determined mean year value of the radon concentration in homes grouped in intervals of 50 Bq/m<sup>3</sup> for homes located on the ground floor in multi-occupant houses.

Table 3. The number of homes grouped by the determined mean year value of the radon concentration in intervals of 50 Bq/m<sup>3</sup>. Homes were located on the ground floor in multi-occupant houses.

	0-50	51-100	101-150	151-200	>200	Number of homes
Home over basement/crawlspace	42	5	0	0	0	47
Ratio i %	89.4	10.6	0	0	0	100
Home with floor on ground	9	7	0	0	0	16
Ratio in %	56.3	43.7	0	0	0	100

Figure 2 shows the mean year value of the radon concentration in homes measured in the winter of 2013/2014 and in the winter of 2014/2015. Results are shown for homes where the

first measurements showed results exceeding the recommended radon level for homes. Homes were located in single-family terraced houses. The mean year value of the radon concentration was determined with an accuracy of 20 Bq/m<sup>3</sup> to 40 Bq/m<sup>3</sup>.

Figure 2. Mean year value of the radon concentration in homes measured in the winter of 2013/2014 (Red Δ) and again in the winter of 2014/2015 (Blue o). Each accommodation is given a number.

## DISCUSSION

This study found a mean year value of the indoor radon level of 30.7 Bq/m<sup>3</sup> ranging between 1 and 250 Bq/m<sup>3</sup>. In total, 5.9% (13 of the 221) homes had indoor radon levels exceeding 100 Bq/m<sup>3</sup>, all located in single-family terraced houses. The variable single-family terraced houses were statistically significant and explained 5.9% of the variation in indoor radon levels.

The mean year value of the radon level of 30.7 Bq/m<sup>3</sup> is somewhat lower than the population-weighted average annual radon concentration of 59 Bq/m<sup>3</sup> for all Danish homes (Andersen et al., 2001a, b). The population-weighted average annual radon concentration of 59 Bq/m<sup>3</sup> was based on 1-year measurements in 3012 single-family homes and 101 multifamily (apartment buildings) in Denmark.

The present study found the indoor radon level exceeded 100 and 200 Bq/m<sup>3</sup> in 10 (4.5%) and 3 (1.4%) homes, respectively. Approx. 75% of homes with indoor radon levels exceeding 100 Bq/m<sup>3</sup> had levels between 100 and 200 Bq/m<sup>3</sup> and 25% had indoor radon levels exceeding 200 Bq/m<sup>3</sup>. Significant differences in indoor radon levels were found in homes located in multi-occupant houses. The risk of indoor radon levels exceeding 100 Bq/m<sup>3</sup> in homes in multi-occupant houses is very low, but if there is a risk, it is most likely to be found in the lowest accommodation in a building with a slab on ground. A risk of indoor radon levels exceeding 100 Bq/m<sup>3</sup> was found in homes in single-family terraced houses.

The municipalities selected in the present study were previously characterised as having the highest levels of residential radon concentration indoors in Denmark (1–30% of homes with levels over 200 Bq/m<sup>3</sup>) (Andersen et al., 2001a). Measurements showed that the soil type was the main determinant of indoor radon levels (Andersen et al., 2001a, b). The present study did not include measuring radon levels in soil. The homes in this study were located on clayey/sandy to clayey soil, with 2–18% sand and gravel content (Andersen et al., 2001b; Greve and Breuning-Madsen, 1999), and although radon variation in these soils can be expected, this is not described at each specific home location.

The mean year value of the radon concentration in homes was measured in the winter of 2013/2014 and again in the winter of 2014/2015. Measurements were carried out twice in homes where the first measurements showed results exceeding the advised radon level for buildings of 100 Bq/m<sup>3</sup>. These homes were all located in single-family terraced houses. Results from the first measuring period correspond with the results from the second measuring period. However, results show that the radon concentration indoors is affected by seasonal variations and the use of the home.

## CONCLUSION

This study found a mean year value of the indoor radon level of 30.7 Bq/m<sup>3</sup> ranging between 1 and 250 Bq/m<sup>3</sup> in homes in rented accommodation. In total, 5.9% (13 of the 221) homes had indoor radon levels exceeding 100 Bq/m<sup>3</sup>, all located in single-family terraced houses. Approx. 75% of homes exceeding 100 Bq/m<sup>3</sup> indoor radon level had levels between 100 and 200 Bq/m<sup>3</sup> and 25% had indoor radon levels exceeding 200 Bq/m<sup>3</sup>. Significant differences in indoor radon levels were found in homes located in multi-occupant houses. The risk of indoor radon levels exceeding 100 Bq/m<sup>3</sup> in homes in multi-occupant houses is very low, but if there is a risk, it is most likely to be found in the lowest accommodation in a building with a slab on ground. A risk of indoor radon levels exceeding 100 Bq/m<sup>3</sup> was found in homes in single-family terraced houses.

## ACKNOWLEDGEMENT

This study was supported by the Danish association of private landlords of multi-occupant houses and the Danish association of non-profit rented accommodation.

### **ABSTRACT**

Radiant cooling power in the humid climates is inherently limited by condensation. This research investigates a type of radiant cooling methodology whereby the cold temperature source is convectively and conductively isolated from the environment with a membrane transparent to visible radiation to allow supply temperatures to be decreased for radiant cooling systems in humid climates. We conduct an FTIR analysis on three candidate membrane materials and fabricate a prototype experimental test panel that allows for thermal performance evaluation at different panel orientation and depths. Our study shows that for a 5 °C chilled panel temperature, the exterior membrane surface temperature reaches 26 °C in a 32 °C / 70% RH environment resulting in an effective panel temperature of 15.8 °C. Such a panel construction would avoid condensation in many humid environments and allow for radiant cooling without any latent load handling.

### **INTRODUCTION**

Radiant cooling environmental systems are a class of measures and technologies for space cooling in the built environment. They involve exposing building occupants to mechanically-cooled indoor enclosures, or parts of entire enclosures, allowing for a greater degree of heat to be rejected radiatively by the human body to the ambient environment than would otherwise occur. While thermal comfort models demonstrate the potential for radiant cooling systems to provide comfortable conditions in spaces with high indoor air temperatures (de Dear et al. 1996; Arens et al. 2006), in practice generating large air-to-panel temperature differences is hard to achieve without risking condensation occurring on chilled surfaces (Teitelbaum and Meggers, 2017; Feng, 2014). It is for this reason that radiant cooling systems are nearly always combined with mechanical ventilation systems that supply dehumidified air to interior spaces, ensuring indoor air dew point temperatures are sufficiently low to prevent condensation arising on cooled surfaces.

An alternative solution to mitigating the risk of condensation can be found through a more focused investigation of the specific radiant heat transfer and convection processes occurring within and around radiant panel assemblies. In 1963, Morse (Morse, 1963) described a new type

of radiant cooling panel for the tropical environments of Australia, whereby a membrane transparent to long wave infrared radiation is used to enclose, or isolate, the cold panel from the warm, humid ambient air as shown in figure 1a. Since the radiant panel and humans emit in the longwave regime, typically defined as wavelengths between 2.5 and 50 microns, their radiation is able to exchange proportionally to the transmissivity of the membrane. If the enclosure volume would be sufficiently large, and filled with dry air, internal convection would not be significant enough to lower the surface temperature of the membrane below the ambient dewpoint temperature of the interior space, thereby preventing condensation.

Today, whilst there are some emerging commercial applications of Morse's original idea (interpanel, 2018), there remains a lack of understanding of the spectral quality of potential membrane materials and how different material and geometric configurations of such panel assemblies affect overall radiant cooling flux and condensation risks. This paper presents an empirical study which expands on Morse's original chilled panel design by carrying out: 1) Fourier Transfer Infrared (FTIR) Spectroscopy analysis of infrared transparent materials to select the most suitable, common building material for a future panel membrane; and 2) an experimental study of the radiant flux achieved with a prototype radiant cooling panel against varying geometric parameters such as the distance between the membrane and chilled panel, and the vertical/horizontal orientation of the panel itself.

The objective of the overall study is to identify a potentially *optimal* radiant cooling panel design which would provide the greatest cooling flux in a very hot and humid environment without condensation occurring.

## MATERIALS AND METHODS

Figure 1: (a) Original infrared transparent radiant cooling panel (Morse, 1963). (b) Test panel prior to black paint. (c) Finished panel with the PP membrane. (d) Visible image of the author holding a sample PP membrane sheet (background) in comparison to the equivalent infrared image of the scene (foreground)

### FTIR Analysis

Many common household materials are transparent to longwave infrared radiation, such as high density polyethylene (HDPE) trash bags and low density polyethylene (LDPE) or polypropylene (PP) bottles. However, the comparatively large wavelengths for infrared radiation and correspondingly low frequencies contribute to faster extinction and absorption of the radiation in materials, so it becomes difficult to select these materials for a potential infrared transparent membrane without a detailed representation of their individual spectral properties. Three specific types of prototype LDPE, PP, and HDPE panels were procured for this research, respectively United States Plastic, 1/32" LDPE #42568; United States Plastic, 1/8" HDPE #42587 and a 50 micron-thick polypropylene panel produced proprietarily for interpanel GmbH, FTIR spectroscopy was conducted using a Nicolet i10 infrared spectrophotometer to measure the wavelength-based transmission spectra for each material between 2.5 and 15 microns. The FTIR transmission spectra was overlaid with a true black body emission curve to visualize the ability of each membrane to transmit radiation between the panel and a human. The resulting curve is a true spectral radiance diagram providing radiant power per steradian per micron. Integrating the curve numerically between the measured wavelengths provides a panel radiance value, in units  $\text{W/m}^2/\text{sr}$ . Assuming a Lambertian emission function over an arbitrary hemisphere about any point on the panel provides the integration constant for converting radiance to radiant exitance as  $\pi$ , providing a panel radiant power in  $\text{W/m}^2$ . This number is calculated for a panel of a known temperature through each candidate membrane. Dividing this number by the radiant exitance of a true black body provided the hemispherical transmissivity,  $\tau$ .

### Panel Evaluation

Figure 2: Schematic of panel and sensor layout on cross section up “upwards” facing panel.

Radiant panel frames were constructed with plywood, foam insulation, copper tubing, and aluminum. Douglas fir lumber was fashioned into a 53 by 20 cm open-face box, 7 cm deep with a 1.3 cm plywood back. The framing wood was 3.9cm thick, providing interior panel dimensions of 45.7 by 12.1 cm. Inside the open faced box, 3 cm foam insulation was cut to fit flush along the back of the frame, followed by a piece of 0.8 mm thick aluminum cut to fit flush against the pink insulation. This provided a base panel depth of 3.5 cm from the front face to the aluminum. A straight through copper pipe was then inserted through the top of the frame into the box,

shown in figure 1. This copper pipe contains the chilled flowing fluid. The interior of the box was then spray painted black to make the metallic surfaces emissive ( $\epsilon = 0.95$ ). A schematic of the cross section of the panel is shown in figure 2.

The performance evaluation of the panel was carried in a 1.5 x 2 x 2 meter room at the Embodied Computation Lab of Princeton University. Ultrasonic humidifiers, steam, and the building's in-floor radiant heat were used to generate indoor conditions in the room that would emulate a hot, tropical environment - maintaining an air temperature of 30 to 32 °C and 70 to 80 %RH. Temperature and humidity were continuously monitored with Sensirion's SHT75 temperature and relative humidity sensor ( $\pm 0.3$  °C;  $\pm 1.8$  %RH) and were recorded at 5 second intervals during experimentation.

The radiant panel frames were then outfitted with either HDPE, LDPE, or PP across the top, sealed in a dry environment to minimize humidity inside the dry air gap. The depth between the membrane and panel backing was varied with wooden spacers to allow for 4 different depths: 3.5 cm, 7.8 cm, 9.9 cm, and 12.4 cm. The panels were outfitted with 4 Omega ® Precision Surface Temperature Thermistors ( $\pm 0.1$  °C), one place on the copper pipe, another inside the panel on the metal heat spreader midway between the copper pipe and the panel wall, and two more on the surface above the two inside. In addition, air temperature and relative humidity were measured inside the panel with an SHT75. Measurements were taken for 4 different panel configurations, facing "upwards" towards the ceiling, "downwards" towards the floor, "horizontally" facing a wall with the long dimension parallel to the floor, and "tilted" angled 30° towards the floor.

## RESULTS AND DISCUSSION

### Spectral Analysis

The calculated hemispherical transmissivity at 278 K for LDPE, HDPE, and PP was found to be 0.247, 0.298 and 0.597, respectively. Additionally, their respective thicknesses were 0.76, 3.4, and 0.05 mm. The values for  $\tau$  were then used through the remaining 15-50 microns in the panel's emission spectrum, estimating the full range of thermal radiation transmission at wavelengths above 15 microns. Spectral radiance curves of each membrane material are shown in figure 3, demonstrating, for each candidate membrane material, the predicted radiant heat transfer between a idealized human body at 30 °C and a chilled panel cooled to 5 °C. Blue represents radiation transmitted through the panel, and is replotted below for comparison. Gray area represents absorbed radiation. In the HDPE plot, radiation above the black body line is caused by a measurement error, with random reflection in the laboratory pushing transmission above 100%.

### Panel Evaluation

Despite initial promising images with a thermal camera measuring reasonably low temperatures of a cold source behind each panel (see figure 1c), it was found after the FTIR analysis that, in comparison to PP, LDPE and HDPE are relatively poor transmitters of infrared heat at temperature ranges of 5°C to 30°C. This was an unfortunate finding, as otherwise the LDPE and HDPE materials could be advantageous in being structurally rigid and able to support dual role as both a membrane and part of the structural housing of an entire cooling panel assembly membrane.

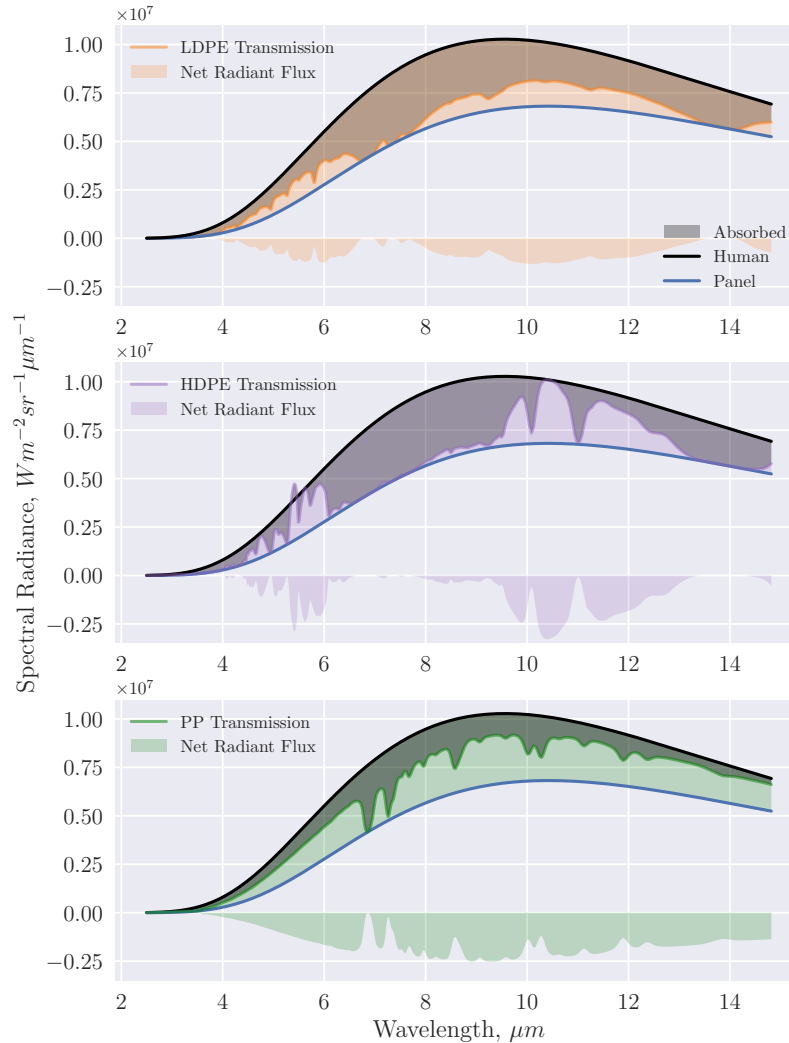

Figure 3: (a-c) FTIR transmission data for each membrane material, LDPE, HDPE, and PP top to bottom, modifying the spectral radiance for a 5 °C panel radiantly exchanging with a 30 °C surface.

The thin PP membrane was therefore the only tested material that was viewed to be able to provide a sufficiently transparent barrier between the chilled panel and ambient environment, and was subsequently used as the membrane for the assembled experimental test panel. Figure 4a shows the temperature profile within the panel at each measurement location for three panel orientations of a 124 mm deep panel outfitted with the PP membrane. The height of each point represents  $\pm$  one standard deviation calculated over 60 sampled points. The outer surface of the membrane always remains above the dew point, confirmed visually and through touch during the course of the experiment that no condensation occurred. Data in figure 4b shows the dependence of the membrane's outer surface temperature on both panel orientation and depth, important design information. There is a rough equivalence between membrane surface temperatures at 99 mm panel depth, implying at this point orientation is a non-contributor. Additionally, horizontally positioned panels do not show much membrane temperature variation. Also on figure 4b is the effective panel temperature of 15.8°C which represents fictitious panel temperature with which a body exchanges. The low value is exciting not only for observing no

condensation at this effective temperature, but it represents a 14 °C gradient from the ambient air temperature, a gradient difficult to sustain with existing technology.

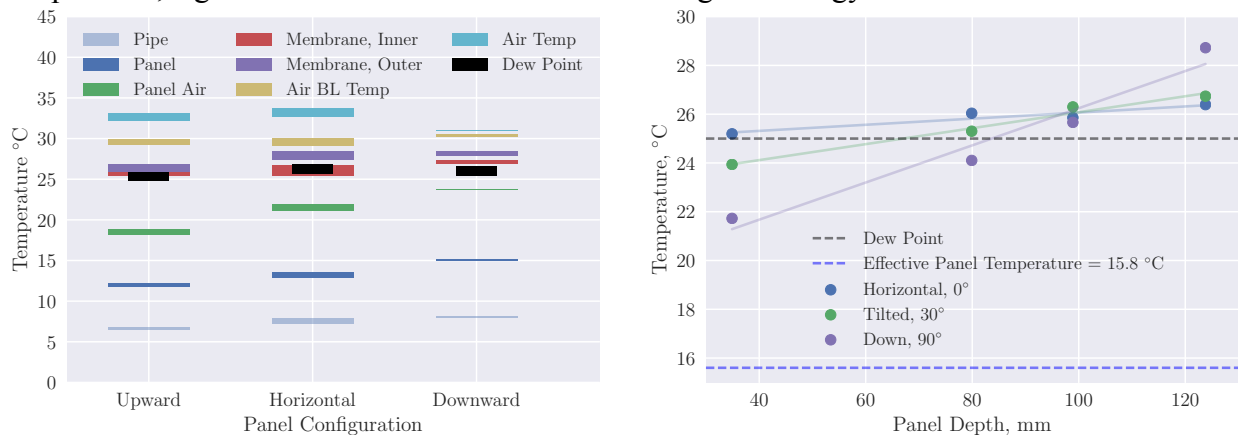

Figure 4: (a, left) Temperature profile within a 124 mm deep panel. The height of each measurement represents +/- one standard deviation of 60 measurements at steady state for each configuration. (b, right) Membrane outer surface temperature measurements for three panel orientations against panel depth.

## CONCLUSIONS

This study was particularly successful at demonstrating required design considerations for increased radiant cooling power through an IR-T membrane in warm and also humid environments. Starting with fundamental understanding about how each membrane influences a body's radiant exchange with a panel with a 5 °C supplied water temperature, and building an applied knowledge base about how to design and operate the type of radiant cooling panel described herein to maximize cooling power while avoiding condensation was achieved. A major result indicates there exist equivalence points between radiation, conduction, and convection, such as the one observed at a 9.9 cm panel depth, whereby membrane outer surface temperatures are the same across all orientations. Future work should seek to further parametrize the data, in particular for panel slenderness ratio of the panel to further improve design guidance. Eventually, a model incorporating FTIR data into CFD analysis, for example, would be worthwhile to create.

### ABSTRACT

Previous studies have demonstrated that displacement ventilation (DV) can provide better air quality than mixing ventilation (MV), and may save energy in buildings. However, since DV introduces supply air to the occupied zone directly, the temperature of supply air it provides is normally higher than in a MV system, so the ability to remove cooling load is limited with the same amount of air. On the other hand, passive chilled beam (PCB) systems have been shown to be able to remove a large cooling load while saving energy. Therefore, this research studied a coupled configuration that combined DV and PCB, and examined its thermal and ventilation performances through the measurements of airflow velocity, temperature, and contaminant (simulated by sulfur hexafluoride, or SF<sub>6</sub>) concentration at various locations. Measurement results were compared with those in the same room but with only DV system. A third set of measurements was also conducted to test how sensitive the results were to room layout and ratio of heat removed by PCB.

Experimental results showed that PCB increased the overall air flow velocity in occupied zone, although the maximum airflow velocity was still observed at floor level, which was similar as in a DV only system. When both PCB and DV systems were used, temperature gradient was observed in most locations of the room. Meanwhile, contaminant concentration stratification was seen to be destroyed by PCB in this experiment. Similar trend was observed in the third set of measurement which had a different room layout and a lower ratio of heat removed by PCB.

### KEYWORDS

Passive Chilled Beams, Displacement Ventilation, Coupled System, Indoor Environment

### INTRODUCTION

Starting from 1980s, displacement ventilation (DV) has been increasingly commonly used in both Europe and U.S. buildings, especially in industrial and office applications (Svensson, 1989; Burt, 2007). Although this ventilation method demonstrated stronger capability in improving air quality and saving energy, when compared with mixing ventilation (MV), one limitation it has is its relatively low ability to remove cooling load, since it supplies fresh air to occupied zone directly. To remedy this weakness, suggestions were made in previous literatures (Riffat et al., 2004; Schiavon et al., 2012) to conjugate DV with other systems. Among the different possible systems to combine DV with, passive chilled beam (PCB) seems to be a very potential option, due to its shown ability to remove large cooling loads (Kosonen et al., 2010). Hence, there needs an investigation on a conjugate system of DV and PCB, to explore how well the merits of these two methods could be integrated.

In the study of indoor environment design, experimentation has always been an important and necessary method for us to understand the physics inside a room, as well as to appraise the

design. For example, to evaluate thermal comfort levels using two well recognized empirical models, PMV (predicted mean vote) (Fanger, 1970) and PD (percentage dissatisfied people due to draft) (ASHRAE, 2013), information on airflow velocity, temperature and turbulence intensity is needed as input. Also, to quantify the air quality via contaminant removal effectiveness, it needs contaminant concentration data at various locations of the room, which could be measured through experiment. Moreover, accurate experimental measurements can provide high-quality data for boundary condition specifications in simulations (such as computational fluid dynamics, or CFD simulations) and model validations.

Therefore, this investigation used experimental methods to measure the airflow velocity, temperature and contaminant (simulated by sulfur hexafluoride, SF<sub>6</sub>) concentration in an indoor air quality (IAQ) chamber which was equipped with the conjugate system of DV and PCB. In the measurement of each type of data, experimental data was collected at 35 locations which were evenly distributed in the chamber that had an office layout. For comparison, a corresponding experiment was performed in the same chamber but with only DV system. This study also explored how sensitive the measured results were to the room layout and PCB cooling power by performing measurements in a third case that had a classroom layout. Through comparing results in the three measurement cases, this study summarized the impacts that PCB made on a DV system in several aspects.

## METHODS

Figure 1. Inside view of IAQ chamber

(a) Office Case\_0 and Office Case\_1

(b) Classroom Case

Figure 2. Room layouts in 3 measured cases (Red box: PC; Yellow box: human dummy)

Figure 1 shows the IAQ chamber where experiments were performed. In the chamber, two displacement ventilation diffusers were installed next to the floor, while the exhaust was placed near ceiling. Two pieces of PCBs were suspended on the central plane of the room, near the ceiling. Heated boxes were used to simulate occupants and computers in the room (Figure 2). Table 1 specifies the total cooling loads, number of heated items, and PCB utilizations in all three measured cases.

Table 1. Cooling loads and PCB utilizations in three cases

Case Name	Total Cooling Load	Cooling load breakdowns (Number of items)			Ratio of Heat Removed By PCB
		Light	Human Dummy	PC	

Office Case_0	61 W/m <sup>2</sup>	4	8	8	0 (PCB not used)
Office Case_1	61 W/m <sup>2</sup>	4	8	8	60%
Classroom Case	30 W/m <sup>2</sup>	4	7	0	40%

Figure 3. Three “loops” that run through the chamber

This experiment designed three loops that ran through the IAQ chamber, which is illustrated in Figure 3. Chilled water was supplied from water reservoir, and after travelling through pipes inside PCB’s, it still returned to water reservoir. Air was discharged into the room via displacement ventilation diffusers. With a developed LabView program, the air flow rate and temperature could be well controlled. Lastly, SF<sub>6</sub> was provided from an SF<sub>6</sub> tank outside of the chamber, and was discharged in the chamber on top of one human dummy (at a height of about 1.1m). All the operations of the three loops could be performed outside of IAQ chamber.

To obtain airflow velocity and temperature data, this experiment employed hot-sphere anemometer probes, whose temperature measurement accuracy is  $\pm 0.3$  °C and velocity measurement accuracy is  $\pm 0.01$  m/s. In addition, a multi-gas sampler, monitor and analyser system was utilized to measure SF<sub>6</sub> concentration at desired sampling points. In each measurement case, data was collected on 5 poles in the room, with 7 heights at each pole.

## RESULTS

This section illustrates and compares the results from the three measurement cases described in the above section. Due to the limit of space in this paper, results from only 3 of the 5 measured poles are demonstrated. However, three locations are sufficient to indicate the air flow characteristics and contaminant distributions in the three measured cases. Results from more measurement locations could be found in Shi and Chen (2018).

### Temperature results

Figure 4(a) shows the temperature distributions in “Office Case\_0” and “Office Case\_1”. “Office Case\_0” demonstrated a very typical temperature distribution in a displacement ventilation case, where a clear temperature gradient could be observed at various locations of the room. Temperature gradient was seen to be largest at near-floor region, especially when the measured locations were relatively close to displacement ventilation diffuser (like Pole 3 and 5), and gradually decreased as the height increased. Meanwhile, in “Office Case\_1”, although PCB was turned on and was removing 60% of heat in the room, temperature gradient was observed as well in three measured locations. This indicated that the cold downward jet PCB generated was pretty local. In addition, it could be noticed that PCB was able to decrease the temperature gradient when “Office Case\_0” and “Office Case\_1” were compared.

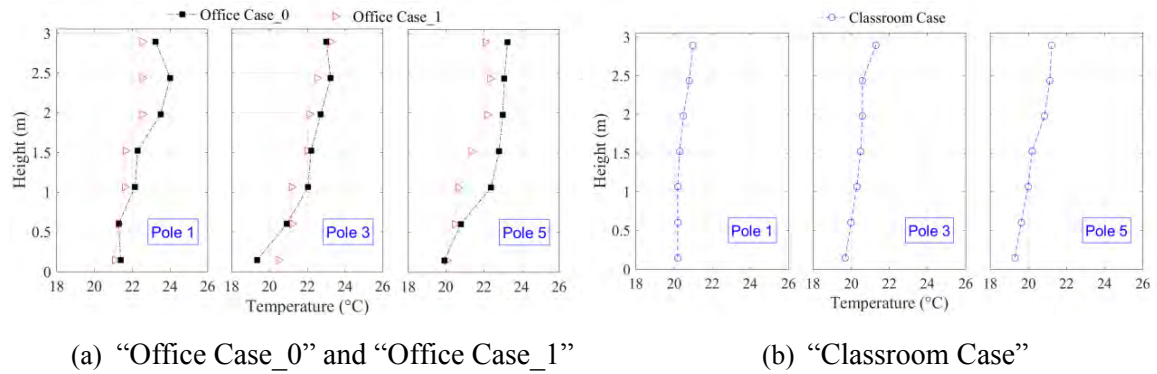

Figure 4. Temperature measurement results

“Classroom Case” also showed similar temperature distribution trend, as can be seen from Figure 4(b), although it had a different room layout and a different ratio of heat removed by PCB.

### Velocity Results

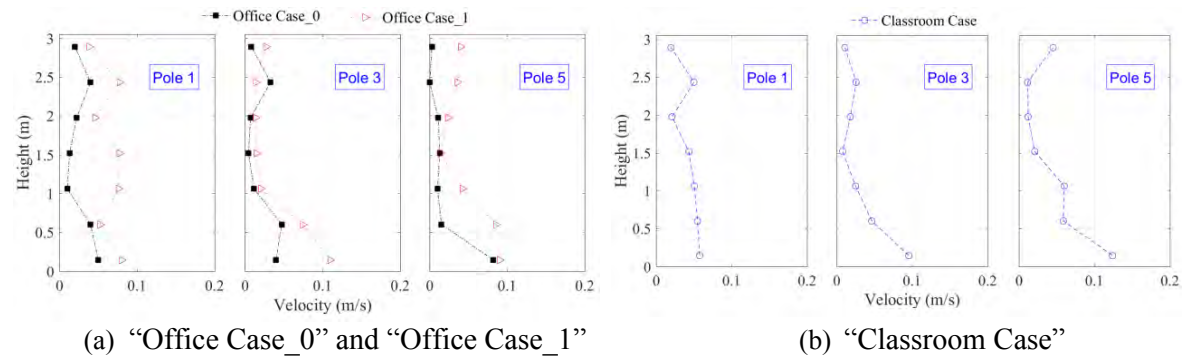

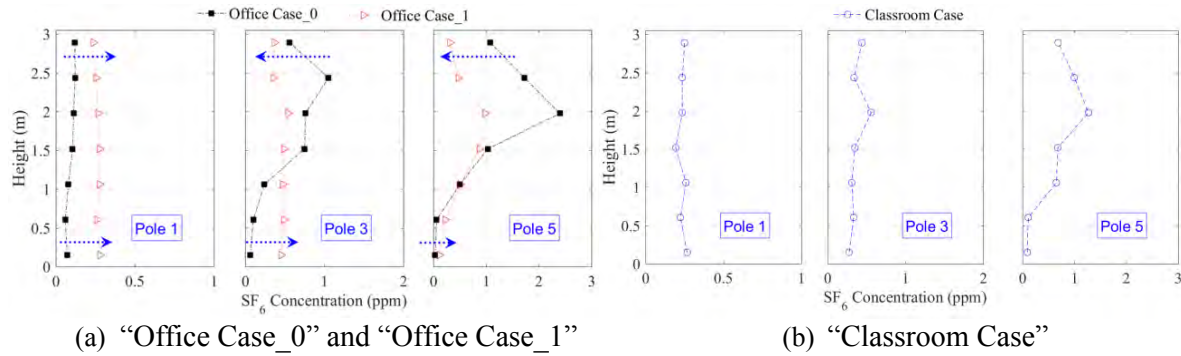

Figure 5. Velocity measurement results

Figure 5 illustrates velocity distributions in three measured cases. Again, results in “Office Case\_0” showed a typical velocity distribution in a displacement ventilation, in which airflow velocity was largest near floor, and became very small as the height enters occupied zone. However, when PCB was turned on, although largest airflow velocity was still observed at floor level, PCB seemed to increase the airflow velocity in occupied zone, as could be observed in the comparison in Figure 5(a). This could be because the air movement was intensified by entrainment induced by PCB downward jet, which could also explain why airflow velocity was seen to have increased more at poles placed close to PCB than poles placed further away from PCB.

Airflow velocity distribution in “Classroom Case” showed a similar trend as “Office Case\_1”, and its airflow velocity magnitude in occupied zone was seen to be between “Office Case\_0” and “Office Case\_1”.

### Contaminant Concentration Results

Figure 6. SF<sub>6</sub> measurement results

Contaminant concentration distributions are demonstrated in Figure 6 (Note that scales in plots of three poles are different.). Results showed that in “Office Case\_0”, there was a clear contaminant stratification at locations (e.g. Pole 3 and Pole 5) close to where SF<sub>6</sub> was released. At locations that were relatively far away from SF<sub>6</sub> release location, SF<sub>6</sub> concentration was seen to be always low from floor to ceiling levels. This could be explained by the fact that in a DV system, contaminant is lifted to the upper part of a room until leaving the room through exhaust, which verified the satisfying contaminant removal effectiveness of DV.

When PCB was turned on, however, the contaminant stratification seemed to be weakened, as observed at Pole 5. Meanwhile, at locations that were further away from PCB, overall SF<sub>6</sub> concentration was seen to be increased, although the concentration level was still quite similar from floor to ceiling. This was because PCB, while turned on, generated downward jet and pushed SF<sub>6</sub> from top region to the lower region of the room. As a result, the SF<sub>6</sub> that was pushed down could re-distribute itself after it hit the floor or desk, and moved horizontally to other locations. In “Classroom Case”, the SF<sub>6</sub> distribution was seen to be similar as “Office Case\_1”. The concentration levels at different locations, though, were about in between “Office Case\_0” and “Office Case\_1”, which could be due to that the ratio of heat removed by PCB (40%) in “Classroom Case” was in between of 0 and 60%.

## DISCUSSIONS

This investigation reported detailed measurement results of airflow velocity, temperature and SF<sub>6</sub> concentrations at three experimental cases, which was valuable for improving the understanding of ventilation and thermal performances of a combined system of DV and PCB. To better evaluate an indoor environmental design, however, there might need more analysis of the measured data by employing indices for appraising thermal comfort and indoor air quality, such as PMV and contaminant removal efficiency. Besides, although measurements took place at as many as 35 locations in each of the measured cases, the resolution of data obtained from measurements was relatively low as compared to a validated CFD simulation. Therefore, at a later stage, adopting indoor environmental appraisal indices and employing CFD method would yield an even more comprehensive study to the current research.

## CONCLUSIONS

This research leads to the following conclusions:

- (1) With the experimental apparatus that was set up in this research, detailed measurements could be performed to obtain airflow velocity, temperature, contaminant concentration

data in the IAQ chamber. Results from “Office Case\_0” showed a typical airflow and contaminant distribution in a DV only system.

- (2) While PCB was used together with DV system, large temperature stratification was observed in most regions of the room, although PCB could produce a local downward jet. Besides, the downward cold jet was able to entrain ambient air, which resulted in slightly increased airflow velocity in occupied zone.
- (3) Experimental results showed that PCB, while turned on, could weaken or even destroy the contaminant stratification built up by DV. The higher percentage of heat was removed by PCB, the more the contaminant stratification appeared to be destroyed.
- (4) This research demonstrated that the observed impacts of PCB made in an office layout was also seen in a room with a different room layout, as could be observed in “Classroom Case”. Therefore, conclusions (2) and (3) could still apply when room layout changes.

### **ABSTRACT**

We have recently demonstrated a new type of moisture absorber using a silicone-based liquid desiccant and a nonporous hydrophilic membrane. The setup consists of a core-shell structure where the desiccant flows inside the hydrophilic membrane (core) surrounded with humid air and confined inside a larger diameter tube (shell). In this work, we propose to extend the capabilities of this moisture absorber prototype by addressing two additional characteristics in order to fully validate its capabilities in the built environment. In the first section of this study, we developed a new setup to demonstrate the regeneration process of the liquid desiccant. The regeneration process takes into account the following parameters: (i) air temperature and relative humidity level, (ii) desiccant temperature and water saturation amount, (iii) air/desiccant contact length, (iv) air and liquid desiccant flow rates. In the second part of this paper, we extend our earlier work with this absorber and propose to further improve its performance. We investigate in detail the water absorption kinetics to favor water access to the bulk liquid desiccant surface through efficient mixing inside a confined volume.

### **KEYWORDS**

Liquid desiccant; hydrophilic nonporous membrane; dehumidification; absorption/desorption kinetics.

### **INTRODUCTION**

The global demand for air conditioning is expected to increase drastically over the next 30 years according to recent studies conducted (Shah et al., 2015). This is predominantly attributed to the rapid economical growth of developing countries in Latin America (e.g. Brazil, Mexico), and Asia (e.g. China, India), which are located in hot and humid climate zones (Shah et al., 2015). To effectively cool buildings using existing Heating, Ventilation, and Air Conditioning (HVAC) systems, a major requisite is controlling the humidity level, commonly known as latent loads. In highly-populated geographical zones, excluding desert climates, latent loads require several times larger energy amounts than sensible loads (Harriman et al., 1997). Nevertheless, conventional HVAC technologies address both loads within the same system using a sub dew point vapor compression air conditioner (Meggers et al. 2013). Overall, this process is energy intensive, and better suited for climates with high latent loads. A promising alternative for dehumidification in the built environment is the use of liquid desiccant technologies which present several advantages over traditional solid desiccant wheel systems available on the market (Lowenstein, 2008; Pantelic et al., 2018). Due to their physical and chemical properties, liquid desiccants have the unique capability of being adaptable to the host environment, and can therefore be easily deployed. Another

important characteristics of liquid desiccant is their ability to be regenerated at a different location from where dehumidification takes place.

In a recent study, we have demonstrated the capabilities and advantages of a liquid desiccant absorber prototype where the two key components are: (i) a noncorrosive alkoxyated siloxane liquid desiccant, (ii) a nonporous hydrophilic membrane to contain the desiccant (Ahn et al., 2013; Pantelic et al., 2018). We have demonstrated that such a system can effectively remove moisture from the air, while also solving carryover problems and eliminating the need for noble metal parts. However, we also pointed out the need to investigate the direct regeneration capabilities of the desiccant after exposure to moisture. In addition, we have mentioned the possibility to further improve the kinetics of water absorption into the desiccant by analyzing the different diffusion mechanisms taking place in the system.

In this work, our objective is to address these two remaining aspects that are required for a successful and complete implementation of this new generation of liquid desiccant absorber. In the first part of this paper, we demonstrate preliminary experimental results that support the regeneration potential of the liquid desiccant under easily achievable experimental conditions. Then, we discuss the remaining improvements and future work required to determine the ideal parameters for the water desorption process. In the second part of this manuscript, we describe a new manifold concept that will be tested to improve the kinetics of water absorption into the desiccant, and improve the dehumidification performances of the device.

## METHODS

The liquid desiccant regeneration setup shown in Fig. 1 consists of the following main components: (i) alkoxyated siloxane liquid desiccant, XX-8810 (Dow), (ii) commercially available nonporous hydrophilic tube, Pebax® 1074 (noted Pebax in the following sections) (Foster Corporation) with 1.50 mm outer diameter, (iii) clear Polyvinyl Chloride (PVC) tube (Advanced Technology Products) with 6.35 mm outer diameter, and inside which the Pebax tube is located.

Figure 1. Diagram of the experimental setup used for the desiccant regeneration.

The liquid desiccant was fed through the Pebax membrane at controllable flow rates using a syringe pump (Harvard Apparatus). The air flow was measured with a gas flow meter (Sensirion SFM 4100), and the temperature (T), relative humidity (RH) of the air were acquired with Sensirion SHT75 type sensors. All raw data were recorded through an Arduino Uno board interface for subsequent analysis.

The desiccant regeneration experiments were carried out by feeding supply air around the Pebax tube which was confined inside a PVC tubes (Fig. 1). The liquid desiccant at room temperature, and saturated with 3 wt.% deionized water was flowing inside the Pebax at various flow rates. The supply air was directly taken from the in-house laboratory system and

subsequently heated through a hot water bath prior to contacting the Pebax membrane. During the desiccant regeneration experiments, we recorded the T and RH of the air before ( $T_i$ ,  $RH_i$ ) and after ( $T_f$ ,  $RH_f$ ) contacting the Pebax membrane across a defined contact length. For all experiments, the supply air and desiccant flows were in counter flow configuration. We let at least about a 15 minute gap between each experiment to ensure that the system was at equilibrium. The air flow rates were determined such that they would be within the range of rates previously used for dehumidification (Pantelic et al., 2018). Two air/desiccant contact lengths of 10 and 30 cm were studied. All experiments were carried out inside a fume hood where the T was near 20 °C and RH fluctuating between 2 and 6%.

## RESULTS & DISCUSSIONS

### Desiccant regeneration experiment with 10 cm air/desiccant contact length

In Table 1, we summarize the first series of the results collected using the setup described in Fig. 1. Experiment A corresponds to the baseline T and RH measurements in the absence of air and desiccant flow. The high humidity value of  $RH_f$  is simply due to the location of the sensor inside the fume hood, i.e. closer to the higher RH indoor environment of the laboratory. In experiment B, no change in  $RH_f$  is observed after running the desiccant (with 3 wt.% water) through the Pebax tube, and in the presence of air flow around it. This clearly indicates no desorption of the water (absorbed in the desiccant) through the hydrophilic membrane. Therefore, in the subsequent experiments, B-E, the liquid desiccant flow rate was progressively decreased by a factor of 2, while maintaining the air flow constant. Despite lower desiccant flow rates, experiments B-E do not result in any obvious water desorption. Therefore, in experiments F and G, we further increased the air flow rate by a factor of 2 to reach higher Reynolds numbers. Yet, higher air flow rates combined with low desiccant flow rates do not result in a water desorption mechanism. All results obtained with 10 cm contact length appear to indicate that the region of air/desiccant contact is insufficient to allow the desorption process to take place.

Table 1. Summary of experiments for 10 cm air/desiccant contact length.

Experiment	Desiccant Flow Rate (L/s)	Air Flow Rate (L/s)	$T_i$ (°C)	$RH_i$ (%)	Desiccant Injection Time (s)	$T_f$ (°C)	$RH_f$ (%)	Duration of Experiment (s)
A	0	0	20.98	2.40	N/A	20.88	6.48	5
B	$1.30 \cdot 10^{-5}$	16.67	43.99	1.66	105	22.24	0.83	260
C	$0.65 \cdot 10^{-5}$	16.67	43.47	1.64	105	22.33	0.90	250
D	$1.67 \cdot 10^{-6}$	16.67	43.49	1.64	105	22.33	1.04	215
E	$0.84 \cdot 10^{-6}$	16.67	43.32	1.63	105	22.35	1.13	220
F	$0.65 \cdot 10^{-5}$	33.40	43.75	1.56	105	21.67	0.27	380
G	$0.84 \cdot 10^{-6}$	33.40	45.15	1.53	105	21.5	0.15	330

### Desiccant regeneration experiment with 30 cm air/desiccant contact length

In these series of experiments, we maintained the desiccant flow rate as low as  $0.84 \cdot 10^{-6}$  L/s and studied the effect of 33.40 and 16.67 L/s air flow rates. The Reynolds number corresponding to the flow rates of 33.40 and 16.67 L/s are  $4.3 \cdot 10^5$  and  $8.6 \cdot 10^5$ , respectively. These results are shown in Fig. 2. When the air flow rate is as low as 16.67 L/s, there is a possible water desorption process taken place, as confirmed by the higher  $RH_f$  values. In this case, the increase in absolute humidity is about 23.10 mg/m<sup>3</sup>. Although the difference between  $RH_i$  and  $RH_f$  is about 10%, we acknowledge that this RH range is within the domain where readings from the sensor can reach up to 4% error. Nevertheless, in all experiments,

including the first series with 10 cm contact length, we have obtained consistent and reproducible data. Therefore, we expect the results obtained with 30 cm contact length to support an effective water desorption process which tends to support the possible regeneration of the alkoxyated siloxane desiccant.

In the next series of ongoing experiments, we plan to investigate the effect of larger air/desiccant contact lengths to confirm these preliminary results. In addition, we will also increase the RH value of the air to reach 10% or more RH. This will ensure that we are in the range where the sensors are the most accurate.

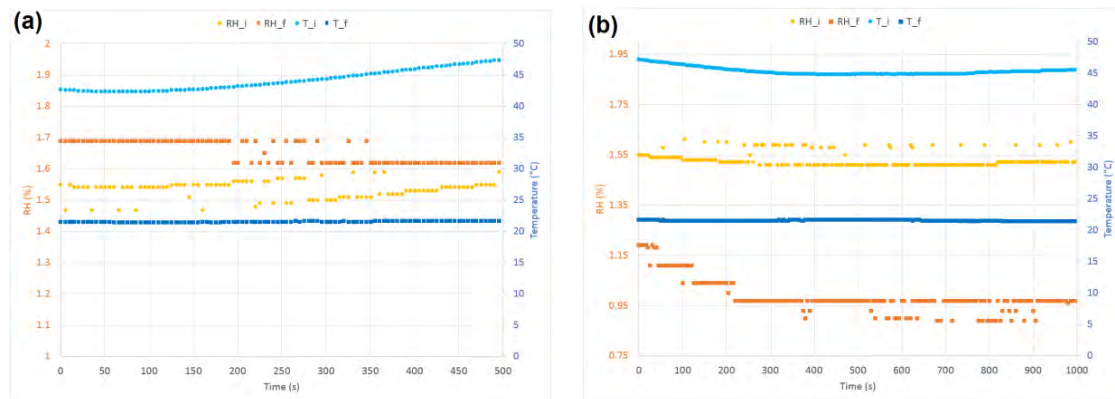

Figure 2. Water desorption experiments for 30 cm air/desiccant contact length. Air flow rate of (a) 16.67 L/s, and (b) 33.40 L/s.

### Improving the performance of the dehumidification prototype

In parallel to the desiccant regeneration experiments, we are currently exploring solutions to enhance the overall performance of the dehumidification system described in our previous study (Pantelic et al., 2018). To achieve this goal, we propose to improve the kinetics of water absorption into the desiccant by designing a chamber to enhance the mixing of the desiccant, and thus to effectively use its total volume for water absorption. The new desiccant mixing chamber is represented in Fig. 3. This initial design includes four inlets for the Pebax and PVC tubes. In our ongoing experiments, our objective is to test the dehumidification performance of the absorber under similar conditions to our earlier study (Pantelic et al., 2018), and directly evaluate the anticipated advantages of the mixing chamber.

Figure 3. Technical drawing of the 3D printed manifold, with dimensions in mm. (a) Top view, (b) Cross-sectional view of the chamber showing the 1.75 mm inlets for the Pebax tubes.

## CONCLUSIONS

In this study, we have covered two fundamental characteristics of the liquid desiccant-based dehumidification prototype. In the first part, we have demonstrated preliminary and ongoing experiments to investigate the regeneration process of the alkoxylated siloxane liquid desiccant in the presence of 3 wt.% water. The preliminary results appear to confirm that at least a 30 cm air/desiccant contact length is necessary to effectively evidence the water desorption. We are currently in the process of evaluating the effect of larger contact lengths on the water desorption from the desiccant.

In the second part of this work, we presented the potential of a new mixing chamber for the liquid desiccant. This chamber is expected to improve the water absorption kinetics by favoring water access to the bulk liquid desiccant surface through mixing. The initial results presented in this paper are still the subject of ongoing research. We expect to complete the two research directions described here and successfully demonstrate the dehumidification and regeneration capabilities of this new generation of liquid desiccant prototype.

## ACKNOWLEDGEMENT

This project is supported by the Intellectual Property Accelerator Fund of the Office of Technology Licensing at Princeton University.

### **ABSTRACT**

In hot and humid regions, in order to provide indoor thermal comfort conditions, most important design strategies are to maximize shady areas and natural ventilation. Courtyard building form was developed mainly in response to climatic requirements especially in hot climates. A courtyard is an unroofed area that is completely or partially enclosed by walls or building spaces. The function of the courtyard is to improve comfort conditions by modifying the microclimate around the building. The proportion of the courtyard affects considerably the shadows produced on the building envelope, and consequently the received solar radiation and the comfort conditions in the building. Moreover, courtyards are claimed to be highly effective in enhancing the ventilation and decreasing humidity level. This study intends to investigate variations in indoor thermal conditions according to different design configurations and scenarios. All calculations are made for a surrounded space of the courtyard. Thermal comfort conditions of this space are evaluated according to its orientation, ventilation type and courtyard configuration. In the study, different courtyard proportions, orientations and ventilation types are developed. Indoor comfort conditions of the selected space are calculated for Antalya which is a representative city of hot and humid region of Turkey. The software EnergyPlus, is used as a tool for simulating the thermal performance of the selected space. Operative temperatures, indoor humidity, and solar gains are calculated by using this dynamic thermal simulation program and a comprehensive evaluation on the aspects of thermal comfort conditions is carried out. In conclusion, the importance of the systematic approach in order to optimize the decisions taken during the design stage of thermally comfortable and conservative buildings is discussed.

### **KEYWORDS**

Courtyard building, hot-humid climate, thermal comfort conditions, orientation

### **1. INTRODUCTION**

The number of new residential buildings has been growing steadily in the southern coastline of Turkey with hot and humid climate conditions due to increasing population. However, contrary to traditional buildings, construction of new buildings without due consideration of energy efficiency and climate responsive criteria increases energy costs and presents itself as an important consequence. Since most of the energy in buildings is used for heating and cooling, reducing consumptions in this area and achieving energy efficiency in buildings have become a priority (Yılmaz, 2007; Manioğlu and Oral, 2015). Reducing energy consumption in residential buildings is possible through taking correct decisions about energy efficient design variables (Kocagil and Oral, 2015).

One of the most effective ways to have thermal comfort conditions in buildings is to design climate responsive buildings according to existing climate conditions for each climatic region (Lechner, 2014). Protection from the heating effect of sunlight and mitigating the effect of excessive humidity in hot-humid climatic regions play an important role in ensuring comfort conditions. In this climatic region, buildings with courtyards are frequently preferred to reduce the area of façades which are affected by solar radiation. It is possible to create shades in the courtyard during the day with spaces surrounding the courtyard and high walls that separate the courtyard from the street. Courtyard dimensions and courtyard orientation are determinant factors to locate shades within the courtyard. When courtyard dimensions change, heat loss and gain through courtyard walls and thus indoor comfort conditions will also change (Muhaisen, 2006; Muhaisen and Gadi, 2006).

The courtyard form has a configuration that also supports natural ventilation (Ghaffarianhoseini et al. 2015). The process of daily changes in temperature and humidity in summer in hot-humid climate regions can be studied in three phases. In the first phase, during the night cool air descends into the courtyard and into surrounding rooms. The courtyard loses heat by radiation. In the second phase, at midday direct sunlight affects the courtyard floor. Some of the cool air begins to rise and leaks out of the rooms. This induces convective currents in rooms. At this phase, the courtyard acts as a chimney depending on its size. In the third phase, the courtyard floor is warmer than interiors and convective currents occur in the late afternoon. After sunset, the air temperature falls rapidly and the courtyard radiates heat and cool air begins to flow to the courtyard and from there to interiors (Gallo et al. 1988; Talib, 1984). During this entire process, due to their effect on solar radiation gain and air movements, courtyard dimensions and sizes of the windows and ventilation types preferred in surrounding spaces have a direct impact on interior thermal comfort conditions (Ok et al. 2007). Therefore, this study evaluates with a parametric approach, indoor comfort conditions of a building with a courtyard in hot-humid climatic region, which are affected and changed according to different courtyard dimensions, different orientation and different ventilation types. Building form and courtyard dimension alternatives evaluated in this study are taken from the author's master's thesis (Bekar, 2018).

## **2. METHODOLOGY**

This study intends to have an approach to evaluate the effects of orientation and ventilation options of a building with varying courtyard dimensions on the thermal comfort conditions in the building. A total of 72 building energy simulations have made by shifting the orientation of the courtyard facing space of 6 building forms with the same courtyard width but different depths to north, east, south and west and by using different ventilation alternatives.

### **2.1 Determining building and climate related variables**

Buildings included in the study are situated on a level land in Antalya with the following coordinates: 30°73'(E) and 36°87'(N). Calculations are made based on the assumption that there are no other buildings that can cast a shade on these buildings and that the buildings are located in the countryside. In the evaluation there are 6 building forms with different courtyards with the same width (400 cm.) but with different depths (50 cm., 100cm., 150cm., 200cm., 250cm., 300cm.). The interior space facing the courtyard with the dimensions 400x400 cm. is the same in every building form. The dimensions of the model created for the study are shown in Figure 1. The transparency ratio on the wall facing the courtyard and the opposing wall is set at 12%. No transparent material is used in other façades in the model. Recommended (TS 825) and existing overall heat transfer coefficients (U values) for Antalya are shown in Table 1.

Figure 1: Dimensions of the building with courtyard model (cm)

Table 1. Recommended (TS 825) and existing U values for Antalya

	$U_{\text{wall}}$ (W/m <sup>2</sup> K)	$U_{\text{ceiling}}$ (W/m <sup>2</sup> K)	$U_{\text{floor}}$ (W/m <sup>2</sup> K)	$U_{\text{window}}$ (W/m <sup>2</sup> K)
$U_{\text{TS825}}$	0.66	0.43	0.66	1.8
$U_{\text{existing}}$	0.633	0.399	0.646	1.5

## 2.2 Determining variables in calculations

The change in comfort conditions when the orientation of this space facing the courtyard is north, east, south and west are analysed. The indoor comfort conditions for 6 different courtyard dimensions and for all orientations (S, W, N, E) when there is one window each on the wall facing the courtyard and the opposing wall (cross ventilation) are evaluated. In the study three different ventilation types are defined: windows are open all day (open between 00:00-24:00); windows are closed all day (closed between 00:00-24:00); and windows are closed during the day and open during night (open between 00:00-09:00, closed between 09:00-21:00, open between 21:00-24:00). There assumed to be 2 occupants in the building and one occupant was present between 08:00 - 19:00 and two occupants were present between 19:00 - 08:00 both during week days and on weekends. Lighting level is set 8 W/m<sup>2</sup> per space.

Calculations of indoor comfort conditions of building models with courtyards with different courtyard dimensions, orientation types and ventilation options were done with EnergyPlus 8.3.0. This is a building energy simulation program with high calculation capacity which uses algorithms such as transfer function, finite difference method and finite elements and with which heating, cooling, lighting, ventilation and other energy flow system can be modelled. Climate data in epw format for Antalya was used in calculations. Operative temperature, relative humidity and solar radiation values on July 21st which represents the hottest day of the year were calculated separately to evaluate the performance of the selected space. Relative humidity and operative temperature values in the spaces with cross ventilation are shown in Figure 2 and total transmitted solar radiation values through windows of the buildings are shown in Figure 3.

## 3. RESULTS

When the courtyard depth changes, operative temperature values in the space depending on whether the window facing the courtyard has a south or north orientation show similarities for all ventilation types. When the courtyard window of the space is east or west oriented and when windows are closed all day and night ventilation is done, operative temperatures increase with the increasing courtyard depth. When the window facing the courtyard is east and west oriented in the models with the same courtyard depth, operative temperature values are higher than those obtained when window is south and north oriented (Figure 2).

The lowest operative temperature values are obtained in the alternatives with night ventilation and the highest operative temperature values are obtained in the alternatives with windows open all day for the models with the same courtyard depth (Figure 2).

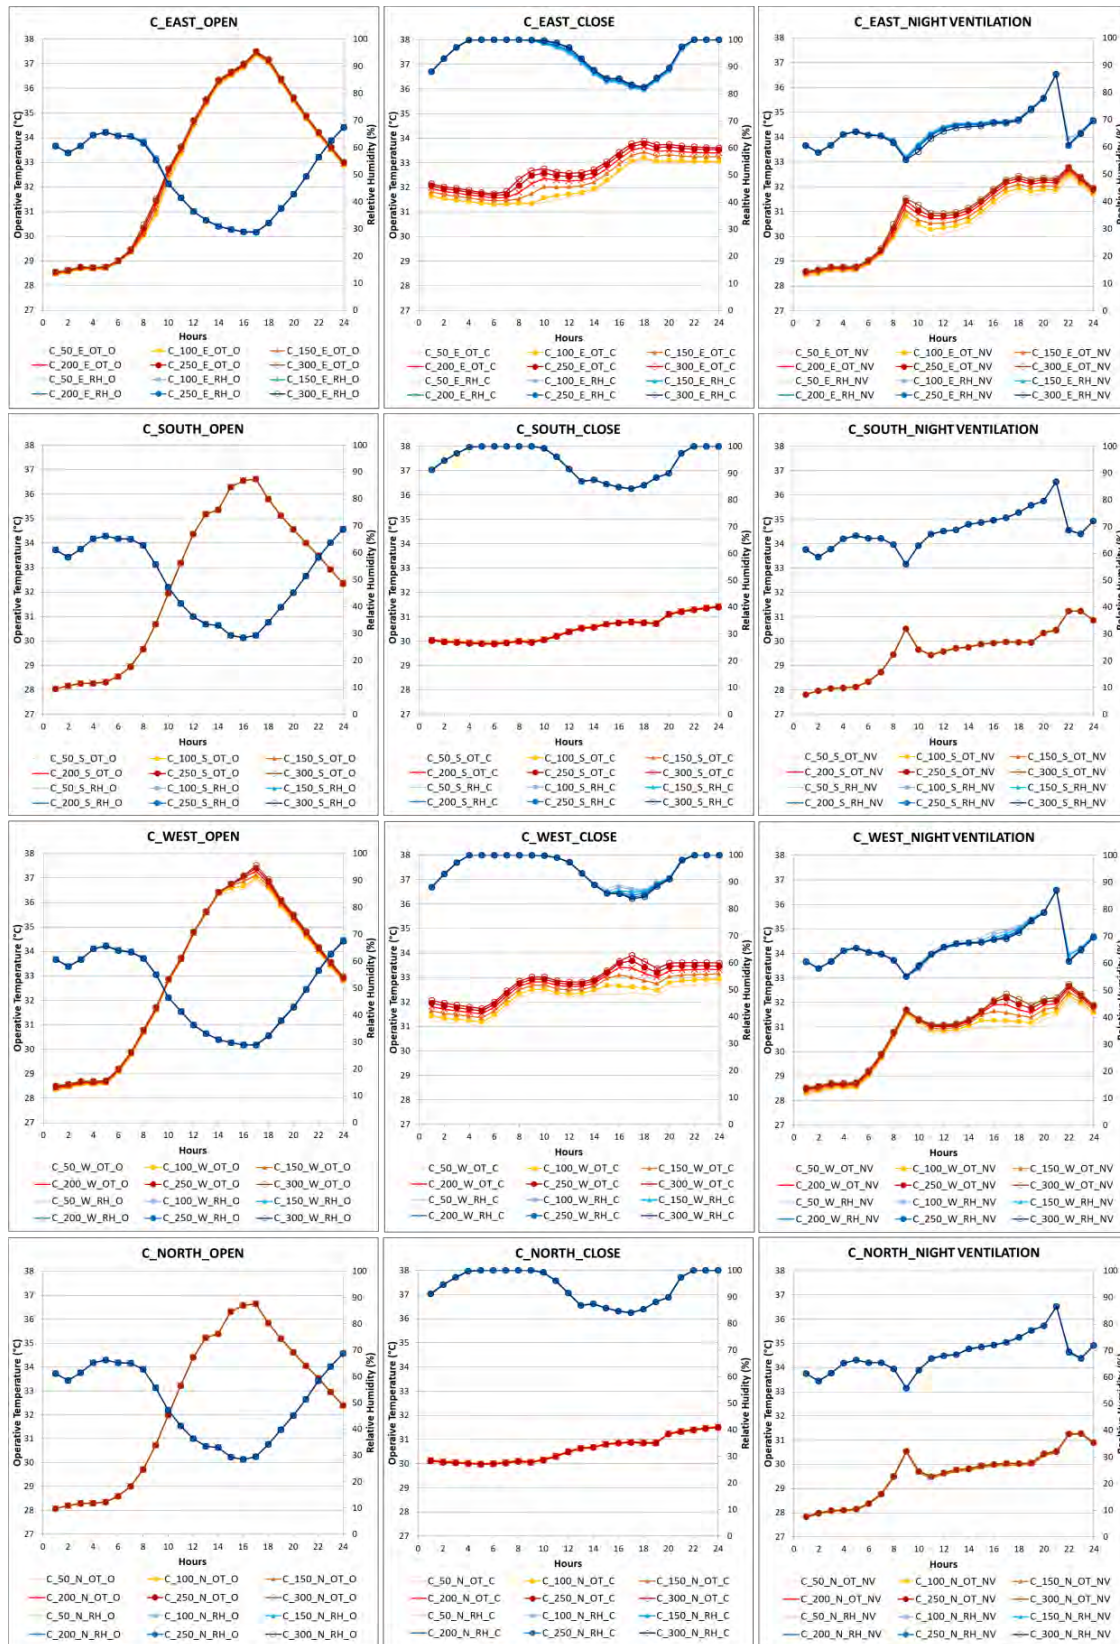

Figure 2. Relative humidity and operative temperature values when windows are open all day (open), closed all day (closed) and with night ventilation

However when a comparison is made for orientation; when courtyard window is west oriented, even if there is night ventilation, lower operative temperature values are obtained between 07:00 - 24:00 hours in all alternatives where courtyard window is north or south oriented and windows are closed all day. The alternative with the lowest operative temperature values is the alternative where courtyard window is south oriented, courtyard depth is 300 cm and night ventilation is used (C\_300\_S\_NV). The alternative with the highest operative temperature values is the alternative where courtyard window is west and east oriented, courtyard depth is 300 cm and windows are kept open all day (C\_300\_E\_O, C\_300\_W\_O) (Figure 2).

When the courtyard depth changes, the relative humidity values in the space, in the case the window facing the courtyard has a south or north orientation, show similarities within themselves when all ventilation types are considered separately. For spaces with east and west oriented courtyard windows; a similar trend continues in the alternative where the window is open all day however in the alternatives where windows are closed all day and night ventilation is done, as the courtyard depth changes, relative humidity values in the space also change albeit small. Relative humidity values in spaces are the lowest in the alternatives where windows are kept open all day and the highest in the alternatives where windows are closed all day (Figure 2).

Figure 3. Total solar radiation values transmitted through windows according to orientation of the windows

When courtyard depth is 50 cm, higher solar radiation values are obtained with south and north oriented windows than with east and west oriented windows. When courtyard depth is 100, 150, 200, 250 and 300 cm., higher solar radiation values are obtained with east and west oriented windows than with north and south oriented windows. Solar radiation values decrease before noon in the alternatives with east facing courtyard window and afternoon in the alternatives with west facing courtyard window and with the decreasing courtyard depth as the opposing courtyard wall casts a shadow. In all models, as the courtyard depth increases, solar radiation transmittance through windows increases. The lowest values are achieved when the courtyard depth is 50 cm and the highest values are achieved when the courtyard depth is 300 cm (Figure 3).

#### 4. CONCLUSIONS

This study examined 72 different alternatives to evaluate the effects of orientation and types of ventilation of a building with varying courtyard dimensions on the thermal comfort conditions in the space. When operative temperature and relative humidity values are evaluated together, the optimum result for indoor comfort conditions is achieved with the alternative C\_300\_S\_NV. The findings of the study are;

- Courtyard dimensions, orientation of spaces facing the courtyard and ventilation alternatives of spaces have a direct impact on the indoor climate conditions and consequently on the energy consumption for cooling.
- Courtyard dimensions in the east and west oriented spaces facing the courtyard have more effect on the change of indoor operative temperature values. Orientation of the space has more effect compared to ventilation options for spaces facing the courtyard.
- When different ventilation types should be selected depending on the building function (office or residential building etc.), the most suitable alternative can be created using different courtyard dimensions and orientation options.
- When the building is used in different times of the day depending on the building function (day or night use) the most suitable alternative can be created using different courtyard dimensions and orientation options.
- Courtyard dimensions affect operative temperature and transmitted solar radiation values through windows depending on the orientation of the space facing the courtyard.

It is possible to identify the most efficient building form alternative, orientation and ventilation option which provide the optimum comfort conditions and minimum cooling loads using the parametric evaluation method discussed in this study. In future studies, designs that provide optimum comfort conditions with minimum cooling energy consumption will be possible by also analysing air movements in building forms using computational fluid dynamic methods.

### **ABSTRACT**

In cold and moderate climates, poorly designed construction joints can lead to local low surface temperatures, which entails local radiant asymmetry. An experiment was set up to test the hypothesis that overall and local thermal sensation is influenced by temperature difference, and position and distance of local radiant asymmetry. In the experiment, 18 subjects participated where they were introduced in a room at 21°C and 45% relative humidity. The subjects were exposed to local radiant asymmetry created by a cooling plate. This plate was positioned at three different heights, and controlled for temperatures at 3, 6 or 10°C below room air temperature. The data was analyzed using general linear modelling.

The results show that thermal sensation is not influenced by local radiant asymmetry directly, but that the deviation from base comfort level is linked to height and temperature of the cold plate, as well as distance of the plate to the subject. This last effect proved to be the strongest. Contrary to what was expected however, participants felt warmer when exposed to local radiant cooling, compared to when not exposed to it. Further research is needed to determine the cause of this effect.

### **KEYWORDS**

Thermal comfort, thermal sensation, radiant asymmetry, experiment.

### **INTRODUCTION**

While renovating existing buildings, planar parts of the building shell are often insulated without proper care for the joints connecting these parts. In cold and moderate climates, poorly designed construction joints can lead to local wall areas with a low surface temperature. These local colder areas lead, next to a higher risk for surface condensation, to radiant temperature asymmetry and can influence thermal comfort of the residents.

McNall and Biddison started the research into radiant asymmetry by placing subjects in a test chamber of which they cooled and heated one wall or the ceiling. They concluded that no significant discomfort could be attributed to radiant temperature asymmetry due to a wall with view factor 0.2 at 11°C colder than the environment. (McNall & Biddison, 1970) Olesen et al. discovered that subjects could sense small degrees of radiant temperature asymmetry, but much larger asymmetry was needed to cause discomfort. (Olesen et al., 1972) Research by Fanger et al. (Fanger et al., 1985) found that cool walls have the largest influence on thermal comfort compared to floors and ceilings. This influence however was relatively limited: if the surface temperature of the cool wall was less than 10 °C under average air temperature, the percentage of people dissatisfied with the environments was less than 5%.

In all these experiments, the asymmetric environment was realized by cooling entire walls. For construction joints, lower surface temperature is only a local effect which can influence only a specific body region. Research has proven that different body regions have different thermal sensitivities. Cooling of the trunk areas of the body (chest, back) strongly affects overall thermal sensation, while the effect is much less noticeable in the bodies' extremities. (Arens et al., 2006) Nakamura et al showed that different parts of the body not only have different thermal sensation, but also have different influences on overall thermal comfort. (Nakamura et al., 2013)

In this paper, a thermal comfort experiment in a semi-controlled environment is reported to test our hypothesis: overall and local thermal sensation are influenced by temperature difference, position and distance of local radiant cooling.

## METHODS

### Subjects

18 subjects (16 men, 2 women) participated in the experiment. Mean subject age ( $\pm$  Standard deviation) was 28.2 ( $\pm$  13.5) years. Average length and weight were 181 ( $\pm$  8) cm and 77.4 ( $\pm$  11.1) kg respectively. Clothing was prescribed for all subjects: short-sleeve T-shirt, non-ripped long pants, underwear, socks and closed shoes. Together with the office chair, the total clothing value was 0.52 according to ISO 9920. (Bureau voor Normalisatie, 2009) During conditioning and testing, subjects had to sit at a desk and perform office work on a computer. This corresponds with 1.2 met according to ISO 8996. (Bureau voor Normalisatie, 2004)

### Conditions

Experiments took place in a 6.4 m x 4.7 m x 4.1 m room with concrete walls at the University of Antwerp, Belgium (test setup in Fig. 1). The building management system controlled air temperature and relative humidity in the room. Average ( $\pm$  standard deviation) air temperature and relative humidity were 21.7 ( $\pm$  0.4) °C and 44.9 ( $\pm$  4.3) %. Radiant temperature was ensured to be equal to air temperature. Air velocity was less than 0.1 m/s at all points.

Plate temperature was based on thermal simulations of typical Belgian construction joints. Setpoints for plate temperature were 0, 3, 6 and 10°C below ambient room temperature.

Fig. 1: Test setup

### Experimental procedure

The experimental procedure is displayed in Fig. 2. Before subjects entered the test chamber, they filled out a preliminary survey in an anteroom. The temperature and humidity in the anteroom was the same as the test room. After this preconditioning, subjects took place in the test room and started their office work. The first 30 minutes in the test room, no test conditions were applied to let subjects acclimatize to the environment. Afterwards, each subject experienced 3 test phase with 1 randomly selected test condition each. A test condition consisted of a set plate temperature, plate position and distance to subject.

**Fig. 2: Experimental procedure**

### Questionnaire

Subjects were asked to fill out a preliminary survey during preconditioning. In this survey, subjects were asked about age, length, weight, caffeine and alcohol consumption, sleep duration and quality and whether subjects were often warm or often cold.

Subjects had to fill out a questionnaire every 15 minutes, and at 10 and 25 minutes in the conditioning phase. A 5-level scale was used to rate overall and local thermal sensation (TSV) and change preference. A 7-level scale was employed to rate overall thermal comfort (TCV). Overall and local draft perception was noted as yes-no choice, just as acceptability. Local TSV and draft perception had to be rated for 9 different body regions (head, neck, chest, upper arm, lower arm, hand, upper leg, lower leg, foot). These scales were selected because of their widespread use in similar experiments. (Van Craenendonck et al., 2018)

### Analysis Methods

Linear regression (McDonald, 2015, pp. 190–208) and chi-square tests (McDonald, 2015, pp. 59–67) were used to determine the influence of demographic data of the sample, such as age and sleep quality, and on general and local thermal sensation votes (TSV) (IBM, 2015). Post-hoc analysis of the standard residuals as proposed by Sharpe (Du Bois & Du Bois, 1989) was employed when the Chi-square test yielded significant results.

The relation between temperature of the cooling plates and local TSV-scores of the subjects was examined using general linear modelling. Temperature of the plate, height of the plate and distance between plate and subject were used as fixed effects.

Analysis was performed in SPSS version 24 (IBM, 2015). A full factorial model was used as a starting point, excluding variables that were not significant for further analysis. Main effects were always included in the model if they were included in a significant second-order effect. Adjusted  $R^2$  (Frost, 2013) was used to assess goodness of fit of the models, and partial  $\eta^2$  ( $p\eta^2$ ) (Levine & Hullett, 2002) was used to compare effect sizes.

### RESULTS

All analysis was performed on the scores each subject gave in the last 5 minutes of each test phase, i.e. at 25 minutes in the conditioning phase, and at 35 minutes in each test phase. Previous research has shown that full adaptation to the thermal environment has occurred at this point. (Van Craenendonck et al., 2018).

First analysis showed that alcohol consumption in the 24 hours prior to the experiment had a significant effect on all thermal sensation scores. It should be noted however that there was only one person who did consume alcohol in the 24 hours prior to the experiment. This person was excluded from further analysis. Age also had a significant effect on TSV-values in the legs (upper legs, lower legs and feet), with people over 60 years old feeling significantly colder. People who self-indicate that they often feel cold, signaled that their head, neck and chest felt significantly warmer than people who don't indicate often feeling cold. All further analysis was performed with the respective influencing groups once included and once excluded to determine their effect on the conclusions of this paper.

When looking at the TSV-scores nominatively, whole-body ( $p = 0.011$ ), neck ( $p = 0.050$ ), chest ( $p = 0.022$ ), upper arm ( $p = 0.003$ ) and upper leg TSV ( $p = 0.029$ ) are all significantly influenced by distance between cold plate and subject. Subjects exposed to the cold plate at

1,5 m mark thermal sensation for these regions lower than subjects exposed to the plate at 0,75 m. Whole-body ( $p = 0.004$ ) and hand TSV ( $p = 0.041$ ) are influenced by the height of the cooling plate, with subjects exposed to the plate at chest height being significantly colder than subject exposed to the plate at feet height in both cases. Excluding people who self-indicate that they often feel cold from the analysis does not influence these results, and neither does excluding people over 60.

Because different subjects may have different base comfort levels in the ambient conditions of the test room, a new analysis was performed on the change in TSV-values under test conditions compared with the TSV-scores after conditioning. The strongest main effect in each of the models and adjusted  $R^2$ -values are displayed in Table 1.

**Table 1: Summary of the models for change in thermal sensation**

	aR <sup>2</sup>	Strongest predictor ( $p\eta^2$ )		aR <sup>2</sup>	Strongest predictor ( $p\eta^2$ )
Whole-body TSV	0.37	Height (0.26)	Lower arm TSV	0.20	Distance (0.20)
Head TSV	0.19	Height (0.17)	Hand TSV	0.08	Distance (0.10)
Neck TSV	0.35	Distance (0.28)	Upper leg TSV	0.47	Distance (0.23)
Chest TSV	0.32	Distance (0.28)	Lower leg TSV	0.40	Height (0.18)
Upper arm TSV	0.23	Temperature (0.20)	Foot TSV	0.23	Height (0.14)

Temperature of the cooling plate is a significant effect in whole-body thermal sensation ( $p = 0.025$ ), as well as neck ( $p < 0.001$ ), chest ( $p = 0.004$ ), upper arm ( $p = 0.004$ ) and lower arm TSV ( $p = 0.017$ ). In all cases, the change in TSV-values indicated that subjects felt warmer as the temperature of the cold plate was lower. In almost all cases, subjects felt warmer than they did after conditioning. Excluding people who often feel cold from the analysis made the effect of temperature on neck TSV insignificant.

Distance between cooling plate and subject had a significant effect on all TSV-values. As can be seen in Fig. 3, the difference in all cases was greater than zero for participants exposed to the plate at 0.75 m, indicating that they felt warmer than after conditioning. Furthermore, in all cases, subjects exposed to the plate at 0.75 m felt warmer than those exposed to the plate at 1.5 m. Participants subjected to a cooling plate at 0,75 m in all cases felt warmer than after conditioning.

**Fig. 3: Difference of TSV value during testing and after conditioning, split by distance between cold plate and subject and by plate height. (Positive indicates warmer during testing)**

Plate height had an effect on whole-body TSV ( $p < 0.001$ ), as well as thermal sensation in the head ( $p = 0.013$ ) and leg region (upper legs ( $p = 0.006$ ), lower legs ( $p = 0.006$ ) and feet ( $p = 0.021$ )). The effect was the same in all cases: difference in TSV between during test and after conditioning was significantly higher for the people exposed to the plate at feet level than those exposed to the plate at chest level, as seen in Fig. 3. People exposed to the plate at chest level always felt colder than after conditioning, while people exposed to the plate at feet level always felt warmer. Removing people over 60 from the analysis made the effect of height of the cold plate on thermal sensation in the feet insignificant.

## DISCUSSION

From the results of the whole-body and local TSV-score analysis, it is clear that neither temperature of the cooling plate, nor position (height and distance to subject) have a strong effect on thermal sensation. Even when a statistically significant effect is found, adjusted  $R^2$ -values show that only a very small amount of variance in the thermal sensation can be explained by parameters related to local radiant asymmetry.

When looking at the change in thermal sensation during testing vs after conditioning, the parameters related to local radiant asymmetry have a stronger effect. Nevertheless the predictive powers of the models for hand TSV remained very low, as shown by  $R^2$ -value in Table 1. The significant effect of plate temperature on neck TSV and height of the cold plate on foot TSV occur to be linked to an uneven distribution of people with different demographics across the test conditions, rather than to local radiant asymmetry.

Distance between cooling plate and subject is often the most important effect in the models for predicting change in thermal sensation. Examining the details, almost all TSV-values are higher during testing than after conditioning, meaning that, on average, subjects feel warmer when subjected to local radiant cooling. These results are counter intuitive: e.g. subjects tend to feel warmer in the leg region when the cold plate at feet level is active. It is also remarkable that all participants subjected to a cooling plate at 0,75 m felt warmer, while the results for participants subjected to a cooling plate at 1,5 m were mixed, with some feeling warmer and some feeling colder than after conditioning. No significant rise in ambient temperature or relative humidity, nor radiant temperature from other parts in the test setup were discovered. Further research will be necessary to determine the cause for this effect.

The results as such confirm previous research by McNall & Biddison and Fanger, in that small radiant temperature asymmetry causes almost no change in thermal sensation in people. Most significant effects are found for bodies' extremities, which suggest that those are more strongly affected by local radiant cooling. However, no logical link existed between the height of the cooling plate and the location of the affected body region. Because results are this unexpected, further validation of the experimental setup will be performed by thermographic imaging with view factor correction to quantify radiant temperature asymmetry at the subjects' position. The results of this validation will provide additional information to explain the results of this experiment. The questionnaire will be validated by running short experiment series in more extreme conditions to test whether it is an adequate instrument to assess the thermal environment.

It should be noted that these results are based on an experiment with 18 subjects. The number of participants is lower than the average of 25 found in literature. (Van Craenendonck et al., 2018) Within these 18 participants, only 2 were female. Schellen et al found evidence for a significant difference in thermal response between men and women. (Schellen et al. 2012) No influence of gender was found in these results, but this may be due to the small amount of females. Further experiments will be conducted to correct for the skewed gender distribution.

## CONCLUSIONS

From the experiments, it can be concluded that the temperature difference and position of local radiant asymmetry does not strongly affect thermal sensation directly, but does have an impact on the base comfort level. The effects however are not as expected, with subjects who are exposed to local radiant cooling indicating that they feel warmer. This effect is noticeable for whole-body thermal sensation, as well as local thermal sensation, except in the head.

# Thermal Effect of Metal Fin inside Elevated Radiant Floor Based on the Thermal Utilization of a Burning Cave

Xueyan Zhang\*, Bin Chen, Jiayi Zhao.

Dalian University of Technology, China

\*Corresponding email: zxychenggong2008@126.com

## ABSTRACT

A rural house integrated with an elevated floor heating system based on the thermal utilization of a burning cave has been established to provide a more comfortable and clear indoor environment. Inside the elevated floor heating system, air is taken as the heat transfer medium and tin layer is designed as metal fin in the middle layer of the elevated floor to enhance heat transfer. In this study, heat transfer process and thermal performance of the inner metal fin were analyzed by theoretical calculations and field measurements. The results show that while the heat flux of the burning cave is decreased from  $460 \text{ W/m}^2$  to  $200 \text{ W/m}^2$ , the convection heat intensity of the hot air inside the elevated floor under each room is from  $2 \text{ W/m}^2$  to  $9 \text{ W/m}^2$ . Finally, it confirms that the effective length of the metal layer should be less than  $0.4 \text{ m}$ . All the above results show that appropriate design parameters can lead to an optimum heat transfer process.

## KEYWORDS

Elevated floor heating, Effective length, Heat transfer performance

## INTRODUCTION

In order to solve existing problems, such as larger indoor temperature fluctuation, poorer indoor air quality, lower thermal efficiency in a rural house (shown in Figure 1(a)), the model house integrated with an elevated radiant floor heating system based on the thermal utilization of a burning cave was presented (shown in Figure 1(b)). The heat is released from the burning cave to each heating room through the raised floor. The thermal efficiency was increased from 30% to 56.7% (Zhang, 2014).

Figure 1. Optimization of a burning cave for residential heating. a) Burning cave is used to heat a room, b) Burning cave is used to heat the whole house.

As a result of lower heat storage coefficient and lower specific heat of the air, an enhanced heat transfer mode was taken into account for improving heat distribution inside the raised

floor. Natural convection in a differentially heated inclined square enclosure with a fin attached to the solar collector for reducing heat losses has been studied numerically (Frederick, 1989). The fin position inside a differentially heated cavity is a major role in heat transfer inside the cavity, the effect of fin position on the heat transfer rate is strongly affected by Rayleigh number and the fin length (Bilgen 2005). The steady laminar natural convection within a differentially heated by square cavity with a thin fin was found that for high Rayleigh numbers, heat transfer can be enhanced regardless of the position or the length of the fin (Shi and Khodadadi, 2003.). Natural convection inside an enclosure with three thick cold walls and a hot thin vertical left wall was studied numerically (Abdullatif and Chamkha, 2007). For the case of highly conductive fin, it was found that the Nusselt number on the cold wall increased compared to the case with no fin (Nag, Sarkar, et al, 1993). Laminar flow regime was found while turbulent flow regime starts to be formed for higher values of Rayleigh number (Bilgen, 2002). Natural convection inside cavities was examined extensively for different boundary conditions, aspect ratios and Rayleigh numbers (Du and Bilgen, 1992.). In this paper, the fin efficiency of the thin metal plate in the middle layer inside the elevated floor can be discussed, and the optimum length of the metal layer can be determined.

## METHODS

In the whole heating house, some parameters are including: air temperature, surface temperature, heat flux. The detailed structure information inside the elevated floor is shown in Figure 2. The measured parameters and test error of test instruments are shown in Table 1 respectively. The record interval of all the analyzers was 10 mins.

Figure 2. Test points and construction. a) Test points in the whole house, b) Test points in each layer inside the elevated floor.

Table 1. The measured parameters and test instruments

Measuring parameters	Name of instruments	Measuring accuracy
The quality of fuels	Desk type electronic scale	$\pm 0.1\text{g}$
Thermal parameter of the building envelopes and heating surfaces	Multi-channel heat flow tester JTNT-A/C (SWP-L816)	$\pm 0.1^\circ\text{C}$ $\pm 1\sim 2\text{ W/m}^2$
Indoor/outdoor air temperatures and relative humidity	Digital thermo recorder TR-72U	$\pm 0.1^\circ\text{C}$
Inner temperature inside the burning cave	High temperature thermocouple	$\pm 1^\circ\text{C}$
Recording system	Automatic communication and recording system	$\pm 0.1\%$

According to the fin efficiency calculation method of heat transfer in reference (Rohsenow, Hartnett, et al, 1998), the heat distribution transferred by metal layer is equal to the heat gained from the basis of metal layer. The equation that applies to this case is:

$$\frac{d\theta}{dx^2} = m_t^2 \theta \quad (1)$$

Where,  $\theta = T - T_\infty$  is the temperature excess,  $x$  is the axial coordinate.

$$L_e = \lambda_t A_L m_t \theta_t h [m_t (l_t + \frac{\delta_t}{2})] + \frac{2\pi}{\sqrt{5}} \varepsilon \delta_t \theta_t m_t, \quad m_t = \sqrt{\frac{l_t U_t}{(\lambda_t + \varepsilon \sigma) A_L}} \quad (2)$$

Where,  $L_e$  is heat changed from metal surface to the air layer at steady state, W.  $l_t$  is the effective length of metal layer, m.  $A_L$  is the effective area of metal layer,  $m^2$ .  $\lambda_t$  is thermal conductivity coefficient,  $W/(m \cdot K)$ .  $U_t$  is the total length of metal layer, m.  $\delta_t$  is the thickness of metal layer, m.  $\theta_t$  is temperature excess,  $^\circ C$ .  $m_t$  is the metal layer performance factor.

$$\eta = \frac{Q_a}{Q_{a,max}} \quad (3)$$

Where,  $\eta$  is the fin efficiency of metal layer;  $Q_a$  is the actual heat transfer, including radiation and convection heat transfer inside the elevated floor, W;  $Q_{a,max}$  is the theoretically maximum heat transfer that can be diffused by the metal layer, under the assuming condition is that the entire area of the metal layer is at the maximum temperature.

## RESULTS

### Temperatures inside the burning cave

During the heating period, temperature field inside the burning cave is shown in Figure 3. After igniting the fuels for 12h, the temperature of test point BN1 (at the height of 1.1m) in Part I is reached to  $300^\circ C$ , but the temperature of test point BS1 (at 1.1m height in Part II) is  $100^\circ C$  lower than BN1. In part II, the burning time for reaching to the highest temperature is 6h longer than which in part I. Because the air inlet was on the wall of Part I. Through calculation, average burning velocity is about 1.31 mm/h, 1.34mm/h respectively in part I and Part II, which is larger than the results in reference (Beijing civil construction society, 2008.), because the moisture of mixed biomass fuels is 3.36% lower than which in reference.

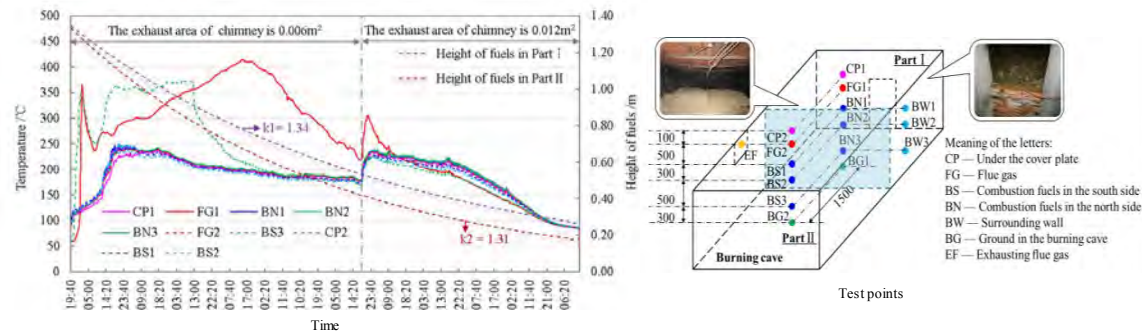

Figure 3. Temperature variations inside the burning cave

### Indoor Air Temperatures in the whole house

Temperature variations of the elevated radiant floor heating system and indoor air temperatures during the heating period are shown in Figure 4. While the outdoor air

temperature is between  $-15^{\circ}\text{C}$  and  $2^{\circ}\text{C}$ , the average indoor air temperature is about  $3^{\circ}\text{C}$  higher than a room heated by traditional Kang. The temperature difference between adjacent rooms is only about  $2.0^{\circ}\text{C}$ . The results show that using the elevated floor heating system is effect for reducing temperature difference between different rooms in the whole house.

Figure 4. Temperature variation inside the elevated floor and in the house

## DISCUSSIONS

As shown in Figure 5(a), the radiation heat is about two to six times more than convection heat. The value of radiation heat on test point 3 in each room is nearly close to zero, and the value of radiation heat on test point 4 in each room is negative. It shows that the effect of the metal plate is heat absorption, and convection is the main heat transfer method. It illustrates that inner heat transferred from heat source to room1 facing south is the best. So that the effective length of the metal layer should be determined to reach the optimum state.

Through comparison in Figure 5(b), the fin efficiency of the metal plate is decreasing as its length was increasing. In order to take the fin efficiency of metal plate maintain at 50%, the effective length of metal plate is determined to be no more than 0.4m by calculation.

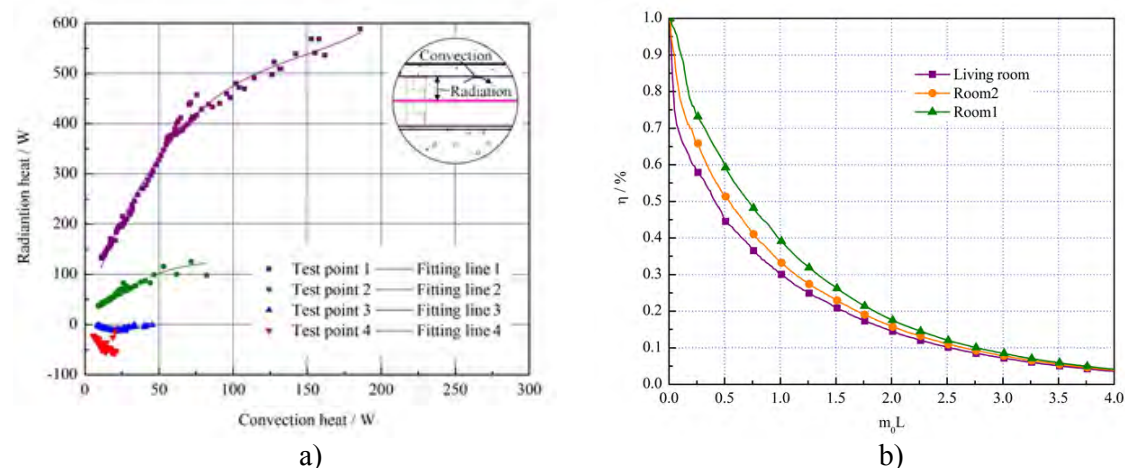

Figure 5. Heat transfer comparison inside the elevated floor. a) Heat transfer analysis, b) The length of metal layer impact on the fin efficiency

## CONCLUSIONS

Some significant conclusions are described as follows: (1) In this elevated radiant floor heating house, the temperature difference between adjacent rooms is only about 2.0°C. It illustrates that the heating environment can be more comfortable than using traditional Kang, and the heating time can be maintained for twenty days with once filling by biomass fuels. (2) The temperature drop rates of inner hot air inside the elevated floor under different function rooms were between 0.3°C/m and 0.9°C/m. (3) To maintain the higher fin efficiency, though thermodynamic criterion analysis on the heat transfer performance of the elevated floor, the effective length of inner metal plate was confirmed and should be no more than 0.4m. The optimized method is enhancing convection heat transfer inside the elevated floor heating system to get a more comfort indoor heating environment.

## ACKNOWLEDGEMENT

The work was supported by a NSFC (No. 51608092), a China Postdoctoral Science Foundation (No. 2015M571306), and the Fundamental Research Funds for the Central Universities (DUT16RC(3)092).

### **ABSTRACT**

Social housing units built in the 1960s and 1970s make up one-fifth of all housing units in Denmark. Their renovation is an important step towards meeting the goals of the national energy road map. Sensors based on wireless technology could be considered a feasible solution to increase occupant's awareness towards their indoor climate and their energy consumption. In the present experimental study, a framework implementing wireless sensors to monitor energy and indoor climate before and after renovation has been applied in two apartments of a Danish social housing site. In the first phase of the study, the accuracy of some commercially available wireless systems was investigated. This was followed by installation in the field, where occupant behavior (e.g. window opening status) was also monitored. Heating energy data monitored before and after renovation indicated savings of up to 34%.

### **KEYWORDS**

Social housing, buildings renovation, data collection, integrated wireless sensors.

### **INTRODUCTION**

Measurement and verification are effective ways of documenting energy savings achieved as a result of buildings renovation, while most of current renovation assessment are based on numerical simulations (Ma et al., 2012). On the other hand and in Denmark, one of the current barriers of energy renovation decision making is the lack of sufficient information about energy consumption and accordingly cost and possible savings (Bjørneboe et al.2018). Wireless sensor technology offers new potential for monitoring energy consumption and indoor environmental parameters such as temperature, relative humidity and CO<sub>2</sub> with less invasive nature to occupants comparing to wired systems (Stojkoska et al., 2014). The idea of using wireless sensors in the built environment is not new, but applications are limited despite the recognized potential of this technology and more research in the domain is needed to lift the barriers (Noye et al. 2018). While, it can be implemented in either new or renovated buildings with means for internal and external communication (Loboccaro et al., 2017), but particularly applying the technology at building renovation projects can help to comprehend the performance of existing systems and to evaluate the improvements after the completion of the renovation (Noye et al. 2018). Another advantage is that it communicates with end-user through user-friendly app's where direct interaction is a priority. On the other hand, very few studies has focused on accuracy checking of these wireless sensors. Petersen et al. (2018) have investigated two commercial indoor climate monitoring systems (IC-METERS and NETATMO) through an experimental campaign. Results showed that the accuracy of latter system to measure the CO<sub>2</sub>

concentrations was highly dependent on the air temperature. For the study reported in this paper, two particular systems (IC-METERS and WIRELESS- TAGS) have been investigated for use in a project for social housing in Aalborg, Denmark to monitor performance before and after renovation. These two WSN systems have been applied in previous projects in Denmark and have shown good reliability to monitor the indoor climate and occupant behavior, (Henriksen and Olsen, 2018) and (Azouz, 2017). The monitored parameters included heating consumption, electricity use measured by SMAPPEE's, air temperature, relative humidity, CO<sub>2</sub>, occupancy with PIR sensors, and window opening. The measuring campaign in the field started with a lab test of the sensors to determine their accuracy and determine the sensibility of CO<sub>2</sub> measurements to temperature variations.

## **METHODOLOGY**

The experimental based study is subdivided into two main steps, the first is calibrating the IC meters and wireless tags, checking how to save and retrieve the collected data on lab level. Followed by the field site installation phase, which included two groups of apartments, renovated and non-renovated cases.

### **Calibration of the wireless sensors**

IC meters and wire-less tags systems were investigated in climatic chambers of the Technical University of Denmark. The IC METER (version 4.3) communicates through a GSM based module and has accuracy of the CO<sub>2</sub> measurements of  $\pm 30$  ppm or  $\pm 3\%$ . The WIRELESS TAGS are square tags with dimension 4.0 x 4.0 x 0.2 cm, which can be distributed over indoor zones and connected to a data router that is connected to the internet via a LAN cable. These tags are capable of measuring air temperature and RH with accuracy of  $\pm 0.4$  °C and  $\pm 2$  % respectively, in addition to being able to track the motion of windows and doors. Both systems have shown good reliability in many projects (Henriksen and Olsen, 2018) and (Azouz, 2017).

The climate chamber has a volume of 22 m<sup>3</sup> and it is well insulated preventing outside factors to influence the temperature stability inside the chamber, see Figure 1a. The CO<sub>2</sub> concentration was measured by a Photoacoustic Gas Monitor "INNOVA 1412i" (LumaSense Technologies Inc., Figure 1b) with a detection limit of  $\pm 1.5$  ppm for CO<sub>2</sub>. Two gas flow meters were used to control the dosing of CO<sub>2</sub>, see Figure 1c.

### **Testing in the field**

The measurements were carried out in two non-renovated and renovated apartments, which were selected in a social housing site (Figures 2a and 2b). Thermal characteristics of the building envelope were different for the two types of apartments. The measured heat transfer coefficients for the external walls of the renovated and non-renovated apartments were 0.12 and 1.4 W/m<sup>2</sup>K, respectively, and 0.85 and 2.6 W/m<sup>2</sup>K for the windows. The heat transfer coefficients were measured by a wireless heat flow meter (GREENTEG) with accuracy of  $\pm 3\%$  for a continuous 3 days in compliance with ISO 9869.

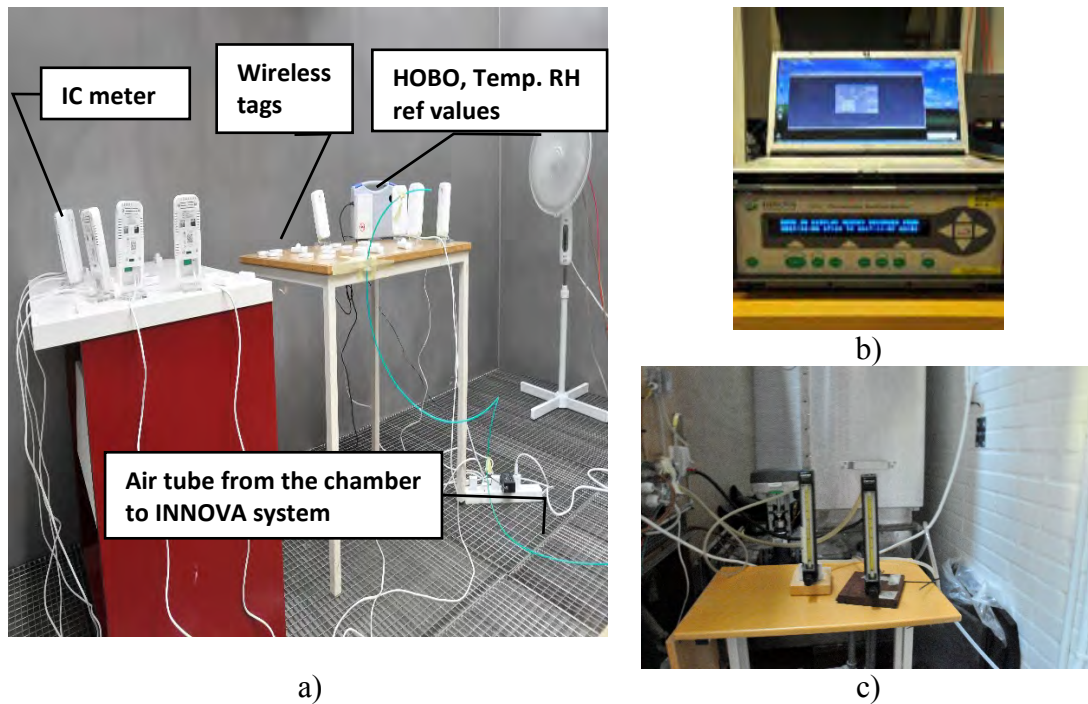

Figure 1. Calibration of the sensors. a) Climatic chamber, b) Photoacoustic Gas Monitor, c) CO<sub>2</sub> flow meters

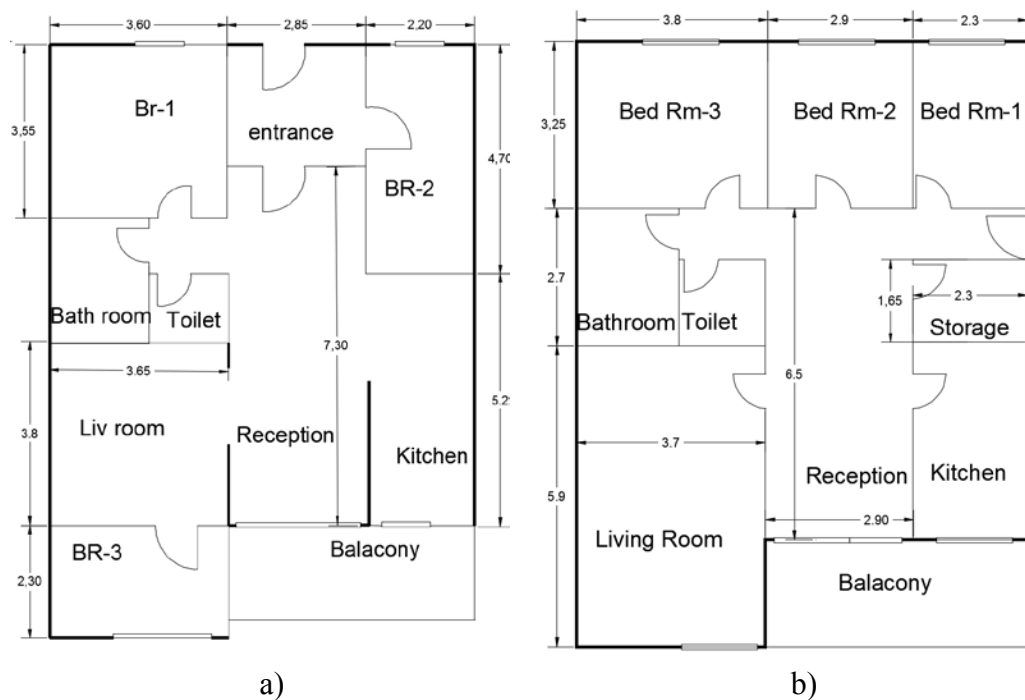

Figure 2. Apartments under investigation. a) Non-renovated apartment, b) Renovated apartment

Both types of apartments have been equipped with wireless sensors to collect dynamic energy and indoor climatic performance data. Time step for the data collection is 5 minutes. The

measurements of heating flowrates and energy has been carried out through an ultrasonic heating meter. The meter is implemented with a wireless M-Bus function, which enables the communication with a stationary multi utility controller, and it supports the open metering system through compliant data transfer

## RESULTS

The results are subdivided into three parts, the lab level experiments that included *i)* the IW sensors calibration. Followed by analysis of the site level monitored data, which included *ii)* the indoor climate and *iii)* heating consumption.

### Accuracy check and calibration of instruments

The performance of the sensors was compared for different levels of CO<sub>2</sub> concentrations, relative humidity and air temperature. Calibration profiles are shown in Figures 3a and 3b. The IC meters Root Mean Square Error (RMSE) values ranged from 0.1 to 0.3°C, 0.6 to 1.5 % RH, and 25 to 50 ppm, for temperature, RH and CO<sub>2</sub>, respectively. For the sensor tags, RMSE values ranged from 0.3 to 0.7°C for temperature readings, and 2.5 to 3% for RH readings.

Figure 3. Sensor calibrations. a) Wireless tag- Air temperature, b) IC meter- CO<sub>2</sub> levels

### Indoor climate profiles

Figure 4 illustrates weekly temperature and RH profiles for the entrance area of the two apartments. The data were retrieved from the IC meter and wireless tag data cloud. The decreasing air temperature between the 22<sup>nd</sup> and 24<sup>th</sup> of February in the non-renovated apartment reflects a reduction in the control setting of the radiator's thermostat by the occupants due to their absence (winter vacation).

### Heating energy profiles

Heating profiles for a renovated and a non-renovated apartment are shown in Figures 5a and 5b. For the non-renovated apartment, the heating consumption was 462 Wh/m<sup>2</sup> per day, while it was 304 Wh/m<sup>2</sup> per day for the renovated apartment.

## DISCUSSION

The measured data has shown that by improving the thermal characteristics of the building-envelope, the overall heating consumption has decreased the about 35%. The monitored air temperature in the entrance and living areas, which are shared by all family members, was between 20 and 22 °C. However, in the bedrooms, where individual preferences are dominating, opening the windows all night caused a drop of air temperature to 10 °C.

Figure 4. Indoor air temperature and Relative humidity profiles

Figure 5. Heating consumption profiles for both apartments. a) a weekly profile, b) a day profile

## CONCLUSIONS

Continuous measuring of the building performance provides opportunity for better design and operative improvements. Integration of wireless sensors as a non-invasive measuring system could be considered an applicable solution for both the tenants and the social housing company to monitor and analyze building performance through the renovation and operation phase. . Implementation of a wireless system saves time and installation efforts, and facilitates distance monitoring of all measured data . The increasing availability of user-friendly monitoring and feedback systems will facilitate the involvement of occupants in their energy use and quality of

the indoor environment. However, further investigations of the accuracy and reliability of the wireless sensor systems under different boundary conditions have to be carried out. In addition, it will be desired to have all the different sensors collected in a single data cloud to ease the retrieving and analysis of the saved data.

### **ABSTRACT**

Humans spend up to 90% of their time indoors, thus building systems should maintain the indoor environment within the comfort range. In this paper, we present LightLearn, a reinforcement learning based occupant centered lighting controller. The control agent interacts with the occupant non-intrusively, learns her/his preferences, and determines actions for achieving both human comfort and energy saving. We present system hardware, control algorithm, and experimental results of LightLearn for an office space. Compared to the full (9am-5pm) and occupancy based control, LightLearn reduced 83% and 63% of operation time, respectively, by adapting to the occupant.

### **KEYWORDS**

building retrofit, occupant behavior, adaptive control, reinforcement learning

### **INTRODUCTION**

Lighting accounts for approximately 20% of the total commercial building energy consumption (DoE 2011). One promising energy efficient strategy is a daylight linked automatic lighting control system, which switches lights on/off depending on the amount of natural lighting. The challenge for this automatic control system, however, is that typically control set-points are not driven by occupant preference but set to a uniform value. In other words, even though different people may have different preference on their comfort, the conventional automatic control uses fixed threshold values for operation. As a result, occupants often either override control settings indicating their discomfort, or in the worst case, they deactivate their control system (Gunay et al. 2013). Note that if occupant comfort is not satisfied, it could have serious repercussions on not only work productivity but also both physical and mental health for humans (Loftness et al. 2003). To put this in a more general perspective, beyond lighting: the objective of building environmental systems should be to provide comfort for the occupants, who spend up to 90% of their time indoors. However, building control research has largely neglected occupant satisfaction (Park and Nagy, 2018).

The occupant centered control system (OCC) has been introduced to address this discrepancy between building control and occupant comfort (Nagy et al. 2015; Nagy et al. 2016). There are two components of occupant comfort, one of which is the actual physical comfort, i.e., the absence of the feeling of pain, and the other is the perception of control over their indoor environment (Nagy et al. 2016). To accomplish the two parts of comfort, the building control system should be focused, or centered, on the characteristics of the occupant. An ideal system should learn the unique preferences of the occupant, and adapt the control set-points to these preferences to balance the decisions of the occupant with the calculated decision for energy

savings. There are several experimental results indicating that OCC approach can save energy without sacrificing occupant comfort (Nagy et al. 2015; Nagy et al. 2016).

In this paper, we introduce LightLearn, a reinforcement learning (RL) controller for lighting in the OCC framework. We describe RL and the OCC framework in general, as well as the specific hardware and control algorithm of LightLearn in the next Section. Finally, we present experimental results and conclude the paper.

## METHODOLOGY

### Reinforcement learning

RL is a machine learning technique (Sutton & Barto, 1998), in which the learning agent interacts with its environment, and uses feedback from the environment to determine the best possible action given the current state (Figure 1a). RL is formalized as a Markov Decision Process (MDP): It is a tuple of states (S), actions (A), transition probabilities (P), and rewards (R:  $S \times A \rightarrow R$ ). Each state has a value  $V^\pi(s)$  which is the expected return for the agent when starting in that state and following the policy, where the policy  $\pi : S \rightarrow A$  maps states to actions. The agent's objective is to calculate the optimal policy, i.e., the one that leads to maximum expected return (Nagy et al. 2018a). We used model based RL for LightLearn, where P and R are determined from experimental data, and the MDP is solved for the optimal policy using value iteration (Sutton & Barto, 1998).

### RL based Occupant centered building control

The general RL-OCC framework acquires two types of data (Figure 1b): 1) Indoor environment, e.g., temperature, humidity, and luminance. 2) Interaction of the occupant with the building systems, which is directly related to occupant satisfaction, e.g., thermostat, blind, and switch usage. For the RL agent, type 1 data is used for states, and type 2 data is the feedback/reward signal. Ultimately, the RL agent determines the optimal action based on states and reward. This action is then used as e.g., set-point for the building control system.

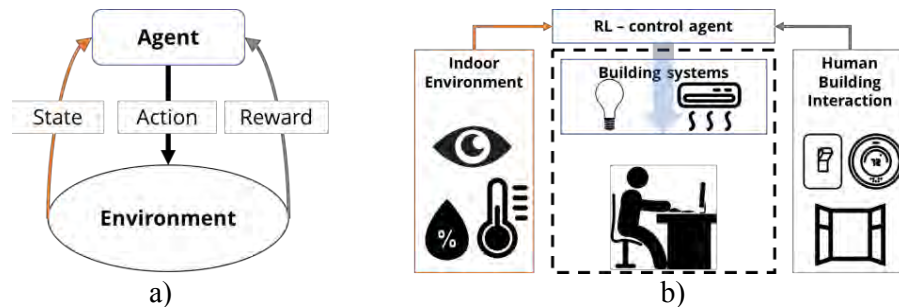

Figure 1. a) Reinforcement learning b) general concept of the RL-OCC framework

### LightLearn: An RL-OCC Case Study

#### Hardware configuration

The hardware of LightLearn consists of low-cost off-the-shelf components to allow retrofitting any manual on/off light switch (Figure 2a). The controller itself is implemented in Python on a Raspberry Pi Zero W (RPi). The gathered environments are 1) luminance (TSL 2561). 2) A personal BT enabled device (mobile phone, watch, etc) paired with the RPi serves as proxy for occupancy (Nagy et al. 2018b). 3) For both sensing and actuating the light switch, we used a product called Switchmate. It uses a DC motor to move the light switch (on/off), while the occupant can switch the lights via a push button. We also designed a custom printed circuit board to interface and control the Switchmate with the RPi.

Table 1. Data acquisition summary

Variable	Type	Values	Unit	Logging Frequency
Switch position	binary	0/1	-	1 minute
Occupancy	binary	0/1	-	1 minute
Room light level	integer	0-10,000	lux	1 minute

The controller has the three components (Figure 2b): 1) Data acquisition of switch position, occupancy, and light level on the wall each minute (Table 1). 2) Learning process by building the MDP and determining the optimal policy once a day at midnight. (see next section) 3) Live control of the lighting system with the most recent learning results. Each minute, the controller determines the states and actuates the action when new state is different from previous state. A LightLearn was installed in a south facing, one person office, retrofitting the previously manual light switch, and an experiment was conducted for three weeks (3/19 – 4/5).

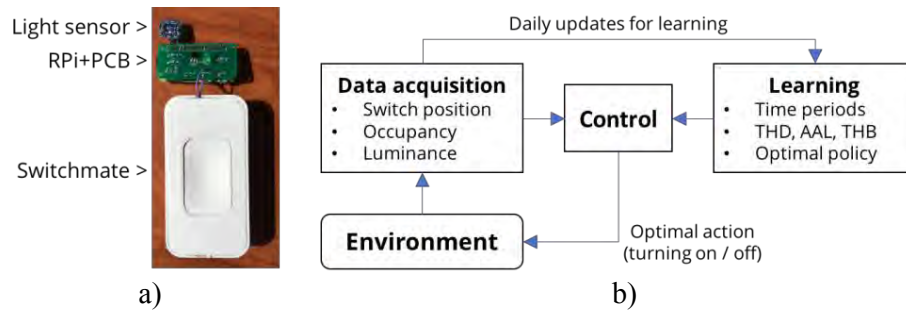

Figure 2. a) LightLearn hardware

b) Control algorithm flow chart

### State-action Space Design and Learning process

The key when developing a robust RL controller is the design of the state-action space for the MDP. For LightLearn, the possible actions (A) are turning on/off. The states (S) are defined by four parameters: 1) Each day is split into four periods according to the trends of increasing (P1), midday (P2), decreasing (P3), and low ambient light (P4). These periods were identified using the gradient between two consecutive luminance data points. P4 is defined when the gradient is constant. If the majority (>80%) of the gradients are positive or negative, the time periods are set to P1 and P3, respectively. P2 is assigned in between P1 and P3. 2) Occupancy, and 3) switch position (on/off) are additional considerations for the states. 4) The indoor light levels that correspond to the cutoffs between Dark, Comfort, and Bright: if the occupant switches the lights on, we assume that he/she feels dark. Thus, the light level at that moment is the threshold for darkness (THD). If the light levels are below THD, it is considered Dark. Typically, the occupant can switch the light multiple times. Then we average the values to obtain THD. The artificial light level (AAL) is measured by the lux level difference between switch off & on. A last threshold value is the threshold for brightness (THB=THD+AAL), which indicates that it is bright enough for occupant. Light levels above THB are considered to be Bright. Light levels between THD and THB are regarded as Comfort.

Figure 3 shows all possible states for the control agent. For example, when the room is occupied during P1, P2, and P3, the agent can be in the Bright or Comfort state if the lights are on or off, and in the Dark state when the lights are off. In brief, each day can be split into, e.g., at most 26 states, and the objective of the agent is to determine the best action for each of those states. Once states and actions are defined, the probabilities of transitioning from one state to any other state are calculated by historical data. For each state, all the state transitions are counted and divided by the total number of state transitions. Finally, we use the reward

values shown in Figure 3. We set negative rewards (-1) for energy wasting, positive rewards (+1) for using energy for occupant comfort, and larger rewards (+2) for energy savings.

Figure 3. State-Action definition by time periods, occupancy, switch position, and light level; Rewards on each state are annotated in parenthesis.

## RESULTS

To illustrate how the controller worked, we show the MDP and the data collection result on March 27th (Figure 4). Historic data (3/19-26) was used to build the MDP (Figure 4a). The controller solved it for the optimal policy for the following day. Specifically, there are 7 states (circles), the transition probabilities are calculated between two states (arrows), and the calculated optimal policy (values) is mapped on each state.

With this optimal policy, the controller actuated the switch to maximize the value based on its current state. For example, the controller determined its state based on the three sensor values (i.e., lux level, occupancy, switch position) in Figure 4b. Based on state transition, the associated values were changed. On March 27th, there were the two control actions: 1) The controller read the current state as S17 (occ-on-bright) and switched off to transition to the state with maximum value (S14, occ-off-comfort) around 13:30. 2) Similarly, the controller read S9 (occ-on-bright) and turned off, transitioning into state S7 (occ-off-comfort) at 10:51 in P1. We emphasize that both actions were taken because the controller transitioned into “Comfort” states.

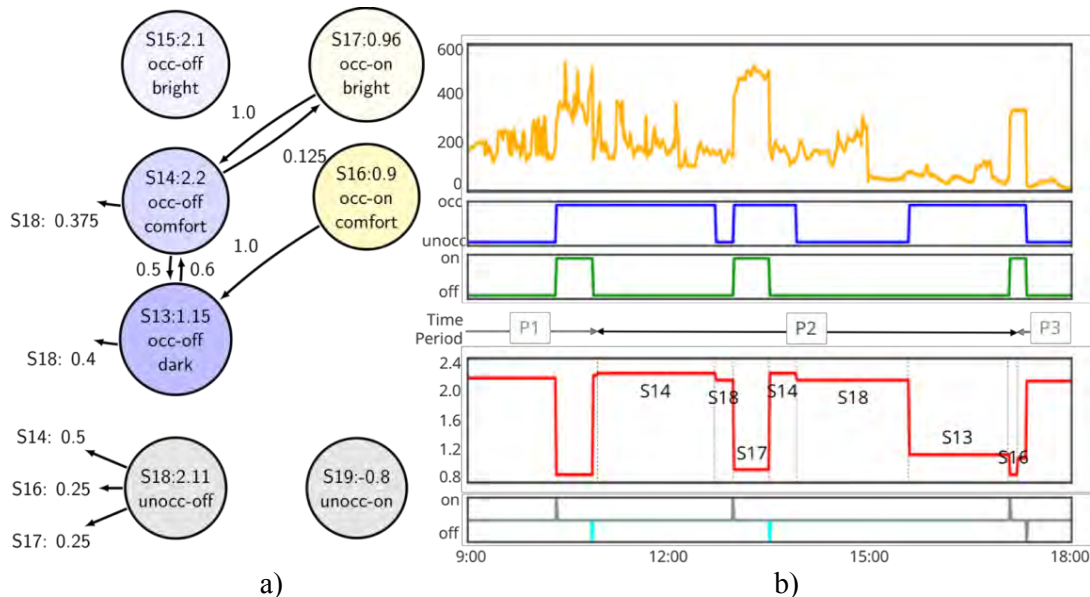

Figure 4. March 27th: a) MDP during P2 b) Data: lux level (yellow), occupancy (blue), switch position (green), value with states (red), and control actions (human-gray, controller-cyan)

The controller calculates the learning outputs every midnight. With these daily outputs, we investigate the evolutions of control parameters: Figure 5a shows how the time period varied by day: the start times of P1 and P4 were relatively constant, because sunrise and sunset time did not significantly change during the experiment. The duration of P2 increased while the durations of P1 and P3 decreased. Because there were no clear patterns for both daylight increasing and decreasing due to the weather condition (cloudy). In figure 5b, we also observe that the THD is around 280 lux until the 7th day. Then, it drops to around 190 lux. This is because the occupant turned on the switch with lower ambient light levels on the cloudy days (7th–10th). This shows how LightLearn adapts its set-points based on occupant interaction.

Similarly, the evolution of the values for states S6, S9, and S10 in Figure 5c demonstrate the adaptation capabilities of LightLearn. Each state has same value (1) on the first day, yet the values of S9 is the lowest until the 8th day, because there was no state transition into S9. However, after the 7th day, the occupant turned on the light often due to cloudy weather, which increased the transition probabilities to the S9 state.

To evaluate energy savings of LightLearn, we calculated the total light-on time and compared with other scenarios (Table 2). Essentially, the operation time serves as proxy for energy consumption. The full operation is the worst-case scenario, assuming the light is on during the normal office schedule (9am–5pm) on weekdays. In addition, the occupancy-based operation was compared. In this case, we assumed that the occupant turns on the light whenever she/he occupies the room. Compared to the full operation and the occupancy-based case, LightLearn reduced the operation time by 83% and 63%, respectively. In brief, the controller successfully saved energy consumption by learning the occupant behavior and the room environment.

Table 2. Operation time (light-on) of each scenario

Scenario	Full operation (9am–5pm)	Occupancy-based	LightLearn
Operation time (hrs)	104	48.8	17.6

## DISCUSSIONS

The learning process can be tuned by varying the RL parameters. First, the controller determines the importance of future reward by discount factor ( $\gamma$ ). Typically, lighting control requires a very small value ( $\cong \gamma 0$ ): If excess weight is given to future energy saving, the controller might keep the switch off in a morning and expect to have sufficient daylight level later. This would cause discomfort situation for the occupant. However, in other types of building control problems, i.e., HVAC, higher discount factors might be required (Vazquez-Canteli et al. 2017). Also, the reward assignment can initialize the objective of controller. For the sake of energy saving, we assigned higher rewards ( $r=2$ ) for the off states (Figure 3). Thus, those states have relatively higher values, and lead the controller to primarily switch off.

## CONCLUSION

This paper introduced RL based OCC framework. As a case study, we implemented LightLearn in an office. LightLearn was successfully deployed and collected occupant related data. Ultimately, the controller generated the MDP and calculated the optimal policy every midnight for the operation on the following day. The results indicate that the controller reduced unnecessary operation time by learning unique characteristics of the occupant behavior and the room environment. For future studies, RL-OCC approach should be further evaluated by different building systems (i.e., dimmable lighting, HVAC), environments (i.e., visual and thermal), more occupants, and for longer periods.

### ABSTRACT

The calibration of building energy models based on in-situ sensor information is generally performed after the measurement period, using all data in a single batch. Alternatively, on-line parameter estimation proposes updating a model every time a new data point is available: this allows observing a direct relation between external events and the identifiability of parameters. The present study uses the Sequential Monte Carlo method to train a RC model, and thus estimate a Heat Loss Coefficient, and other parameters, sequentially. Results show the direct impact of solicitations (solar irradiance and indoor heat input) on this estimation, in real time. The method is validated by comparing its results with the Metropolis-Hastings algorithm for off-line estimation.

### KEYWORDS

Bayesian inference; on-line; SMC

### INTRODUCTION

The calibration of simplified building energy models using in-situ measurements is now a widespread research topic (Rouchier, 2018). It is commonly performed for two general types of applications: the characterisation of intrinsic building performance (Heo et al. 2012; Bauwens and Roels, 2014), and the identification of a model for predictive purposes, for instance in the aim of model predictive control. State-space models, which include the simplified resistor-capacitor (RC) model structures, are a popular choice for both applications. When written as a set of Stochastic Differential Equations, they allow accounting for modelling approximations (Madsen and Holst, 1995) and offer a more reliable parameter estimation than deterministic models (Rouchier et al. 2018).

Parameter estimation is typically performed *off-line*: measurements of indoor and outdoor conditions are first carried in a test building, and data is processed after the experiment in a single batch. An interesting challenge is to carry parameter estimation *on-line*, during the observation period: starting from an initial guess for parameter values, these estimates are updated sequentially, every time a new observation becomes available. The motivation is twofold: first, it would allow using the measurement period for computations, thus reducing the total time of the procedure (Raillon and Ghiaus, 2017). Second and foremost, it would allow directly observing which phenomena “bring information” to the parameters, by correlating the reduction in their estimation uncertainty with observed events.

Bayesian inference offers the possibility of on-line estimation with Sequential Monte-Carlo (SMC) methods (Doucet et al. 2000). Originally developed for the sequential estimation of states (Handschin 1970), SMC was later adapted to state and parameter estimation (Kantas et al. 2015). Building physics applications are scarce and very recent (Raillon and Ghiaus, 2017), but may become more common due to the motivations listed above. The present paper

applies SMC for the on-line estimation of the heat loss coefficient (HLC) of a test building. Starting from a highly uncertain prior knowledge of HLC, the target is to dynamically observe what leads its estimation to narrow down to a more precise value. The identifiability of HLC regarding available data is then discussed.

## CASE STUDY

### Test case

This study uses measurements that were carried in the Round Robin Test Box (RRTB), within the framework of the IEA EBC Annex 58 (Jimenez et al. 2016). This experimental test cell has a cubic form with dimensions of one cubic meter, identical wall components on all sides and one window with dimensions 60x60cm<sup>2</sup>. It was installed outdoors, in the LECE laboratory at Plataforma Solar de Almeria, in the South East of Spain. Experiments were carried during a 43 days period in the winter of 2013-2014. More information on the conditions of the test is available in the Annex 58 report (Jimenez et al. 2016).

Figure 1. Measured indoor and outdoor temperature, heating power and solar irradiance

A period of six days was chosen for the present investigation, shown on Fig. 1. The indoor temperature is left free floating during the first three days, although it is impacted by daily peaks of solar irradiance. Then, a ROLBS heating signal was imposed inside the test box during the remaining three days. The motivation behind the choice for this sequence of measurements is that these boundary conditions are not very informative at first, then become more informative: we expect to witness their effects on the evolution of the estimation of the heat loss coefficient.

### Model

The test box is represented by a 2R2C model described by:

$$\begin{bmatrix} \dot{T}_e(t) \\ \dot{T}_i(t) \end{bmatrix} = \begin{bmatrix} -\frac{1}{R_1 C_1} - \frac{1}{R_2 C_1} & \frac{1}{R_2 C_1} \\ \frac{1}{R_2 C_2} & -\frac{1}{R_2 C_2} \end{bmatrix} \begin{bmatrix} T_e(t) \\ T_i(t) \end{bmatrix} + \begin{bmatrix} \frac{1}{R_1 C_1} & 0 \\ 0 & \frac{1}{C_2} \end{bmatrix} \begin{bmatrix} T_a(t) \\ q(t) \end{bmatrix} + w(t) \quad (1)$$

$$y(t) = \begin{bmatrix} 0 & 1 \end{bmatrix} \begin{bmatrix} T_e(t) \\ T_i(t) \end{bmatrix} + v(t) \quad (2)$$

where  $T_i$ ,  $T_a$  and  $T_e$  are the indoor, ambient (outdoor) and envelope temperatures. The model has two states  $T_e$  (unobserved) and  $T_i$  (observed);  $q$  (W) is the indoor heating power;  $I_{sol}$  (W/m<sup>2</sup>) is the solar irradiance on a southern vertical plane;  $R_1$  and  $R_2$  (m<sup>2</sup>.K/W) are two thermal resistances,  $C_1$  and  $C_2$  (J/K) are thermal capacities, and  $k_1$  and  $k_2$  (m<sup>2</sup>) are two solar

aperture coefficients, one for each state of the model.  $\mathbf{w}(t)$  denotes a Wiener process that represents modelling errors with an incremental covariance  $\mathbf{Q}_c$  (Madsen and Holst, 1995), and  $\mathbf{v}(t)$  is the measurement error of the indoor temperature, normally distributed white noise with zero mean and variance  $\mathbf{R}_c$ . Both are considered unknown and will be estimated along with the other static parameters of the model, which are all denoted by a single vector  $\theta$ .

The stochastic model described by Eq. 1 and 2 must be discretized to specify its evolution between discrete time coordinates.

$$\begin{aligned} x_t &= F x_{t-1} + G u_t + w_t \\ y_t &= H x_t + v_t \end{aligned} \quad (3)$$

$$(4)$$

where  $\mathbf{x}_t$  denotes the vector of states at the time coordinate  $t$ , and  $\mathbf{y}_t$  denotes the observations. The reader is referred to (Madsen and Holst, 1995) and (Rouchier 2018) for more details regarding the discretization steps.

Given a state transition probability  $p(x_t \vee \theta, x_{t-1}, u_t)$  (Eq. 3) and an observation probability  $p(y_t \vee x_t)$  (Eq. 4), filtering produces  $p(x_t \vee y_{1:t}, \theta)$ , the probability distribution function of each state given measurements and parameter values, and the marginal likelihood function  $L_y(\theta) = p(y_{1:T} \vee \theta)$ . The Kalman filter algorithm is not described here for the sake of concision, but has been described by many authors including (Madsen and Holst, 1995; Rouchier 2018).

### BAYESIAN PARAMETER ESTIMATION

The target of the on-line parameter estimation exercise is to assess the value of all static parameters of the model, at each time coordinate of the measurement period: the expected output is a sequence of posterior distributions  $[p(\theta \vee y_{1:t}), t \in 1 \dots T]$ , where  $T$  is the number of data points in the measurement period. This sequential estimation is performed by the SMC algorithm. For the sake of validation, the estimation has also been carried in a “traditional” off-line fashion with the Metropolis-Hastings algorithm. Both methods are described below.

#### Off-line estimation: Marginal Metropolis Hastings

The Marginal Metropolis Hastings (MMH) algorithm is part of the family of Markov Chain Monte Carlo (MCMC) methods. Given one batch of data  $y_{1:T}$ , a parameter prior  $p(\theta)$  and a model specification (Eq. 3 and 4), the MMH algorithm returns a finite sequence of samples  $[\theta_n, n \in 1 \dots N]$  approximating the posterior distribution  $p(\theta \vee y_{1:T})$ . Examples of applications to the calibration of building energy models include (Heo et al. 2012; Rouchier et al. 2018).

The algorithm employs a Kalman filter to compute the states  $p(x_{1:T} \vee \theta, y_{1:T})$  and likelihood  $L_y(\theta)$  associated to each proposal for  $\theta$ . If the state-space model (Eq. 3) is non-linear, this filter can be replaced by a particle filter: this approach is known as Particle Markov Chain Monte Carlo (PMCMC).

#### On-line estimation: Sequential Monte Carlo

The SMC algorithm for parameter estimation is an adaptation of particle filtering for state variables. The foundation of this method is the Importance Sampling paradigm as described by (Cappé et al. 2007): simulating samples under an instrumental distribution and then approximating the target distributions by weighting these samples using appropriately defined importance weights. The reader is referred to (Cappé et al. 2007) and (Kantas et al. 2015) for a deeper explanation of SMC and its application to parameter estimation. The method used

here is inspired from the Iterated Batch Importance Sampling algorithm (Chopin 2002). It is described on Fig. 2.

Figure 2. Principle of the Sequential Monte Carlo algorithm

The algorithm starts with the generation of a population of  $N_\theta$  particles drawn from a prior distribution  $p(\theta)$ . Each parameter is assigned an initial state  $\mathbf{x}_0$  and weight. At each time step  $t$ , a Kalman filter computes the states  $\mathbf{x}_t^{(j)}$  and likelihood  $L_t^{(j)}$  associated to each particle  $\theta_t^{(j)}$ . By this operation, the population of particles is updated so that at each time  $t$  they are a properly weighted sample from  $p(\theta \vee y_{1:t})$ . After several time steps, there is a risk that only a few of the initial particles are significantly more likely than the others and concentrate most of the total weight: a resampling step is then performed to generate a new population of particles from the most influential ones, and a MCMC rejuvenation step then restores the diversity of particles (Murray 2013).

Resampling does not occur every time a new observation becomes available, but only when required: this is measured by the effective number of particles that significantly contribute to the total weight of all particles (Murray 2013). This operation decreases the number of unique particles, hence the subsequent MCMC rejuvenation step that restores diversity. The choice of the proposal distribution for the MCMC rejuvenation step was proposed by (Chopin 2002) and ensures a reasonable acceptance ratio while leaving  $p(\theta \vee y_{1:t})$  invariant. The rejuvenation step makes the algorithm quite computationally expensive, since the total likelihood of all particles must be recalculated every time resampling occurs. This problem is mitigated by the fact that particles can be resampled independently, making this effort parallelizable.

## RESULTS

The MMH and SMC algorithms were used to estimate the parameter vector  $\theta$ , either off-line or on-line, using the batch of measurements shown on Fig. 1 from the RRTB test cell represented by a 2R2C model (Eq. 1). First, the sufficiency of the 2R2C model to recreate the indoor temperature time series in checked. This is ensured by the autocorrelation function of the residuals after parameter estimation shown on Fig. 3.

Figure 3. Autocorrelation of one-step prediction residuals

As pointed out by (Madsen and Holst, 1995), the low value of this function ensures that residuals are uncorrelated and thus are close to white noise, in accordance with the hypothesis is the model. This observation allows us to analyze the parameter estimation results. All estimation results from both MMH and SMC are assembled into Fig. 4.

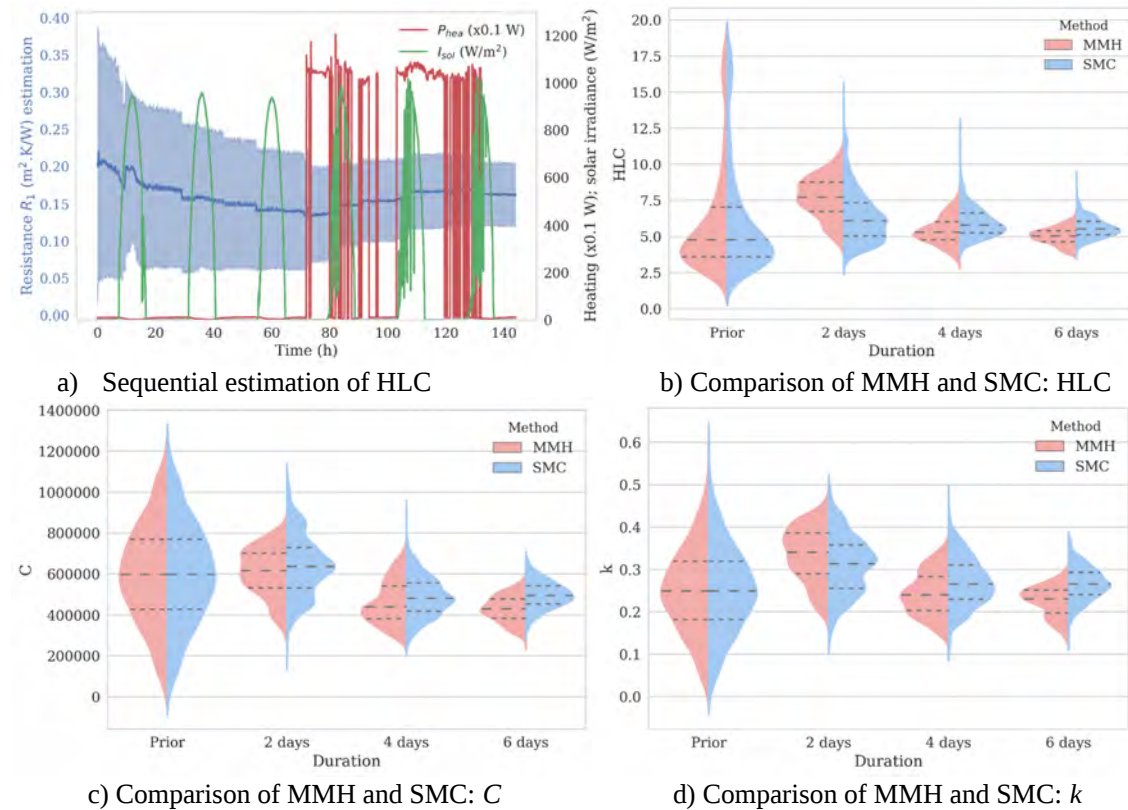

Figure 4. Parameter identification results

First, Fig. 4(a) shows the progression of the estimation of the parameter  $R_1$  by SMC during the six days of measurements. The blue area denotes the mean and the 95% confidence region of  $R_1$  at each time coordinate. The indoor heating power and solar irradiance are superimposed over it and allows the interpretation of the estimation. During the first three days of measurements, the value of  $R_1$  can be seen to narrow down to a more confident estimation during the day, when the solar irradiance is positive. An important uncertainty however remains on this parameter. The heating is then turned on inside the test box, which causes the estimation to narrow down more abruptly. These results are consistent with the general knowledge that some indoor solicitations are necessary to make a building energy model identifiable. The originality of the present study is that we can observe the information brought to the parameter estimates in real time.

The performance of SMC is then compared to the MMH algorithm, which estimates parameters from a single batch of data at once. Fig. 4(a), 4(b) and 4(c) respectively show estimates of the heat loss coefficient  $HLC=1/(R_1+R_2)$ , the total heat capacity  $C=C_1+C_2$  and the total solar aperture  $k=k_1+k_2$ . Each plot shows the prior distribution of these properties, and their estimation after 2 days, 4 days and 6 days of measurements. The MMH algorithm had to be run separately with each measurement length, while the SMC algorithm only had to run once to return all results. Starting from vague Gaussian prior distributions for each parameter, both methods resulted in mostly matching results.

## CONCLUSION

The present study uses the Sequential Monte Carlo method to train a RC model, and thus estimate a Heat Loss Coefficient, and other parameters, sequentially. Results show the direct impact of solicitations (solar irradiance and indoor heat input) on this estimation, in real time. The method is validated by comparing its results with the Metropolis-Hastings algorithm for off-line estimation.

### **ABSTRACT**

In order to reduce the energy use of residential buildings, regional governments in Belgium established, amongst others, mandatory criteria for the energy performance to be achieved after retrofitting. However, due to construction deficiencies, deviating boundary conditions, and non-modeled physical phenomena and interactions, the actual energy performance may differ significantly from theoretical design value. Several studies indicate this as the performance gap. This paper focuses on analyzing the actual impact of the refurbishment measures applied to a single-family home in Belgium. Hereto, in-situ measurements assessing the building envelope's thermal performance, described by the overall heat loss coefficient HLC [W/K], are performed both before and after the retrofit. To analyze this HLC, a quasi-steady state test, the so-called co-heating test, has been performed before and after renovation of a single-family home in Belgium, renovated to the nearly Zero Energy Building (nZEB) level.

As a result, the HLC determined with linear regression and an Auto-Regressive model with eXogenous inputs (ARX) show similar estimates, except for a smaller confidence interval for the ARX. Furthermore, it is shown that data set lengths shorter than 10 days are quite sensitive to sample times. For our case study, the gap between the theoretical and measured HLC enlarges after retrofit. Finally, the influence of a unheated neighboring zone on the HLC is assessed.

### **KEYWORDS**

Heat loss coefficient – In-situ measurement – Renovation – Residential buildings – Regression techniques

### **INTRODUCTION**

Since households have a 25 % share in the total energy use in Europe (Eurostat 2017), and a large share of the buildings has a poor energy performance (Cyx et.al 2011), there is a high need to renovate existing buildings in order to increase energy savings. However, several studies indicate discrepancies between the theoretical and the actual energy use after renovation, a phenomena most-commonly known as the 'performance gap'. (Hens 2007 & Bell 2010)

This paper aims to assess the building envelope performance and identify the performance gap before and after retrofit by evaluating the overall heat loss coefficient (HLC) using a co-heating test (Bauwens 2015). Three aspects of the HLC estimation are evaluated for a single-family, terraced house. First, different sample times and data set lengths are evaluated for HLC estimation with linear regression and ARX models. Secondly, the performance gap of the pre-retrofit and post-retrofit dwelling state is assessed. Thirdly, the influence of the garage as a neighboring unheated room is evaluated for the post-retrofit HLC.

The methodology section consists of three parts: first the test case is described, then the heat loss coefficient is calculated from theory and finally the two data assessment models for HLC identification are presented. The results section discusses the HLCs and the performance gap.

## METHODOLOGY

### Test case

The case study is a terraced dwelling in Belgium, which has been renovated in the framework of the 'Ecoren'-project, one of the Flemish pilot projects for renovation. The characteristics of this dwelling before and after renovation are presented in Table 1. The table distinguishes between the situation with and without the garage enclosed in the protected volume, which enables to evaluate the garage's influence on the HLC, since the walls between the dwelling and its garage are uninsulated. As the attic floor was already insulated before renovation, the attic is assumed to be a neighboring unheated zone. The envelope renovation was realised by replacing the outer cavity leaf of the original uninsulated wall by a prefabricated building component. The air permeability and the air change rate at 50 Pa shown in Table 1 represent the resulting values of the blower door tests performed according to NBN EN 13829:2001.

Table 1. Characteristics of the dwelling case

	Pre-retrofit With garage	Pre-retrofit Without garage	Post-retrofit With garage	Post-retrofit Without garage
Protected volume [m <sup>3</sup> ]	467	408	467	408
Building envelope [m <sup>2</sup> ]	261	261	261	261
Air permeability at 50 Pa $V_{50}$ [m <sup>3</sup> /(h·m <sup>2</sup> )]	18.11	9.03	24.49	21.63
Air change rate at 50 Pa $n_{50}$ [1/h]	15.95	9.59	21.57	22.98

A quasi steady-state co-heating test, as elaborated by Bauwens (2015), was carried out on the last three dwelling scenarios in Table 1. The co-heating tests of the protected volume without garage enables to compare the HLC of the same volume before and after renovation, while the tests of the two different volumes of the post-retrofit state can be used to estimate the heat losses through the garage. Before renovation, the protected volume without garage was kept at a constant indoor temperature of 20 °C for a period of 34 days in January 2016. After renovation, in February 2018, the indoor set temperature was 22 °C. During the first 20 days the protected volume included the garage, and secondly for 14 days the garage was excluded from the protected volume by closing the door. During these co-heating tests, the heating power was monitored, together with the outdoor climate, and the indoor air temperatures (accuracy ± 0.4 °C) in all rooms of the protected volume and neighboring zones, i.e. the attic, the garage and the two neighboring dwellings. The mean indoor temperature of the tested volume, used to estimate the HLC, was calculated as the volume-weighted average temperature  $T_{i,avg}$  of all rooms enclosed by the protected volume. Additionally, the heat flux in between the protected volume and neighboring zones was measured using Hukseflux HFP01 sensors (3 % accuracy).

### Theoretical heat loss coefficient

The HLC, composed by ventilation heat losses  $H_v$  and transmission heat losses  $H_{tr}$ , is calculated using equation (3) based on the approach of Bauwens (2015):

$$HLC = H_v + H_{tr} \quad (3)$$

With  $H_v = c_a \rho_a n_{actual} V_i$  &  $H_{tr} = \sum_{j=1}^c U_j A_j$

First, for ventilation heat losses  $H_v$  the following parameters are used: specific heat capacity of air  $c_a$  ( $\text{Jkg}^{-1}\text{K}^{-1}$ ), air density  $\rho_a$  ( $\text{kg/m}^3$ ), actual air change rate per hour  $n_{\text{actual}}$  (1/h), and the net air volume  $V_i$  enclosed by the building envelope ( $\text{m}^3$ ). The actual air change rate per hour is estimated by dividing the air change rate at 50 Pa by 20 (Kronvall 1978) or by a tracer gas test.

Second,  $H_{tr}$  is calculated using the thermal transmittance  $U$  ( $\text{Wm}^{-2}\text{K}^{-1}$ ) and the surface area  $A$  ( $\text{m}^2$ ) of all building envelope components. As the original  $U$ -values cannot be identified exactly,  $H_{tr}$  is defined as a range to incorporate uncertainties. Therefore, for the original dwelling the thermal resistances of the building components are based on the national standard NBN B 62-002 2008, while for the renovated state an accuracy band of  $\pm 5\%$  was set to the designed  $H_{tr}$ -value. In these  $H_{tr}$ -calculations, an equivalent, increased thermal resistance is determined for the floor addressed to the unheated attic following the national standard. (NBN B 62-002 2008).

Table 2 shows the resulting HLC calculated with equation (3) and the intermediate results of the actual air change rates  $n_{\text{actual}}$  and the heat losses  $H_v$  and  $H_{tr}$ . First, for all dwelling states  $n_{\text{actual}}$ -values in Table 2 were calculated from the  $n_{50}$ -values divided by 20. Additionally a tracer gas test was carried out for the full protected volume of the renovated dwelling, which resulted in a  $n_{\text{actual}}$ -value of 0.31 using the decay regression method (Sherman 1990). This is about three times lower than the resulting value based on the  $n_{50}$ -value, which was 1.08 1/h (Table 2). Therefore, the ventilation heat losses  $H_v$  of the post-retrofit dwelling are given as a range, of which the minimum is based on the tracer gas test and the maximum is based on the  $n_{50}$ -values. Finally, the resulting values of the HLC indicate an influence of 26 % to 31 % of excluding the garage from the pre-retrofit dwelling and 6 % to 10 % for the post-retrofit dwelling.

Table 2. Theoretic overall heat loss coefficient and its components

	Pre-retrofit With garage	Pre-retrofit Without garage	Post-retrofit With garage	Post-retrofit Without garage
Actual air change rate $n_{\text{actual}}$ [1/h]	0.80	0.48	1.08	1.15
Ventilation heat loss $H_v$ [W/K]	83	41	32 – 112	32 – 99
Transmission heat loss $H_t$ [W/K]	310 – 366	260 – 314	114 – 126	105 – 116
<b>HLC [W/K]</b>	<b>393 – 449</b>	<b>301 – 355</b>	<b>146 – 238</b>	<b>137 – 215</b>

### Data assessment models

In this work, the HLC is estimated using both a linear regression model and an Auto-Regressive model with eXogenous inputs (ARX). Using linear regression, the HLC can be estimated from equation (1) as the regression parameter  $\omega_i$ , following the recommendations of Bauwens (2015):

$$\phi_h^h - \phi_{tr}^n = \omega_i T_{i,avg} + \omega_e T_e + \omega_{sol} I_{sol} + \epsilon \quad (1)$$

with  $\phi_h^h$  the heating power,  $\phi_{tr}^n$  the heat losses towards the neighboring zones,  $T_i$  the volume-weighted average of the indoor temperature,  $T_e$  the outdoor temperature,  $I_{sol}$  the global horizontal solar radiation,  $\epsilon$  the residuals and  $\omega_x$  the estimated regression parameters. Note that the intercept of equation (1) is equal to zero. The heat losses  $\phi_{tr}^n$ , calculated from the heat flux signals, depend on the two tested volumes. When the garage is included in the protected volume,  $\phi_{tr}^n$  consists only of the heat losses towards the neighboring dwellings, else the heat losses towards the garage are also accounted for.

The research of Bauwens (2015) assessed that one disadvantage of the linear regression model is that it tends to underestimate the confidence interval, and that the result is often less robust.

The ARX model however, leads to a more reliable confidence interval. Therefore, the second model used is the ARX model, represented by a similar equation as the linear regression model:

$$\Phi(B) [\phi_h^h - \phi_{tr}^n] = \omega_i(B)T_{i,avg,j} + \omega_e(B)T_{e,j} + \omega_{sol}(B) I_{sol} + \epsilon_j \quad (2)$$

However, in this model backshift operators are applied to the inputs and output of the model ( $\Phi(B), \omega_i(B), \omega_e(B), \omega_{sol}(B)$ ), each of them being a polynomial of a different order. (Madsen et al. 2015) The overall HLC is now estimated as  $\frac{\omega_i(1)}{\Phi(1)}$ . The order of each backshift operator is determined by backward elimination: a 12-order model is reduced eliminating insignificant high-order parameters stepwise.

Following the statistical guidelines from IEA EBC Annex 58 (Madsen et al. 2015), the models are validated performing different tests: (1) testing for white noise residuals by autocorrelation plots or cumulative periodograms, (2) testing for uncorrelated inputs by cross-correlation functions between the residuals and their inputs, but also in between the inputs (3) testing for high parameter significance, and (4) testing for similar results using different data subsets and sample times. This fourth test is quite important, since the results of both models might be varying for different data subsets and sample times. Since cross-correlations might be affected by autocorrelations, an ARIMA(1,1,0) model is used to pre-whiten the inputs. (Bauwens 2015)

## RESULTS

### HLC estimation using linear regression models

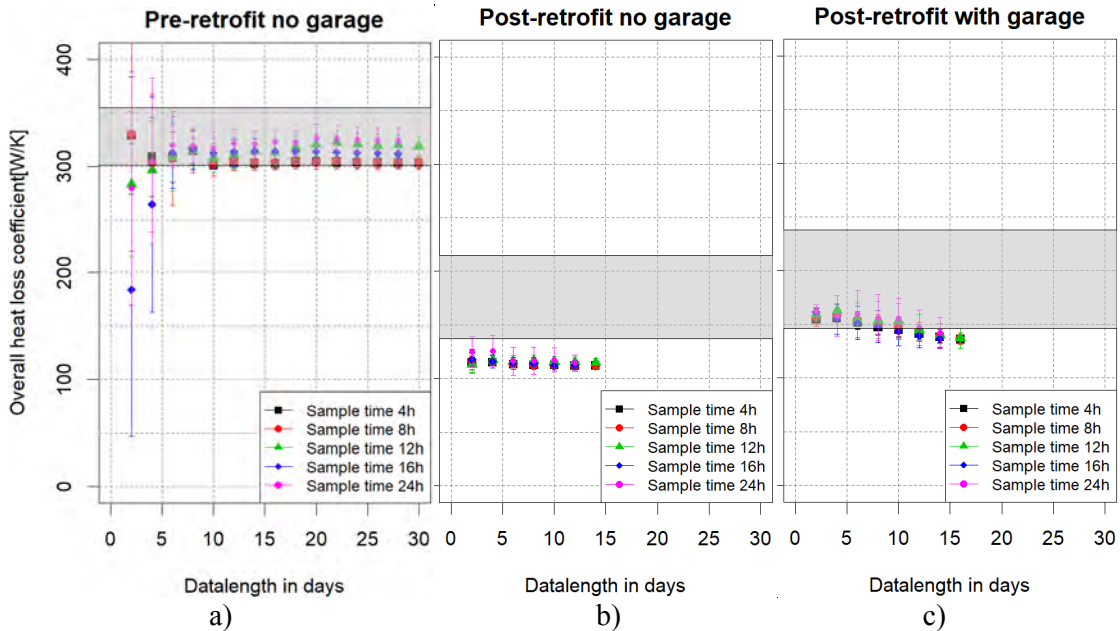

Figure 1. HLC estimated by linear regression a) pre-retrofit state without the garage enclosed in the tested volume, b) post-retrofit without garage, c) post-retrofit with garage.

Figure 1 shows the resulting overall heat loss coefficients and the related confidence intervals (2 times the standard deviation,  $2\sigma$ ), estimated by linear regression using different sample times and data set lengths. The grey band presents the theoretical HLC (Table 2). For the original dwelling (pre-retrofit Figure 1.a) the estimated overall heat loss coefficient ( $HLC_{estim}$ ) in general

corresponds to the theoretical value ( $HLC_{theo}$ ). The  $HLC_{estim}$  values for data set lengths of more than ten days are quite similar. The sample time, however, seems to influence the estimates: for small sample times (4h and 8h)  $HLC_{estim}$  is ca. 10 % lower than for large sample times (24 h). Validation plots in Figure 2.a and 2.b show that the estimates of larger sample times are more reliable, although these results are less robust (i.e. more susceptible to the input) since less data points are involved. Therefore, a 12h sample time was selected to compare the linear regression model to the ARX model (further in Table 3), being more reliable than short sample times and more robust than long sample times. (see Figure 2.c)

For the post-retrofit dwelling scenarios, the gap between  $HLC_{estim}$  and  $HLC_{theo}$  has increased:  $HLC_{estim}$  is now lower than  $HLC_{theo}$ , although this discrepancy diminishes if the garage is enclosed in the protected volume (Figure 1.b and 1.c). Next, compared to the pre-retrofit state, the influence of sample time has decreased:  $HLC_{estim}$  of the first post-retrofit state is quite constant for a dataset length of more than ten days. The results for the second post-retrofit state, however, are more scattered and also less reliable (Figure 1.d and 1.e).

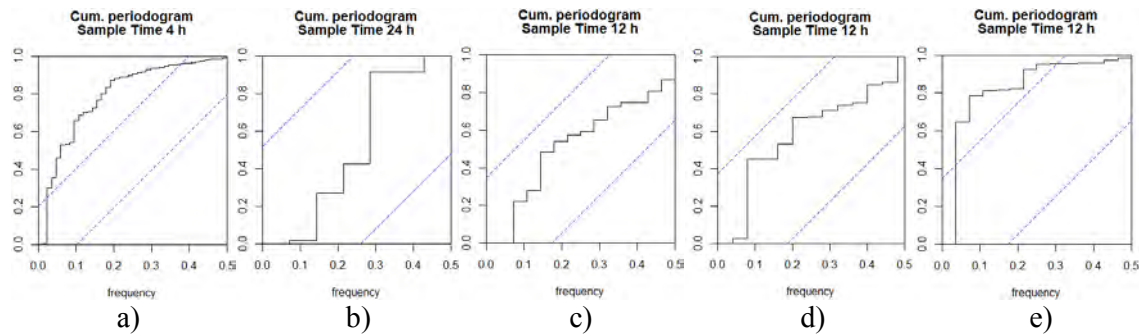

Figure 2. Validation plots of the linear regression model of a 14 day data set, first for the pre-retrofit dwelling scenario for a sample time of a) 4 h b) 24 h and c) 12 h, second for the post-retrofit dwelling scenario for a sample time of 12 h d) without garage and e) with garage

### Performance analysis using different models

The dynamic ARX model was the second model from which the HLC was estimated. Since this model type can incorporate dynamic effects like the influence of solar radiation and thermal inertia of a building, the sample time can be reduced considerably. Out of four sample time models – 15, 30, 60 or 120 minutes – a 30 minute model was selected as the most reliable, based on the validation plots. The resulting  $HLC_{estim}$  for this model are compared to the theoretical values and the estimates of the linear regression model in Table 3. This table shows quite similar estimates of the HLC for both models, but with smaller confidence intervals for the ARX model.

Table 3. HLC values and confidence intervals ( $\pm 2\sigma$ ) using the different models, for a 14 days dataset length. Linear regression: 12 hours sample time. ARX model: 30 minutes sample time.

Dwelling state	Theoretical $HLC_{theo}$ [W/K]	Linear regression $HLC_{estim}$ [W/K]	ARX $HLC_{estim}$ [W/K]
Pre-retrofit no garage	301 ~ 335	$313 \pm 12.31$	$308 \pm 6.68$
Post-retrofit no garage	137 ~ 215	$115 \pm 4.61$	$115 \pm 3.66$
Post-retrofit with garage	146 ~ 238	$139 \pm 11.04$	$142 \pm 10.21$

As a result, table 3 shows a quite small performance gap for the pre-retrofit state, since  $HLC_{estim}$  is identified in the range of  $HLC_{theo}$ . Conversely, the  $HLC_{estim}$ -value for the first post-retrofit dwelling scenario deviates ca. 20 % from the theoretical lower boundary. However, the

discrepancy decreases for the second post-retrofit scenario to ca. 5 %, although here a larger confidence interval was found. Altogether, the measured HLC increases by 20 % if the garage is included in the protected volume, which is higher than the theoretical influence (10 %).

## CONCLUSIONS

In this paper, the building envelope performance of a terraced single-family dwelling was assessed before and after renovation by means of the overall heat loss coefficient (HLC), identified from co-heating tests. First, for linear regression analysis, the estimated HLC is quite constant for a data set length of more than 10 days, although the pre-retrofit results are varying with about 10 % for different sample times. Using ARX models results in similar estimates albeit with a smaller confidence interval. Hence, a co-heating test of 10 days should suffice to estimate a quite reliable HLC of a dwelling. Second, the measured HLC corresponds quite well to the theoretical HLC for the original dwelling state, but deviates ca. 20 % for the post-retrofit dwelling state without garage. Third, the garage's influence on the HLC is theoretically lower (10 %) than was measured (20 %), indicating the need for further assessment on the influence of an unheated neighboring zone on a dwelling's HLC.

## ACKNOWLEDGEMENT

This research has been conducted as part of the pilot project 'Ecoren', supported by 'Vlaams Agentschap innoveren en ondernemen' (VLAIO). It contributes to Annex 71 "Building energy performance assessment based on optimized in-situ measurements".

### **ABSTRACT**

Buildings are responsible for a large share of the worldwide energy use. For new buildings very strict objectives for the energy performance of buildings are set. The main energy use however occurs in existing buildings emphasizing the need for renovation of the older building stock. In order to detect deviations from the theoretical performance, in-situ measurements of the envelope performance after renovation can give insight in the workmanship and issues with different renovation techniques. Therefore, the focus of this paper is to determine the thermal resistance of building components from in-situ measurements, before and after renovation.

Different methods were applied to examine the thermal resistance of the building components: the average method, linear regression, Anderlinds' method, ARX modelling (Auto-Regressive models with eXogenous inputs) and Grey Box Modelling. All of these methods seem to lead to similar results with only a small variation in confidence intervals, except for linear regression, which couldn't capture dynamic heat flows due to solar radiation.

For the assessed exterior walls, different phenomena influencing the thermal resistance were noted. The measured thermal resistance answers the estimated theoretical value of the building components quite well before renovation, but after renovation the difference is varying due to cavity air flows.

### **KEYWORDS**

Thermal resistance – In-situ measurement – Renovation – Building components – Characterization techniques

### **INTRODUCTION**

Being responsible for ca. 25 % of the total energy consumption (Eurostat 2017), the residential sector holds a large opportunity to increase energy savings. However, for each renovated dwelling, the resulting energy savings can deviate from the theoretically designed energy savings, amongst others because of poor workmanship for instance causing short circuiting of the insulation layers (Hens 2007 & Baker 2011). Several phenomena can be distinguished: wind-washing (air cavity flows due to wind pressure), rotational air flows (air flow loop around the cavity insulation), inside air washing (caused by air leaks in the interior cavity leaf), etc.

Therefore, the focus of this paper is to assess discrepancies between the actual and the designed renovated building envelope, by thermal resistance characterization based on in-situ measurements. Besides the most commonly used average method (EN ISO 9869-1:2014), four other characterization methods are compared. In the methodology section, first the case study and the performed measurement campaign are explained, followed by an overview of the used characterization methods. Subsequently, the estimated thermal resistances and the discrepancies with the theoretical values will be discussed both before and after renovation of the dwelling.

## METHODOLOGY

### Case study

The analysed case is part of the 'Ecoren' project, one of the Flemish VLAIO renovation pilot projects. It concerns a terraced house that is chosen from a block of four single-family dwellings, originally constructed in 1975 and renovated in 2017.

Table 1 shows the theoretical thermal resistances of the exterior walls, calculated following the national standard (NBN B 62-002 2008). The wall before renovation is an uninsulated wall that consists of an outer leaf made out of bricks, an air cavity of which it is unknown whether it has a (partly) ventilated air cavity or not and an inner brick leaf finished with a gypsum layer. During renovation, the outer brick layer was replaced by an insulated prefabricated element, constructed of a timber frame construction. For both dwelling states, the thermal resistance is shown for non-ventilated and ventilated walls: The thermal resistance of the original ventilated cavity wall is calculated as the thermal resistance of only the inner cavity leaf and its finishing (NBN EN ISO 6946:2007), while the thermal resistance of the renovated structure is decreased by 50 %, based on findings of Maroy (2017) and Deconinck (2016).

Table 1. Range of theoretical thermal resistance of the exterior wall of the case study before and after renovation

	Before renovation			After renovation		
	$\lambda$ (W/mK)	d (m)	R (m <sup>2</sup> K/W)	$\lambda$ (W/mK)	d (m)	R (m <sup>2</sup> K/W)
Outer cavity leaf	0.61 - 1.24	0.09	0.07 - 0.15	0.053	0.21	3.87
Non-ventilated air cavity		0.05	0.18		0.03	0.18
Inner cavity leaf	0.30 - 0.64	0.14	0.22 - 0.47	0.30 - 0.64	0.14	0.22 - 0.47
Gypsum layer	0.52	0.01	0.02	0.52	0.01	0.02
R <sub>non-ventilated</sub> (m <sup>2</sup> K/W)			0.49 - 0.81			4.29 - 4.54
R <sub>ventilated</sub> (m <sup>2</sup> K/W)			0.24 - 0.49			2.15 - 2.27

### Measurement campaign

Several in-situ measurements are carried out on the dwelling. First, the air permeability of the dwelling in both states was measured using a blower door test (NBN EN 13829:2000), and an infrared scan was performed. Second, the heat flow meter method was carried out, for which the surface temperatures at both sides of the building component and the heat flux through the component must be measured (EN ISO 9869-1:2014). The surface temperatures are measured with thermocouples, having an accuracy of  $\pm 0.50$  °C, which corresponds with  $\pm 7$  % for a mean temperature difference of 15 °C. The Hukseflux HFP01 sensors, used to measure the heat flux, have an accuracy of  $\pm 3$  %, and are attached with silicone as recommended by the manufacturer (Hukseflux Thermal Sensors 2018). Hence, the overall measurement accuracy is  $\pm 10$  %.

The heat flow meter method was performed before and after renovation of the dwelling. As this method is a local assessment, multiple locations of the exterior wall were carefully chosen, aiming to minimize the influence of thermal bridges. Before renovation, two exterior façade locations were monitored, namely the back and the front façade of the dwelling. Subsequently, after renovation, four locations were monitored: the back façade at the ground floor and first floor, and the front façade at the first floor at two locations. Since the dwelling was uninhabited, a constant indoor temperature could be maintained, which is preferable since the research of Deconinck (2016) showed that a free-floating indoor temperature complicates the thermal resistance estimation. The measurement campaigns are summarized in Table 2, with  $T_{\text{int}}$  the interior set temperature,  $T_{\text{ext}}$  the outdoor temperature and  $I_{\text{sol}}$  the global horizontal irradiation,

of which first the variation during daytime is given in W/m<sup>2</sup> and second the hours in % for which  $I_{sol}$  exceeds 100 W/m<sup>2</sup>.

Table 2. Measurement campaign boundary conditions

Campaign	Period	Duration	$T_{int}$ °C	$T_{ext}$ °C	$I_{sol}$ W/m <sup>2</sup>	$I_{sol}$ % hours
Before renovation	05/Jan/2016 - 09/Feb/2016	35 days	20	Min. -7.67	Min. 0.42	11.2 %
				Mean 5.84	Mean 85.84	
				Max. 16.22	Max. 405.4	
After renovation	07/Feb/2018 - 22/Feb/2018	15 days	22	Min. -6.62	Min. 0.45	26.3 %
				Mean 1.85	Mean 164.5	
				Max. 10.4	Max. 486.5	

### Data assessment models

Consecutively, five data processing models are applied to estimate the thermal resistance: two semi-stationary models, i.e. the average method and linear regression, and three dynamic models, i.e. Anderlind's regression, ARX modelling (Auto-Regressive models with eXogenous inputs) and Grey Box Modelling (GB modelling). Semi-stationary models are quite easy to use, but they rely on steady state boundary conditions, which are never encountered on site. The dynamic models, on the other hand, capture dynamic building behavior more accurately, although they are more complex in usage. (Madsen et al 2015 & Deconinck 2016)

First, the average method assumes that the thermal resistance  $R$  can be calculated by dividing the mean temperature difference by the mean heat flux  $q$  over a period of time  $n$ . This method results in a single value (equation (1)), without further knowledge of the reliability of the estimated value. The second semi-stationary model is simple linear regression, for which the estimated slope is the inverse of the thermal resistance (equation (2)).

$$R = \frac{\sum_{j=1}^n (T_{si,j} - T_{se,j})}{\sum_{j=1}^n q_j} \quad (1)$$

$$q_j = \frac{1}{R} (T_{si,j} - T_{se,j}) + \epsilon_j \quad (2)$$

The first dynamic model is the Anderlind's regression method, which assumes that the heat flux  $q$  at given time  $j$  is a function of the temperature difference over the building component, but also of the interior and exterior surface temperature changes in the past. A 24-hour time lag is applied here, following the recommendations of Deconinck (2016), leading to equation (3):

$$q_j = \frac{1}{R} (T_{si,j} - T_{se,j}) + \sum_{l=j-p}^{j-1} A_l (T_{si,l+1} - T_{si,l}) + \sum_{l=j-p}^{j-1} B_l (T_{se,l+1} - T_{se,l}) \quad (3)$$

For the ARX model, a backshift operator  $B$  is applied to the input and output, using the polynomials of which the order ( $n_q$ ,  $n_i$  and  $n_e$ ) indicates how many data points from the past are taken into account (equation (4.1)). For this model type, the thermal resistance is calculated using minimum variance weighting of the first-order polynomials (equation (4.2)).

$$\begin{cases} Q(B)q_j = \omega_{si}(B)T_{si,j} + \omega_{se}(B)T_{se,j} + \epsilon_j & (4.1) \\ \frac{1}{R} = \lambda \frac{\omega_{si}(1)}{Q(1)} - (1 - \lambda) \frac{\omega_{se}(1)}{Q(1)} & (4.2) \end{cases}$$

The used Grey Box model belongs to the class of stochastic state space models, existing of a system equation (5.1) and a measurement equation (5.2), with  $C$  the thermal capacitance. Since

in this paper a one order model is used, there is only one system equation. For this model, the total thermal resistance of the component is the sum of  $R_1$  and  $R_2$ .

$$\begin{cases} dT_1 = \frac{1}{c_1 R_1} (T_{si} - T_1) dt + \frac{1}{c_1 R_2} (T_{se} - T_1) dt + \sigma_i d\omega_i & (5.1) \\ Q_{hfm,j} = \frac{1}{R_1} (T_{si} - T_1) + \epsilon & (5.2) \end{cases}$$

All five characterization methods are applied to the collected data, which was averaged to hourly data sets. The models were validated by two major checks, following the guidelines of Annex 58 (Madsen et al 2015): (1) the parameters and related model orders were selected on their significance (p-value) and (2) the residuals were tested to be white noise by plotting the AutoCorrelation Function (ACF), the QQ plot and the time series plot of the residuals.

## RESULTS

### Air tightness of the renovated dwelling

As a result of the blower door test of the dwelling, air permeability at 50 Pa was identified to be 18.11 m<sup>3</sup>/(hm<sup>2</sup>) before renovation, and 24.49 m<sup>3</sup>/(hm<sup>2</sup>) after renovation. Hence, the air tightness is decreased, indicating the presence of air leaks. In addition, the infrared scan also visualized air leaks after renovation. Figure 1.a) shows low interior temperatures at the bottom of the back façade, caused by cold air infiltrating the cavity from the outside at the bottom of the prefabricated element. Figure 1.b) shows high temperatures at the top of the back façade, indicating rising warm air that infiltrated the cavity from the inside.

Figure 1. Infrared scan of the renovated dwelling. a) Inside view: Cold air infiltration at the bottom of the back façade b) Outside view: Warm air exfiltration at the top of the back façade

### Thermal resistance estimation

The thermal resistances estimated by the five prediction models with usage of the complete dataset are shown in Figure 2; Note the different vertical scales for Figure 2.a and 2.b. First, Figure 2.a) shows that the calculated thermal resistances correspond to the unventilated reference value for the original façades. For both façades, the results of the five different models differ by maximum 5 % which is within each other's confidence interval. Comparing front and back, it is observed that the thermal resistance of the front façade is about 10 % higher than for the back façade. This may be caused by solar radiation, as the front façade is southeast oriented and thus influenced by solar radiation. However, linear regression of both night-time and daily-averaged values resulted in similar results, so different air cavity behavior is more plausible. Still, it can also be a measurement error, since the accuracy is about 10 %.

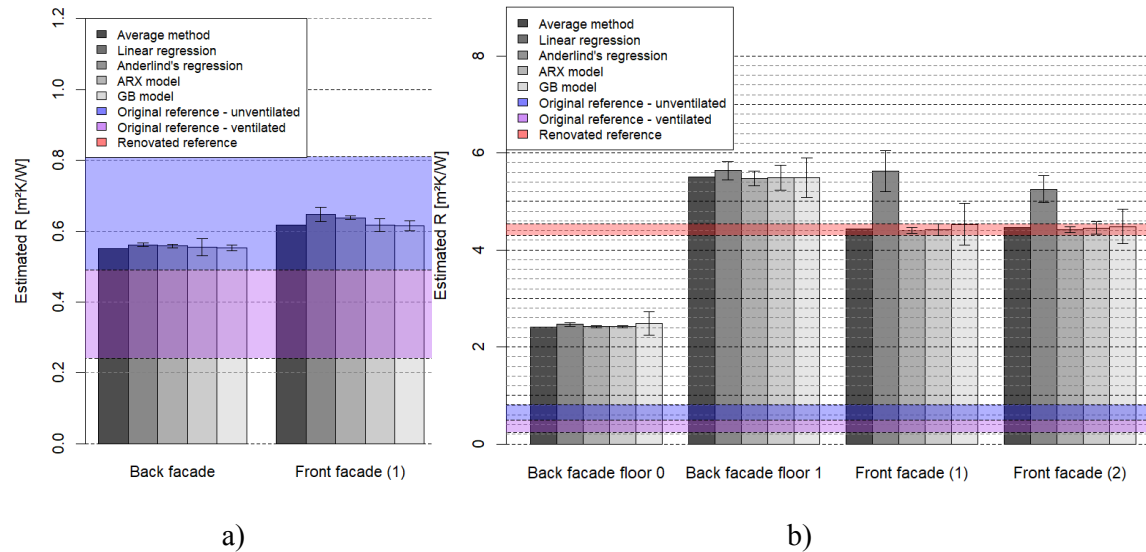

Figure 2. Estimated thermal resistances using the five analysis methods of (a) the original terraced dwelling (b) the renovated terraced dwelling. Note the different vertical scale.

Subsequently, Figure 2.b) shows the results for the renovated dwelling. Firstly, it can be noted that both measured resistances of the back façade do not correspond to the reference value. The measured thermal resistance on the ground floor is only 50 % of the reference value here, while on the first floor the result is about 20 % higher than the reference value. These findings can be explained by the influence of the air leaks shown in Figure 1, causing natural convection. As Lecompte (1989) and Maroy (2017) assessed in their numerical analysis of cavity walls, the measured thermal resistance of a building component will be lower if air infiltration from the outside decreases the temperature in the cavity. Hence, the temperature difference increases and the thermal resistance will decrease (see equation (2)). Inversely, at the top, air cavity temperature will increase due to interior air leaks, resulting in a higher thermal resistance.

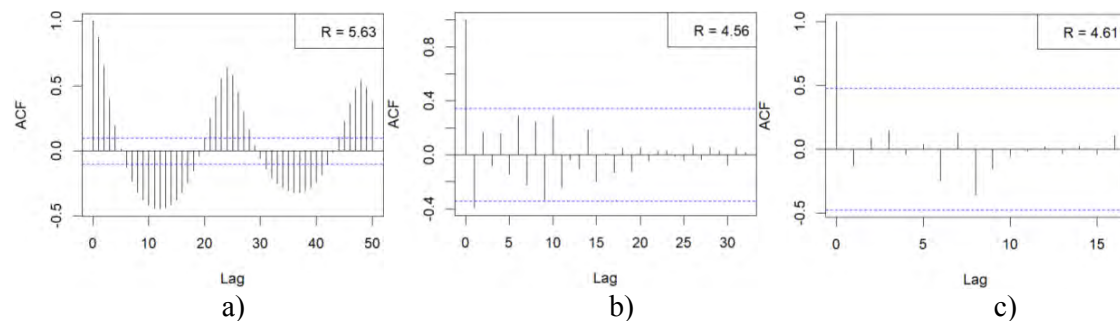

Figure 3. AutoCorrelation Function (ACF) of the linear regression for the renovated state of the front façade (1) with a) 1 hour sample time b) 12 hour sample time and c) 24 hour sample time

A second observation from Figure 2.b) is that the five models result in similar values for the back façade, while linear regression is an outlier for the front façade. Since linear regression is a semi-stationary model, here applied to a one hour data set, the model fails to capture the dynamic heat flows through the wall due to solar radiation. (Deconinck 2016) However, linear regression with an increased sample time estimates a thermal resistance similar to the results of

the other models. Hence, if the sample time of the data set is increased, the linear regression model is more reliable, as can be observed in the ACF-plots of the residuals in Figure 3, because now the dynamics are averaged out. This also explains why the average method estimates a similar thermal resistance as the dynamic methods, as the dynamic effects are also averaged out for this model. Still, this method does not give any information on the reliability of the estimate.

## CONCLUSIONS

First of all, quite similar thermal resistances of the exterior façades were estimated by five characterization methods, besides a varying confidence interval size. Only the linear regression model failed to capture dynamic building behaviour for a 1 hour data set. Hence, longer sample times should be used here. Secondly, only one of the two exterior facades of the renovated dwelling corresponded to the reference value, despite the fact that the same renovation measure was performed. Discrepancies were caused by different cavity behaviour and the air leaks.

## ACKNOWLEDGEMENT

This research has been conducted as part of the pilot project ‘Ecoren’, supported by ‘Vlaams Agentschap innoveren en ondernemen’ (VLAIO). It contributes to Annex 71 “Building energy performance assessment based on optimized in-situ measurements”.

### ABSTRACT

The integration of a wireless-transponder system into building components (“intelligent building materials”) with built-in relative humidity and temperature sensors (RH, T) allows for a cost-efficient and non-destructive measurement of data regarding the current hygro-thermal conditions of a building. Even during long-term use, quality assurance of the building system can be achieved by “looking into” the component. This supports the sustainability of the building from both a technical and an ecological point of view. In this paper, the development, the functionality and the exemplary application of Radio Frequency (RF), as well as an hygro-thermal analysis for solving the challenges of building-climatology planning is presented. Built on the measurement data of a real case study, the results of hygrothermal simulation tools are confirmed. Based on this, the use of thermal insulation in buildings for energy saving has been verified and the implementation into a hygrothermal simulation tool is shown. For the verification of results, a case study in Berlin was chosen, in which interior and exterior temperature and relative humidity values were recorded. Even with the peculiarity of irregular user behaviour of the building, good accordance between measured and calculated values could be achieved. Based on the analysis and evaluation of measurement data, as well as the implementation of hygrothermal simulations, the presented study provides a guideline for planning of ETICS with particular respect to extremely climate conditions.

### KEYWORDS

hygrothermal, ETICS, intelligent façade, ultra-low power sensor system, wireless sensor node

### INTRODUCTION

External thermal insulation composite systems (ETICS) on energy efficient façades are widely used under cold and hot climate conditions. However, the construction in both cases should be investigated in order to ensure avoidance of moisture damage. By an integration of wireless transponders into the installed insulation systems, it is possible to obtain information about the hygrothermal (temperature and relative humidity) condition of the system. In the case of critical measured values, concrete measures for the avoidance of damage (e.g. condensation within the construction, mold growth, algae) can be developed and implemented timely. In addition, the measured data can be compared with the results obtained from hygrothermal simulation tools that are used for verification and calibration of the data for further hygrothermal planning tasks. The wireless technology used here is a new transponder system with integrated humidity and temperature sensors. This system has been developed in order to check the material conditions in components such as exterior walls, ceilings or roofs, and to evaluate their structural-physical quality during the construction process. It allows for a non-destructive measurement data acquisition (cost effective, minimal effort) and an early detection of hygrothermally critical points within an insulated building structure, and thus contributes significantly to the prevention of structural damage. Traditional wired systems are cost intensive and always come with a high on-site installation effort (see figure 1). Moreover,

extra imperfections (thermal bridges) are introduced into the construction due to the wiring of the sensor and can bias the result. In addition, wired system could be installed only if power connection is available in situ. Wireless system can be installed also in inaccessible places.

Figure 1 a) Traditional wired sensor system, b) Wireless sensor system in the adhesive layer

### WIRELESS SENSOR SYSTEM

The main challenge for long-term monitoring systems is to provide energy for the operation for a long period of time. Traditionally, batteries are used to provide the energy for such a system. For the mentioned application of intelligent facades, size does matter: only small and low height electronic systems can be embedded into the facade in a simple way. This means that the energy supply cannot be enlarged indefinitely - only coin cell batteries can be used. This results in additional technical challenges, such as limited maximum discharge currents and self-discharges. These challenges have to be addressed when designing the wireless sensor system. The system is sourced from a pair of low leakage lithium manganese dioxide coin cells. Since it is difficult to change the batteries, the main focus of development of such a sensor system is the energy optimization of the whole system. This starts with the component selection, the hardware design, goes over to specific energy management and sleep strategies and optimized filter algorithms, and ends with an energy enhanced wireless protocol.

Figure 2. a) Block diagram of the wireless sensor system, b) Wireless node of the system.

Figure 2 (a) shows the block diagram of the wireless sensor node hardware. To enable the intended operation duration of more than 3 years, the system uses two ferroelectric-random-access-memory blocks (FRAM). One of these blocks holds the program execution context for the microcontroller. This enables the implementation of a programming model, utilizing an ultra-deep sleep mode without active RAM retention while significantly reducing the system

boot time and thus the energy consumption. The second memory block is for long-time storage of the recorded data, which is stored in a proprietary format. By choosing a FRAM technology, a non-volatile random access memory alternative to flash memory, the required energy for data storage is reduced by more than one order of magnitude, still guaranteeing the data retention for more than a decade and reducing the write/read times, which in turn reduces the energy consumption (Fujitsu, 2013). Figure 2(b) shows the final sensor node hardware before encapsulation. For wireless sensor systems, it is typical that the actual wireless transmission consumes the most energy in the system (Heinzelmann, 2000). Therefore, the design and optimization of the radio frequency sub-system is essential, and results in a large benefit for the operational time of the sensor system. For the described sensor system, a 2.4 GHz ultra-low power transceiver circuit has been selected. This circuit enables the design and implementation of custom wireless transmission protocols. The energy consumption of the transmitter circuit has been measured. Based on the measurements, an energetic model has been derived. Using this model, an energy optimized proprietary wireless communication protocol has been implemented. The protocol uses a net data rate of 2 Mbit/s with an automatic acknowledgement (ACK) packet generation and automatic retransmission of lost RF frames to ensure reliable wireless data transmission. The range has been limited to around 10 meters in indoor environments to reduce the energy consumption of the RF transmission. The sensor hardware uses an integrated humidity and temperature sensor circuit, which is connected to the microcontroller unit via the Inter Integrated Circuit (I<sup>2</sup>C) bus (NXP, 2014), a standard bus to connect peripheral ICs to microcontrollers. The sensor itself is factory calibrated. The accuracy of the sensor system has been evaluated using several experiments in a climatic chamber and with long term measurements. At the time of writing, this evaluation test has run for 30 months, and will be continued until the battery stops supplying power. The measurement of the battery voltage does not show any sign of wear-out for the near future.

#### **APPLICATIONS OF WIRELESS TECHNOLOGY IN BUILDING CONSTRUCTION**

Digitization of building materials and components, by means of the above described innovative transponder system with integrated temperature and humidity sensors (e.g. insulation board, façade elements) is important to carry out non-destructive monitoring of components for further physical investigations of the buildings, and thus preventing structural damage. For this purpose, a digital temperature and relative humidity sensor, embedded in a wireless-transponder, is installed in a wall structure. SHT21 sensor was chosen for the case study described below. It provides calibrated, linearized sensor signals in digital format. It contains a capacitive type humidity sensor, a band gap temperature sensor and specialized analog and digital integrated circuits. This yields an unmatched sensor performance in terms of accuracy and stability as well as minimal power consumption. Every sensor is individually calibrated and tested. Also the resolution of SHT21 can be changed on command from 8/12bit (0,7/0,04%) up to 12/14bit (0,04/0,1°C) for RH/T. Accuracy tolerance are  $\pm 2\%$ ,  $\pm 0,03^\circ\text{C}$ , hysteresis is  $\pm 1\%$ , and operation range are 0% to 100%,  $-40^\circ\text{C}$  to  $125^\circ\text{C}$  (Sensirion, 2014).

#### **APPLICATION OF WIRELESS SENSOR SYSTEM IN A CASE STUDY IN BERLIN**

With the goal of investigating the functionality of different ETICS by the use of a wireless measurement system and hygrothermal simulation tools, a case study in Berlin (Maerkische Scholle) was chosen. Five multi-story residential buildings are located in the same street, identical in terms of general dimensions, area, function, construction and direction. They were insulated with different insulation materials (EPS, hemp, wood fibre and mineral wool), and equipped with the newly developed measuring system as follows: Two measuring points were set up in each test house, points A and B (northeast façade, southwest facade). Each measuring point contains 3 sensors (RH, T), resulting in a total of 60 sensors. The reading out

of the sensor systems takes place via a read-out station with a reading distance of 10 meter (see figure 3). The temperature and relative humidity are recorded within the construction, as well as inside and outside. This examines the moisture absorption of the plaster and the change of the insulating effect of the five ETICS under changing daily and seasonal conditions, with regard to their protective effect against summer heat, winter cold and rain.

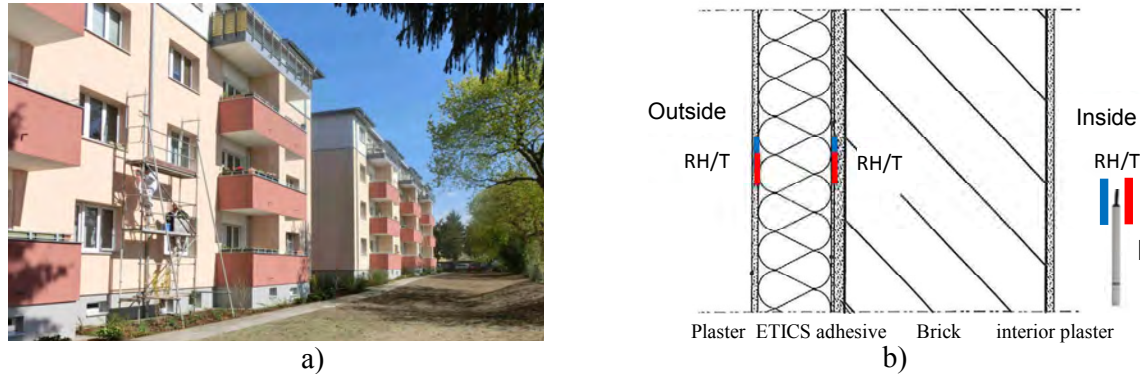

Figure 3. a) The case study in Berlin, b) location of the RH/T Sensors in the building

### MEASUREMENT RESULTS AND HYGROTHERMAL ASSESSMENT

In addition to the functionality of ETICS for reducing energy consumption, the hygrothermal situation and the indoor air quality should be examined for damage-free construction. For a hygrothermal performance assessment of the walls, the temperature and humidity measurements, recorded by above described innovative wireless sensors, were evaluated for buildings 1 to 5 at both sides of the insulation boards as well as indoors in each measurement section. The measurements of the test houses are shown in the sample below. Figure 4 (a) presents the measured temperature and relative humidity on hemp (measurements started October 17, 2016) under the plaster level as well as in the adhesive layer (between insulation and solid wall). At the beginning, the moisture in the adhesive layer is relatively high, which can be related to residual construction moisture, in addition to the fact that the apartment was not inhabited until mid-December. After that, the humidity drops significantly, remaining between 40 and 50% from December until the end of April, and raising to about 60% starting in May. The moisture under the plaster layer, in contrast to the moisture in the adhesive layer, rises significantly in winter and reaches the max. value of 100%, then beginning to decrease in March. The hemp moisture is also evaluated here according to the data-sheet of Scientific-Technical Association for Building Preservation (WTA). It defines a limit curve for the relation of temperature and relative humidity in the wood-pore to keep wood non-destructive (WTA 2002). For the evaluation the daily average values of temperature and humidity were used. Only in two days, at the beginning of the measurement, the hemp moisture slightly exceeded the limit; this is normal, because the flat was not heated and the building moisture had not dried out yet (see figure 4 (b)). Figure 5 shows the temperature profile on both sides of the hemp as well as of the mineral wool for comparison. We see that both systems keep the room-temperature relatively constant in summer as well as in winter. More precisely, the temperature on the inner side of the mineral wool is about 2 K higher than that on the inner side of hemp or wood fibre mainly in the summer. Hemp reacts slowly to the outside temperature, compared to mineral wool. It has a temperature time shift of about 4-6 hours. This is due to the high heat storage capacity of hemp and wood fibre, and provides also a positive feature for the summer heat protection. The temperature time-shift between that of hemp and that of mineral wool can be seen clearly in figure 5 (b), which presents the temperature curves on both sides of insulation board during a 3- days period in a bigger scale.

Figure 4. a) Measured RH/T on both sides of hemp, b) Evaluation of hemp RH/T by WTA

Figure 5. a) Measured temperature on both sides of the wood fibre, hemp and mineral wool, b) The same measurements in bigger scale during a period of three days

The conditions for mold growth on the inner wall surface depending on the indoor climate are also evaluated according to ISO 15026/13788 in all five buildings with four different ETICS. Here the daily average of absolute indoor humidity is assessed (calculated as a function of measured indoor relative humidity and temperature). Figure 6 shows the evaluations of buildings insulated with hemp (a) and with mineral wool (b) in comparison. All values of the building insulated with hemp are below the limit for normal occupancy (conditions for mold growth not given). For the building insulated with mineral wool few values exceed the limit for normal occupancy, and in about 7- days the values exceed even the limit for high occupancy.

Figure 6. a) Relationship between outdoor air temperature and indoor absolute humidity for the building insulated with hemp, b) the same for the building insulated with mineral wool

## COMPARISON OF THE MEASUREMENT AND SIMULATION RESULTS

For the comparison of the measurement and simulation results the hygrothermal model WUFI® is used (WUFI-Manual, 2015). For the calculation, the real outdoor climate conditions of Berlin and a constant indoor climate (20°C, 50%) according to ASHRAE 160 as well as the all hygrothermal material parameters, determined in laboratory (thermal conductivity, vapour division resistance, water absorption coefficient, thermal capacity, porosity) are considered. Figure 7 shows an exemplary comparison of measured and simulated relative humidity and temperature between hemp and massive wall. The results of calculated and measured RH/T are in good agreement. Little deviation is seen on occasion, which can be attributed to user behaviour (inconstant indoor climate). However, both results indicate moderate moisture values between hemp and massive wall. Since the calculation results using WUFI® are in good agreement with the measured one, the simulation model could be used for hygrothermal calculations, which could be needed for further analysis considering real climatic conditions.

Figure 7. a) Measured and calculated (RH, T) between wall and hemp, b) The same in 4 days

## CONCLUSIONS

On the basis of wireless technology an innovative sensor system for the humidity and temperature measurements (RH, T) has been developed. For ensuring a long-lasting, energy-efficient and performing measuring system an energy model has been derived from lab measurements and thus an optimized wireless protocol was implemented. Using this developed wireless technology, non-destructive effective measurement and diagnosis about the current state of building component were recorded and evaluated. Additionally to the fact that insulation does have a big effect of significantly reducing the heat flow through the wall, the results of the wireless system show that measuring after two years, no damage and no rain penetration were found in all variants. The moisture content of hemp/wood fibre ranged between 8 - 12M%. Hemp and wood fibre have a positive effect on summer heat protection. The indoor climate in both buildings, insulated with hemp and wood fibre, is comparable to other systems. So the conditions for mold growth on the inner wall surface are not given. This study proves that, an intelligent façade with integrated wireless- sensors (RH/T) guarantees a long-term, damage-free construction, during building use, by “looking into” the construction.

### **ABSTRACT**

In Europe the management costs and lack of flexibility of the sports halls, built in the second half of the '900, brought to the progressive abandonment of many structures. In this context the environmental, social and economic sustainable aspects of a refurbishment project of an Italian large sports hall, named "Palasport", are presented. It was designed by a group of architects and engineers and completed in 1962. It is located in the expo area of Genoa, a north Italian city, called "Fiera del Mare" and it plays a strategic role in the social community.

In the past it hosted several international events such as concerts, fairs, exhibitions and sporting events. Today the building is completely unused for several reasons, including the obsolescence of the mechanical and technological systems, the high operating costs, the lack of versatility and adaptability of the structure. For these reasons, it has been developed a project in the name of environmental, social and economic sustainability for a building that could attract different types of users during the day. The project is realized with the support of Building Information Modelling (BIM) methodology. The BIM is used to execute various simulations and scenarios to obtain the best possible results, to analyze functional, social, energetic and economic aspects. Furthermore, it is used to simulate Palasport in dynamic condition to understand its real behavior with dedicated applications (Equest, ElumTools). In the presented refurbishment project renewable energies are used: from the sun for the production of electrical energy, from the seawater to improve the performance of the Heat Ventilation and Air Conditioning (HVAC) system and from the wind to refresh the pavilion. This project makes the Palasport a flexible and resilient construction and adapt it to the future needs of society.

### **KEYWORDS**

Resilient refurbishment, BIM applications, dynamic lighting simulations, thermal behavior.

### **INTRODUCTION**

The urban fabric, mostly in Europe, is saturated and therefore it is increasingly the need to optimize existing heritage, improving its qualities and transforming the criticalities in new strengths. In the European cities often there are disused buildings because they are no longer able to meet the functions for which they were designed and the needs of the urban context in which they are located. The Genoa "Palasport" is certainly one of this kind of buildings, despite the historical importance it represented.

The Palasport, also known as "Pavilion S", stands in the Sea Fair of Genoa (Figure 1), whose urban design is attributed to the engineer Luigi Carlo Daneri. Today the fairground is developed among the following buildings: Pavilion B (designed by Jean Nouvel), Pavilion D (old place of University of Genoa), Pavilion C (exhibition places with historical and "experimental" tensile structures). The actual project of the Municipality of Genoa to transform the entire area offers an opportunity to return a sea view to the city and to relocate

the recreational activities in areas suitable for the performance of sports and nautical activities. This reconversion follows the design of the New Waterfront of Levante (masterplan by Renzo Piano) and combines the development needs of one of the most important industrial sectors of the city (naval repairs) with the process of modifying one of the most delicate and precious stretches of the entire urban coastline. The new places thus released will host, in addition to the navigable canals of the new marinas for pleasure boats, residential/receptive, directional, sporting and commercial functions; places and opportunities for meeting, exhibition, development and enhancement in the areas of leisure, sport and culture, with the relative parking spaces.

Figure 1. (a) The coast of Genoa; (b) The pavilions of Sea Fair of Genoa: S (Palasport), B (designed by Jean Nouvel), D (old place of University of Genoa), C (exhibition places with historical and “experimental” tensile structures) (Cenci, 2018).

The Palasport, object of this writing, has an area of 30.000 m<sup>2</sup>, split in three different levels: the ground floor, just below the external reference quote, has a diameter of 160 meters and it's surmounted by two concentric ring galleries. The central zone with two grandstands with 2.000 seats has a large space at full height. From the inauguration, the Palasport is characterized by its great multi-functionality, hosting international sport events, concerts, exhibitions with great success. However, with time, the previous events were too sporadic to justify the high running costs; this aspect, with the age of the technological systems, has brought to a progressive inactivity of the pavilion. The project of the new functions and consequence design for the Palasport regeneration was based on the resolution of these problems and took advantage from the inclusion of different activities inside and outside, because inserted in the masterplan by Renzo Piano.

## METHODS

The requalification project of the Palasport wants to give back the building to Genoa, making it the pivot of sports agonistic and amateur activities. So it was chosen to make a project table with CONI Liguria to understand the real needs of the sports federations, located in the Ligurian territory. This collaboration has brought to an optimization of the internal spaces in order to host the large number of sports activities, like as basketball, volleyball, tennis, boxe, rhythmic gymnastics, football, ping pong, badminton, etc. To cover the operating costs is necessary to include other collateral activities, for example commercial establishments, restaurants, conference rooms and entertainment spaces.

Thanks to the collaboration with sports federations it's born the need for a sport medicine center, agreement with CONI, to be included in the Genoese urban context. Therefore the project includes a large space dedicated to sports medicine in the building, that could become a landmark for all of Liguria.

The careful study of the spaces has allowed to insert a large number of activities, without precluding the possibility of hosting large sports events, exhibitions and concerts (Figure 2).

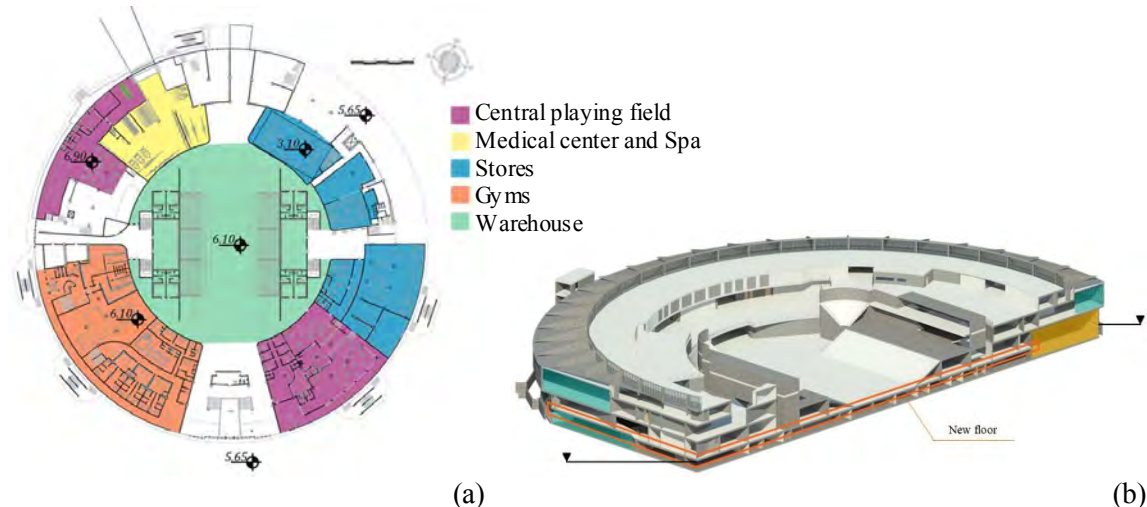

Figure 2. The requalification project of Palasport, examples of project development in BIM mode: (a) first floor; (b) the new floor.

Thanks to the new floor at the same elevation of outside, the Palasport has four floor, so there was the necessity to design some new side stands, that can host 4.000 spectators. As previously stated, one of the standards on which this design is based is the versatility of the interior spaces; this has been achieved with the use of slight prefabricated walls to give greater freedom to the interior arrangement, that could change according to the needs of users. The independence of the rooms hasn't pursued only at the planimetric level, but also from the plan engineering point of view, especially under the thermal and lighting aspects.

For the outer casing only some interventions are necessary in order to keep the original characteristics of the Palasport as much as possible; furthermore, insulating and compartmentalizing the rooms it wasn't necessary to modify the roof and the vertical curtain walls to obtain good thermal insulation values.

The plant engineering aspects were addressed to minimize consumption; in particular, the lighting and thermal conditioning systems, incorporating renewable energies: infact the heat generation system was granted to seawater heat pumps, while the electrical requirements were partially satisfied by the use of photovoltaic panels.

All the simulations of this project have been performed with BIM technology. This type of design is based on a parametric modelling, born in the '80s, whose innovative aspect is the ability to report the changes made on an element, or some of its features, throughout the model, keeping it continuously updated, in function of the context changes too. Through BIM technology you can do a lot of operations, such as architectural, structural, plant engineering simulations, controlling temporal and economic variables too. For these reasons Building Information Modelling is considered a 5D technology.

## RESULTS

In the BIM's mode several dynamics simulations are used to verify the project hypotheses for energy efficiency and comfort conditions. In particular, are conducted: lighting simulations,

thermal-hygrometric simulations (for energy efficiency and indoor thermal-hygrometric comfort); irradiation analyses (for renewable energies production) and wind flow analyses (for indoor thermal-hygrometric comfort).

Figure 3. Used tools for dynamic simulations: lighting simulations (ElumTools, EnergyPlus), thermal-hygrometric simulations (Green Building Studio, Equest), irradiation analyses (Solar-Autodesk) and wind flow analyses (FlowDesign-Autodesk).

The first topic was the lighting project, with the purpose of obtaining the maximum illuminance value, respecting the quality parameters required by current legislation (UNI EN 12464-1:2011), namely: general uniformity, glare, color rendering and color temperature.

Figure 4. Examples of results for lighting simulations in lux.

The next step was the insertion of a control system for many applications: to optimize the luminous flux of the luminaires, according to the specific requirements of the regulations for the different activities, to keep the best visual comfort, to have, overall, the greatest energy savings possible.

The thermal-hygrometric project was studied using dynamic energy simulations, in order to analyze in detail the Palasport behavior and needs. As an example of the conducted dynamic analyses, the hourly values of the energy demand are shown (Table 1). In this case the dynamic simulation permitted to determine the exact peak load for heating and cooling through which the heat pump was sized.

Table 1 - Peak load values.

Peak loads	
Heating peak load [kW]	-1896.6
Peak cooling load [kW]	2926.7

Consequently, a seawater source heat pump (SWHP) was chosen which harnesses the Mediterranean sea thermal energy as a means of generating renewable energy. Three modular SWHP were, therefore, assumed to be used (Table 2).

Table 2 – SWHP Specification.

Heating		Cooling	
Rated Heating Output [kW]	1188	Rated Cooling Capacity [kW]	1061
Power Consumption [kW]	242	Power Consumption [kW]	204
Coefficient of performance (COP)	4.89	Energy efficiency ratio (EER)	5.21
Evaporator water flow [m <sup>3</sup> /h]	205	Evaporator water flow [m <sup>3</sup> /h]	185

In this way, the winter requirement is satisfied thanks to the use of only two SWHP, achieving savings in terms of electricity consumption. The third, therefore, would be used during the cooling season or in case of failure of one of the other two.

BIM simulations were used to sizing the renewable energy systems too; in particular, for the photovoltaic systems it has been planned the use of CIS panels, composed with copper, indium and selenium. These panels have an excellent efficiency, so we can ensure a greater production than the use of traditional photovoltaic panels maintaining the aesthetics of the Genoese roofs.

Figure 6. Photo insertion of photovoltaic panels and annual irradiance on Genoa "Palasport".

To fully exploit the context in which the building is located, it was decided to use natural ventilation to condition the premises during summer, checking beforehand the intensity and the direction of the prevailing winds. The natural ventilation takes place through the opening and closing of windows controlled by a Building Automation system that conveys the air inside the building, in function of outdoor and indoor temperatures and wind's characteristics.

Figure 7. Analysis of the summer wind regime and the schematic dynamic natural ventilation.

## DISCUSSIONS

Building automation is a fundamental element in this project: thanks to it, it's possible to control the ventilation, the heating system, according to the individual indoor use destinations, monitoring the thermal-hygrometric conditions of each rooms, the lighting requirements with presence and twilight sensors and the optimization of photovoltaic panels.

## CONCLUSIONS

In the end we can say that the design solutions chosen in the project, such as the subdivision of the rooms, the plant engineering independence, the use of sea water to refrigerate the heating system, the use of LED technology for lighting, natural ventilation to counteract the heating in summer and the Building Automation, have led to an important reduction in operating costs, that are equal to about 200.000 €/year. This amount is in particular due to electricity consumption which is further reduced by 40% thanks to the use of photovoltaic panels, making the Palasport sustainable from an environmental and economic point of view.

## Dynamic Life Cycle Assessment Integrating Cultural Value

### ABSTRACT

Lack of spatial and temporal flexibility is a well-known limitation of current life cycle assessment (LCA). Exclusion of human and time consideration in LCA can also limit the potential of results. This paper explicitly proposes a dynamic life cycle framework and assessment model and demonstrated the potential importance of the method by integrating the cultural theory of risk. Cultural theory (CT) of risk was developed by anthropologist Mary Douglas and is originally a societal social anthropology approach based on the structure and functioning of groups within societies. Different society produces its own selected view of the natural environment, a view which influences its choice of danger worth attention. Applying the set of views of natural environment helps us to understand how occupants behave and make important decisions that produce substantial environmental impacts during the building use phase. Cultural theory results in five archetypes of people: the individualist, hierarchist, egalitarian, hermit, and fatalist. Each archetype reflects a composition of ideologies, cultural biases, social relationships, moral beliefs, and concerns of interest. One of the reasons to apply CT in this LCA research is the fact that the different archetypes can be considered as theoretical constructs that facilitate a comprehensive classification of decision makers in LCA. A case study of an elementary school is used to illustrate the importance of the method and demonstrate the differences between conventional static LCA and dynamic LCA. The results showed a noticeable difference and illustrated some unique environmental impact trends by integrating value choice and human factors in the LCA model. The findings suggest changes during a building's lifetime can influence the analysis results to a greater degree, and that long-term indicators and short-term indicators have different impacts on results. Therefore, adapting a dynamic framework could increase the applicability of LCA in decision-making and policymaking.

### KEYWORDS

Dynamic life cycle assessment, school building, value choice

### INTRODUCTION

As designers, engineers and building industry practitioners become increasingly aware of the environmental impact caused by building products, building systems and early design decisions, accurate environmental assessment has become important for the building and construction industry to achieve a more sustainable future. Life cycle assessment (LCA) can aid in quantifying the environmental impacts of whole buildings by evaluating materials, construction, operation, and end of life stages, with the goal of identifying areas of potential improvement (Junnala et al. 2006; Scheuer et al. 2003; Kofoworola and Gheewala 2008; Wu et al. 2011). Effective improvement and utilization of life cycle assessment in building industry, particularly design phase, hinge upon identifying current barriers that burden LCA. One of the critical barriers is the integration of ever changing factors during the entire life span of a building. Unlike other commercial products, a building has a much longer life span, 50-75

years, and the use phase can have large environmental impacts with multiple renovations and building upgrades related to building technology developments. Variations (such as multiple renovations) within the use phase can sometimes be greater impact than the total impacts of materials, construction, or end-of life phases (Collinge et al. 2013), and the variations are often caused by the users' choice and decisions, human factors. The proposed dynamic LCA framework and model allow the integration of value choice in the LCA of building.

## CULTURAL THEORY

Cultural theory (CT) was developed originally as a societal social anthropology approach based on the structure and functioning of groups within societies. Any form of society produces its own selected views of the natural environment, a view which influences its choice of danger worth attention (Douglas 1982). Applying this set of views of the natural environment will help us to understand how people behave and make important decisions that produce substantial environmental impacts during a building's entire life cycle. Douglas argues that the variety within an individual's social life can be adequately captured by the two dimensions of sociality: group and grid. Group is the extent to which an individual is incorporated into bounded units, and grid denotes the degree to which an individual's life is circumscribed by externally imposed prescriptions (Mamadouh 1999, Hofstetter et al 2000). The two dimensions together define an archetype: strong group boundaries along with minimal prescriptions produce *egalitarian*; *hierarchist* is characterized by strong group boundaries and prescriptions; *fatalist* is excluded from group decisions coupled with binding prescriptions; *individualist* is defined by neither group incorporation nor prescribed social roles; *hermit* is the individual completely withdrawn from social involvement. These five archetypes could be understood as perspectives that are taken to view and manage the system, dealing with risks presented from natural disasters or man-made catastrophes. Among the five archetypes, "*fatalist*" will not take long-term or life cycle perspective and take no active role in decision making, and "*hermits*" withdraw from social involvement altogether (Hofstetter et al 2000), therefore, only three are active in public decision-making: the *individualist*, *hierarchist*, and *egalitarian*. Using CT could help us understand and predict the decisions made by a group of people, a community, or a society. *Egalitarians* have the longest time horizon for building life. They would argue that exposure in the distant future is at least as important as exposure today and society should adjust its needs to limit the exposure of future disasters or risks (Frischknecht et al 2001). The *individualist* views humans as having a high adaptability through technological and economic advancement; therefore, their decision-making will be based on known damage or threats. They concentrate on the present effects over future loss and gain, and their time horizon for a building's service life span is the shortest. The *hierarchist* considers nature to be in equilibrium. They view the present and future as equally important. They seek proper management to avoid future risk and search for a balance between manageability and precautionary principles. Their time horizon for a building's service life span falls in between the *egalitarian* and *individualist* and typically coincides with the current life span used among the building industry which is 60-70 years (De Schryver 2011; Hofstetter 1999). Collectively, the different social groups' views on building longevity and impact are reflected in their approach of pursuing energy efficiency while reducing environmental impact. The *Individualist* group focuses on short-term payback and result, thus site net zero energy is their interest. The *hierarchist* group focus on long-term energy balance and impact reduction, so source energy is their main concern. We could assume different countries could be viewed as collective social groups. For instance, we assume United States is an *Individualist* dominated group, and China is a *hierarchist* dominated group. The different views of the natural environment could result in different, localized approaches to energy conservation and environmental reduction. The understanding

of each groups' decision-making mechanism and their view of the built environment could eventually feed into policy making, particularly the policies and regulations in the building industry, since building industry has a profound impact on the natural environment.

## METHODS

Figure 1 represents this dynamic LCA framework. Compared to the static method, this proposed framework counts character change along with the time horizon (CT horizon) analysis, which is also discounted based on choice value. Time is influential when a life cycle assessment method is used to estimate the environmental impact of an object. An impact rarely occurs instantaneously but rather occurs over an indefinite period of time. In the proposed framework, instead of allowing only one time horizon, we used a finite time horizon to define the system evolvement through the entire life span. To incorporate the human factor to LCA decision-making, user value choice based on the archetype and the discount rate were used to rank the importance of different parts of multiple objectives. An existing elementary school in the state of Maryland was used as the case study to test the framework and model. Quarterfield Elementary School is a one-story masonry building about 44,000 square feet.

Proposed Life Cycle Assessment Framework

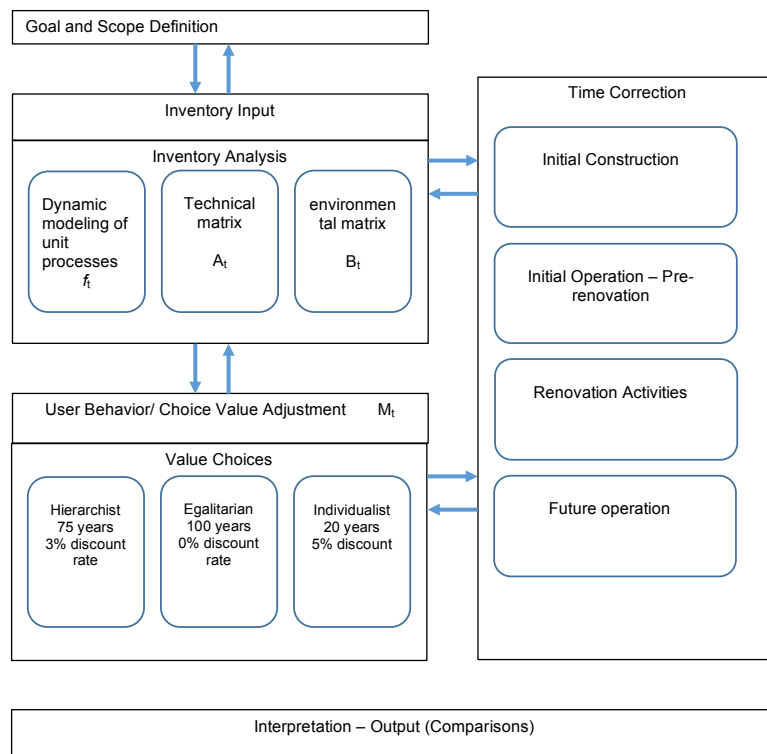

Figure 1 Dynamic framework and model

The major difference between the static model and proposed model is (1) the use of time sequence tables to simulate dynamic variation in matrix coefficients representing modeled relationships. If there is no particular time sequence assigned to variables, then we assume to use a constant value for all time steps; the same as what is used in the static model. The full lifetime in the dynamic model encompasses four time sequences/steps that are explained in Table 1. The future operation includes potential renovation, future operational repair, and

maintenance. The second major difference between the models is (2) the adjustment of results through the user's value choice to predicate different scenarios.

Table 1 Time sequence/adjustment included dynamic model

Time Sequences/Steps	Duration	Timeline	Annual Average Energy Usage
Initial Construction (DY-IC)	1 year	1968	
Initial Operation – Pre-renovation (Dy-PA)	23 years	1969-1992	375,400KWh (electricity) 2,4 Million ft <sup>3</sup> (gas)
Renovation Activities (DY-RA)	16 years	1992-2008	319,090KWh (electricity) 2,0 Million ft <sup>3</sup> (gas)
Future Operation (Dy-FO)	35 years	2008-2043	225,240KWh (electricity) 1,4 Million ft <sup>3</sup> (gas)

## RESULTS

The results have been normalized to the final static LCA results for each environmental impact category. The categories included in this study are global warming potential, acidification potential, Particular Matter effect on human health (HH Particulate) impact, and ozone depletion potential. The static LCA model was set up based on the original construction documents without any renovation and modification and with a life span of 75 years, which includes the embodied energy and operational energy consumption. The dynamic model was created based on the four time steps explained in table1.: initial construction (year 1), initial operation (before the first major renovation), renovation activities (including multiple renovations across a 16-year life span), and future operation. Figure 2 illustrates the results before integrating the users' value choice. The static model results are higher than the results from the dynamic model in all categories. The largest difference is in the ozone depletion category with the static model projecting more than an 8% higher impact. For the rest of the categories, the acidification potential is 1% higher, human health particulate potential is 2% higher, and global warming potential is less than 1% higher.

Figure 2 Environmental impact comparison between static model and dynamic model

Three different archetypes have been analyzed and compared. The actual values have been normalized and compared as annual impacts. For egalitarians, the global warming impact takes higher priority. The second and third impacts are the human health particulate potential and smog potential, which could be due to the long-term view of egalitarians and long-term service life span of the building. Those three categories are influenced by long-lived impact

indicators, especially those factors particularly related to human health that are embedded in building materials and assemblies, lasting the entire building life. Without discount, the time compounding effect shows a big difference. Hierarchists and individualists have similar impact profiles, with the ozone depletion potential being the primary concern. Most ozone depletion indicators have a relatively short-lived term. Both hierarchists and individualists have shorter building lives with discount; therefore, those short-lived indicators illustrate a bigger impact. Overall, the egalitarian has very different trends from the individualist and hierarchist, which indicate that the discount rate factor has a higher impact than life span, meaning the integrating users' preferences and value choices could create very different results from those using the existing static model. For a society or community who holds a long-term vision and an enduring perspective of its future development, paying attention to those long-lived environmental indicators is imperative. If we translate the perspective of building design and construction for building types such as institution, health care, and civic buildings, whose owners and operators are usually the same, then the categories that will contribute the most to environmental impacts would be global warming and human health particulate impact potential.

Figure 3 Value choice comparison

## CONCLUSION

Therefore, adopting a more dynamic LCA approach, as demonstrated herein, seems likely to provide a more detailed and project-specific projection and equip policymakers and decision-makers with a more accurate and holistic estimation. More importantly, using the cultural theory demonstrated, that the user's choice and cultural context will play a critical part in the LCA of the same building, and the results could vary largely due to the community's and group's perception of building use and tolerance of the risk. In order to fully account for all necessary uncertainties in the LCA study, future research needs to include users and cultural factors, and additional exploration of the interactions with dynamic, temporal, or cultural variables will be very useful to fully understand the environmental impact of individual buildings.

### ABSTRACT

Building energy modelling has become an integral part of building design due to energy consumption concerns in sustainable buildings. As such, energy modelling methods have evolved to the point of including higher-order physics, complex interconnected components and sub-systems. Despite advances in computer capacity, the cost of generating and running complex energy simulations makes it impractical to rely exclusively on such higher fidelity energy modelling for exploring a large set of design alternatives. This challenge of exploring a large set of alternatives efficiently might be overcome by using surrogate models to generalize across the large design space from an evaluation of a sparse subset of design alternatives by higher fidelity energy modelling or by using a set of multi-fidelity models in combination to efficiently evaluate the design space. Given there exists a variety of building energy modelling methods for energy estimation, multi-fidelity modelling could be a promising approach for broad exploration of design spaces to identify sustainable building designs. Hence, this study investigates energy estimates from three energy modelling methods (modified bin, degree day, EnergyPlus) over a range of design variables and climatic regions. The goal is to better understand how their outputs compare to each other and whether they might be suitable for a multi-fidelity modelling approach. The results show that modified bin and degree day methods yield energy use estimates of similar magnitude to each other but are typically higher than results from EnergyPlus. The differences in the results were traced, as expected, to the heating and cooling end-uses, and specifically to the heat gain and heat loss through opaque (i.e., walls, floors, roofs) and window surfaces. The observed trends show the potential for these methods to be used for multi-fidelity modelling, thereby allowing building designers to broadly consider and compare more design alternatives earlier in the design process.

### KEYWORDS

Building energy modelling, multi-fidelity, modified bin, degree day, dynamic simulation

### INTRODUCTION

Advancements in building energy modelling methods have helped building designers to gain more insights into the energy use of prospective building designs (Lam et al., 2014). However, the increased complexity of these methods has often hindered their use to broadly explore and compare design alternatives early in the design process. In various fields of engineering design, some of the approaches to resolving this issue have included fitting a surrogate model to data from high fidelity (i.e. expensive) model evaluation of a sparse subset of the design space (for example Forrester, 2007, Unal et al., 1996), or through multi-fidelity modelling approaches (Jin, 2001; Simpson et al., 2001). One method in particular, uses a set of multi-fidelity models in sequence to evaluate the design space whereby low-fidelity models are used to remove non-optimal designs prior to evaluation by higher fidelity models (Miller et al., 2017). In the building

design field, prior efforts have been taken to review and categorize load estimation methods such as ASHRAE's Cooling Load Transfer Function (CLTD), Radiant Time Series (RTS), Transfer function methods and Heat Balance Method (HBM) based on their increasing levels of complexity and accuracy (ASHRAE 2009). However, such efforts were focused on comparing the differences of the underlying calculation procedures and to our knowledge, there is a limited number of studies comparing the outputs of the various energy modelling methods in the context of a *multi-fidelity modelling approach*. Given that the building design community possesses many energy modelling methods ranging from simple spreadsheets utilizing temperature-bin methods to simulation-based energy modelling tools such as EnergyPlus (Mao et al., 2013; Crawley et al., 2008), a multi-fidelity modelling approach could be a viable solution to the issue of exploring large sets of design alternatives. Here we investigate energy estimates from three candidate energy modelling methods to assess how they compare to each other, if there are any general trends across the methods, and whether they may be suitable for a multi-fidelity modelling framework.

## METHODS

### Selection of energy modelling methods

Annual building energy use can be estimated using three types of energy modelling methods: (1) *forward or classical methods* - based on a building model and engineering calculation methods (ASHRAE, 2009); (2) *data-driven methods* - based on building system parameters from actual measured data (ASHRAE, 2009); and (3) *simulations* - that estimate energy requirements using differential equation solvers for transient simulations and time-stepping weather data (Mao et al., 2013). Forward methods include the thermal response factor method (Mitalas & Stephenson, 1967), weighting factor method (ASHRAE, 1981) and the heat balance method (Buchberg, 1958; Kusuda, 1999) for annual heating/cooling load estimation and degree day method, equivalent full load hour method, bin method (Ayres and Stamper, 1995) and modified bin method (Knebel, 1983) for annual energy use calculation. Simulation methods used in the United States typically include whole building dynamic simulation tools such as DOE-2, eQuest, EnergyPlus, TRNSYS, TRACE, HAP, and others (Mao et al., 2013; Crawley et al., 2008). Forward and simulation methods have also been categorized based on varying complexities into benchmarking, degree day, bin, quasi steady-state, lumped parameter, and dynamic simulation methods (CIBSE, 2015). Each of the methods may require different time steps of climate data, such as annual, seasonal, monthly, daily, hourly, and even sub-hourly intervals. This study investigated forward and simulation methods only, since data-driven methods rely on actual data from buildings. A comprehensive review of energy modelling methods and tools can be found in the papers by Mao et al. (2013) and Crawley et al. (2008). From the above methods three modelling methods were selected, namely the modified bin method, degree day method (manual calculation methods under the forward method category) and dynamic simulation method (EnergyPlus), as potential candidate energy modelling methods to be used in the multi-fidelity modelling approach.

### Case study design scenario

The three candidate energy modelling methods were used to estimate the energy consumption of a set of sixteen design alternatives for a hypothetical generic office building in four locations with a mix of hot, mild, cold, humid, and dry climates. The locations included Fairbanks, AK, Philadelphia, PA, Phoenix, AZ and Sydney, Australia. The building's fixed parameters included: gross area of 932 m<sup>2</sup>; commercial office type; serving 50 people; lighting intensity 9.69 W/m<sup>2</sup>; plug load intensity 14.42 W/m<sup>2</sup>. Additionally, all of the sixteen design alternatives had the same slab on grade and roof construction as well as requirements for interior climate (e.g., interior temperature setpoints). Four variables namely wall type, window type, window-

to-wall ratio and building shape (i.e., number of floors and their dimensions) with two options per variable were considered, resulting in sixteen total design combinations. Table 1 shows the variables, options, descriptions, and main attributes; Table 2 shows all the design option combination with associated numbers to identify each (ids). Note that the options were selected to represent reasonable higher or lower technical possibilities. This study's goal was not to create a code-compliant design, but rather to investigate the energy modelling methods' ability to simulate different conditions.

**Table 1: Varied parameters for 16 building designs.**

Variables	Options	Description	Attributes
Wall Type	Option A	Plaster, brick, plaster	U-value: 1.57 W/m <sup>2</sup> K
	Option B	Brick, EPS, CMU, plaster	U-value: 0.44 W/m <sup>2</sup> K
Window Type	Option A	Single glazing, 1/4 in pane	U-value: 3.19 W/m <sup>2</sup> K; SHGC: 0.86
	Option B	Triple glazing, 1/4 in panes	U-value: 1.53 W/m <sup>2</sup> K; SHGC: 0.56
Window-to-Wall Ratio (WWR)	Option A	Small window area	WWR: 0.2
	Option B	Large window area	WWR: 0.8
Building Shape	Option A	1 level	Dimensions: 3.7x45.7x20.4 m
	Option B	3 level	Dimensions: 11.0x10.2x30.5 m

**Table 2: Building design options with corresponding variables.**

Design id	Wall assembly	Glazing	WWR	Floors
1	Plaster, Brick, Plaster	Single	0.2	1
2	Brick, EPS, CMU	Single	0.2	1
3	Plaster, Brick, Plaster	Triple	0.2	1

### Calculation and simulation setup

The calculation procedures for the modified bin (MB) and degree day (DD) methods were followed as prescribed by Knebel (1983) and ASHRAE (2009) respectively and computationally executed using Microsoft Excel. The histogram function in Microsoft Excel was used to convert TMY-3 weather data into 5-degree interval temperature bins to be used in the modified bin calculations. The same hourly temperature data was used to estimate the annual heating and cooling degree days to be used in the degree day method. The EnergyPlus™ (EP) simulations were run for four time-steps per hour, using the TARP and DOE-2 surface convection algorithms and the conduction transfer function heat balance algorithm. Zone and system sizing was auto-calculated for each weather file and design. The buildings were modelled using Revit 2017 and then exported into an EP input data file (IDF) format using Autodesk® Green Building Studio. The HVAC system setup did not export from Green Building Studio, and a default packaged variable-air-volume template in EP was used instead. HVAC system efficiency details from the same template were used in the system sizing

calculations of modified bin and degree day methods as well. The annual energy use intensity (EUI) in kWh/m<sup>2</sup>/year was calculated for the sixteen design alternatives using the above modelling methods. Subsequently, to gain better insight on the differences in energy estimates, results were then disaggregated in two categories, following EP's categorization schemes: by end-use (i.e., heating, cooling, lighting, equipment, and fans) and by loads (i.e., heat gains and losses associated with opaque surfaces, windows, infiltration, people, lighting, and equipment).

## RESULTS

In our empirical study, MB and DD methods consistently yielded higher annual building energy use estimates than EP, although they showed similar trends for design-to-design comparisons. The results in Figure 1 show the total energy use intensity of each building design using the three methods for one of the four locations, Philadelphia, Pennsylvania, USA. The results are also disaggregated into individual end-uses as defined in the methods section. The results for this location show the predominant energy use for climate control, i.e. heating, cooling, and fans. The same trend was seen in other locations, although its contribution in warmer climates was smaller than in colder climates. The differences between individual methods generally show higher cooling demands in MB and DD results than EP, and this trend was even more evident in warmer climates. The calculated cooling demands were 275-699% higher using MB and DD methods for the design ids 1 through 12, and 171-266% in the 3 story, high window-to-wall ratio designs (ids 13 through 16). Heating demands were relatively similar between methods, although EP values were slightly higher (by 1 to 25% in Philadelphia) in most design scenarios across all locations. The overall energy demand estimated by MB and DD methods were 3-26% and 7-27% higher than that of the EP estimates, respectively, except for design id 14, where the MB estimate was 1.5% lower than EP.

**Figure 1. Example end-use results for Philadelphia, PA using three methods. Each design shows results from modified bin method (MB, left), degree day method (DD, middle), and EnergyPlus (EP, right).**

Sample results for Philadelphia, PA disaggregated into individual loads are shown in Figure 2. Building designs and modelling methods are presented in the same order as in Figure 1. The results show that window heat gains and opaque surface heat losses are the primary contributors to heating and cooling demands in most design cases across all methods. The opaque surface heat transfer as well as heat gains from people, lights, and equipment (i.e., plug loads) are similar across the three methods, with sometimes slightly lower values from EP. The most noticeable difference is in the window gain values, which are 30-60% higher in MB and DD methods than in EP, especially in designs with high window-to-wall ratios. This trend is even more pronounced in the warmer climates of Phoenix and Sydney.

Figure 2. Example load results for Philadelphia, PA using three methods. Each design shows results from modified bin method (MB, left), degree day method (DD, middle), and EnergyPlus (EP, right).

## DISCUSSION

Empirical results show that modified bin and degree day methods yield energy use intensity estimates of similar magnitude to each other but are relatively higher than results from the dynamic simulation method (EnergyPlus). Predictably, the differences in the results were traced to the heating and cooling end-uses, and specifically to the heat gain and heat loss through opaque (i.e., walls, floors, roofs) and window surfaces. It should be noted that the findings are specific to the medium office use type, default schedules and HVAC setup, and that the findings may not be applicable to all other design scenarios. It is also important to note that the temperature interval used for binning (5°C in our case) might impact the performance of the method by increasing or decreasing the load estimates. Future research may investigate other design scenarios and bin discretisations.

Plausible explanations for the differences in surface heat gains and losses could be due to each method's underlying treatment of convection, conduction and radiation. For example, degree day and modified bin methods assume steady-state heat transfer in their calculations, whereas EnergyPlus considers transient heat transfer in its calculations. Furthermore, our investigation revealed, although not presented here for brevity, that radiation contributes significantly to the heat gains/losses and that modified bin and degree day method use approximate calculation methods to account for radiation whereas EnergyPlus utilizes advanced calculation methods that account for long wave and shortwave radiation effects. Understanding the effects of the varying heat transfer methods on the energy estimates is part of our ongoing efforts.

## CONCLUSIONS

Our empirical results showed trends in differentiation between methods that could be utilized in a multi-fidelity energy modelling design framework. Ongoing research is focusing on a more theoretical explanation of the methods' differences in the underlying heat transfer calculations (i.e., steady state and transient) as it pertains to the surface heat gains and losses. An in-depth understanding of these differences is necessary to determine how to sequence these energy modelling methods in terms of fidelity and how lower fidelity models will inform higher fidelity models. For example, using the approach of Miller et al. (2017), bounding mechanisms (i.e., a method for the lower-fidelity models to bound the more precise estimate from the higher fidelity model over the entire design space) will be required to eliminate non-optimal building designs from large sets of early design alternatives efficiently.

## **Optimal passive design strategies for nearly zero-energy dwellings in different Chilean climates using multi-objective genetic algorithms**

Daniela Besser<sup>1,\*</sup> and Frank U. Vogdt<sup>1</sup>

<sup>1</sup>Technische Universität Berlin, Berlin

### **ABSTRACT**

At present, most developed countries attempt to highly diminish the energy consumption of buildings towards nearly zero-energy performances. This study assesses passive design strategies by means of multi-objective optimizations with genetic algorithms, aiming to minimize the heating and cooling demand of typical single-family dwellings in Chile. The results show that the thermal transmittance and airtightness of the whole building envelope should be highly improved from the current limiting values in all assessed locations. Complementarily, strategies for managing overheating would be crucial for avoiding to shift the heating demand into cooling. With this regard, the use of thermal mass, natural ventilation and shading devices in the east and west façades would be highly determining for achieving a balance between the two conflicting objectives throughout climatic zones in Chile.

### **KEYWORDS**

Low energy dwellings, passive design, energy performance, multi-objective optimizations.

### **INTRODUCTION**

The Chilean government aims to highly improve the energy-environmental quality of new Chilean dwellings to comparable standards with the OECD countries by 2035 (Ministerio de Energía, 2015). However, the current Chilean Thermal Regulation (TR) only limits the thermal transmittance of the major building envelope components of residential buildings, being its levels usually not enough for achieving low energy, high quality homes, as demonstrated by several studies (Bustamante et al., 2009; OECD, 2012). Complementarily, a ‘Code for Sustainable Homes’ (CSH) was published in 2014 and recently amended in 2018 by MINVU, highly tightening the energy-environmental requirements of dwellings when compared with the compulsory ones. This standard might set the path towards the necessary update of the TR, imperative for achieving low energy dwellings by 2035. Consequently, this study assesses its impact and explores the remaining gap for achieving nearly zero-energy demands in Chile, using multi-objective optimizations with evolutionary genetic algorithms, which is a probabilistic search technique based on nature that assumes that in a random initial population of individuals (being here each individual a certain combination of design variables), natural selection would foster the survival of the fittest. Their reproduction by recombination (i.e. crossover), together with mutations, would convey robustness and diversity to the new population, evolving until a solution is found (Eiben and Smith 2003). Having more than one objective to optimize would lead to a set of optimal solutions, i.e. Pareto front, being all of them equally suitable when no other objective or constraint exists (Deb et al., 2002).

### **METHODS**

The research uses Design Builder v5 software to perform multi-objective optimizations to a Case Study (CS) in four climatic zones (Z) of Chile (See Figure 1). The CS is a 114m<sup>2</sup> single-family, detached, two-story dwelling, which is one of the most built housing typologies in the

country according to the National Statistics Institute ([www.ine.cl](http://www.ine.cl)). For the external walls, both brickwork (CS-A) and timber-frame (CS-B), the most used building systems for single-family dwellings, were assessed. The new CSH requests minimum heat capacity levels per  $\text{m}^2$  of building element for each climatic zone, calculated according to ISO 13786:2007 (Annex A) and classified into light, medium and heavyweight. Accordingly, a typical 140mm brickwork wall represents a medium weight solution and a typical timber-frame wall a lightweight one. In both cases a lightweight timber-frame roof and a medium weight concrete slab-on-ground were used. With regards to the simulations, the software optimizes with a non-dominated sorting genetic algorithm (NSGA-II) developed by Deb et al. (2002). Two objective functions were used: to minimize the heating demand and to minimize the cooling demand of the CS; simulating with ideal loads, at  $20^\circ\text{C}$  and  $26^\circ\text{C}$  ( $25^\circ\text{C}$  in ZI) operative temperature respectively, whenever when demand. Each story was considered a single thermal zone with constant internal gains of  $4.8 \text{ W/m}^2$ . As design variables, ten passive design strategies were simultaneously tested, each of them ranging between two to four levels, which are summarized in Table 1 and briefly described below. The levels in bold in Table 1 were used for the ‘reference cases SH’, that assess the U-values and airtightness suggested by the CSH, whereas the ‘reference cases TR’ evaluate the CS when minimally complying with the TR. The optimizations were set to a maximum of 200 generations, with an initial population of 20 individuals and a maximum of 50 per generation, and crossover and mutation rates of 0.9 and 0.5 respectively.

- Opaque envelope (**Env**): this parameter varies the U-value of the external walls, roofs and suspended floors in four levels, progressively increasing them from the CSH values.
- Floor-on-ground (**FGr**): its insulation level was separately assessed, since it is not regulated by the TR and since the perimeter vertical insulation proposed by the CSH would have a low impact according to a previous study (Besser and Vogdt, 2017). Instead, horizontal insulation under the slab was assessed in three levels, together with a non-insulated option.
- Windows (**Win**): the CSH levels plus three more options that are currently available on the market were tested, varying both the U- and g-values of windows. Since the TR still allows single-glazing along the country when small windows’ proportion, the reference cases TR were simulated using O1 in all locations (See Table 3).
- Window-to-wall ratio (WWR) on the North (**wwN**) and on the East-West façades (**wwE**): Both the TR and the CSH limit the WWR according to the windows’ U-value, the former for the whole building and the latter for each façade. Generally speaking, the colder the climate, the smaller the WWR that is allowed in both standards. This parameter was separately assessed for the North and for the East-West façades, assuming the lowest tested values for the reference cases TR and SH, and a constant 5.5% WWR on the South façade.
- Overhang Nord (**OvN**): It assesses the suitability of a fixed horizontal shading device above the North windows to help seasonally regulating solar access.
- Temporary shades on the East and West facades (**ShE**): Evaluates using external blinds on the East and West windows when internal temperatures are above  $23^\circ\text{C}$  ( $22.5^\circ\text{C}$  in ZI).
- Infiltration rate (**n50**): The limiting airtightness levels proposed by the CSH and two further levels were tested for each location. The values were normalized according to the DIN V 18599-2:2016-10 procedure, and  $1 \text{ h}^{-1}$  ( $14.28 \text{ h}^{-1}$  at 50Pa) was assumed for the TR cases.
- Ventilation for cooling (**VfC**): All cases consider natural ventilation for air quality purposes that seasonally varies according to DIN V 18599-2:2016-10. In addition, ventilation for cooling was assessed, increasing in  $3 \text{ h}^{-1}$  the ventilation rate when internal temperatures are above  $23^\circ\text{C}$  ( $22.5^\circ\text{C}$  in ZI) and they are not below the external one.
- Internal thermal mass (**ThM**): In CS-A, two types of internal partitions were assessed: lightweight timber-frame (L) and medium weight 140mm brickwork partitions (M), while a 120mm concrete slab remained constant. In CS-B, the timber-frame internal partitions

remained constant, but the timber-frame slab was tested with (M) and without (L) a 50mm concrete screed. For the TR and SH reference cases the lightweight options were used.

## RESULTS AND DISCUSSION

The optimizations results are shown in Figure 2, highlighting the Pareto front (OP) and conveying the energy demand of the Pareto point with the lowest heating (OP<sub>h</sub>) and the one with the lowest cooling (OP<sub>c</sub>) for each case. The reference performances TR and SH were added, demonstrating that a high reduction in both, the cooling and especially the heating demand could be achieved in zones ZD, ZE and ZI when tightening the envelope's thermal transmittance and airtightness as proposed by the CSH. Furthermore, it becomes clear the high potential for achieving low energy dwellings in all locations when properly combining passive design strategies. Nevertheless, it becomes clear as well that the cooling demand could highly increase from the reference performances TR and SH and become even higher than the heating demand, especially in the warmer locations ZA and ZD, and in the lightweight cases. Moreover, it evinces that some combinations of parameters could have a counter-productive effect when aiming to diminish the heating demand, shifting it into cooling or vice versa.

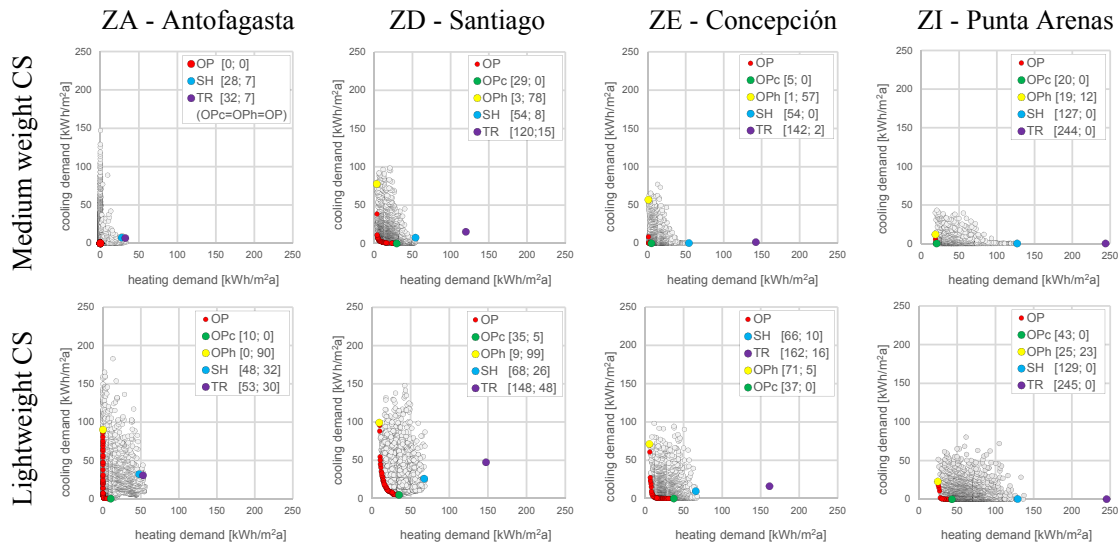

Figure 2. Optimization results plus reference performances TR and SH

Consequently, each Pareto front was analysed, aiming to identify those parameter combinations and levels that would lead to the optimal energy performances in each location. Since the Pareto front is the set of solutions not dominated by other solutions (Deb et al. 2002), and since minimizing the heating and the cooling demand are conflicting objectives, the lower the heating, the higher the cooling and vice versa for every Pareto point, which makes possible to simultaneously list the solutions by ascending heating and descending cooling demand. The outcomes are summarized in Tables 4 to 11, conveying the average heating (AvH) and cooling (AvC) demand of groups of solutions that achieve similar performances and showing the relationship between the ten design variables and the respective levels that would lead to Pareto solutions. In addition, the amount of Pareto points in every group of solutions is given by its frequency (Freq), being 100% the total amount of points within the Pareto front. The set of points with the lowest heating are located on the top of each table, the solutions with the lowest cooling at the bottom, and the trade-offs points are located in between. The highlighted level when grouped conveyed corresponds to the  $OP_h$  and  $OP_c$  point accordingly. It is worth mentioning that not all combinations among the grouped levels would lead to Pareto solutions.

When looking at Tables 4 to 11, it becomes clear that tightening the envelope thermal transmittance to the best levels together with increasing thermal mass are determining strategies to drastically reduce both the heating and the cooling demand in all locations and for both constructive systems, since these levels are present in 100% of the points forming the Pareto fronts. The  $OP_h$  points had additionally in common not considering ventilation for cooling, nor shading devices or overhang, plus the highest  $wwN$ , windows with the best U-values, the best  $n50$  rate and the highest or middle floor insulation level, but they resulted in extremely high cooling loads when compared with the TR reference cases in all locations, in spite of reducing heating by 90 to 100%. On the contrary, the  $OP_c$  points had in common to allow  $VfC$ , to consider the lowest  $wwE$  with shading devices, plus windows with the lowest g-values and either a short or a large overhang, in addition to the previously mentioned levels of Env and ThM. These cases would eliminate the need of cooling in all locations, except for the lightweight CS-B in ZD, where nonetheless a 90% reduction would be achieved when compared with the TR performance. Moreover, the resulting heating demands would be 75 to 100% lower than in the TR reference cases in all locations. In ZA it would even be possible to achieve zero energy demands for space conditioning when enough levels of thermal mass, as in CS-A. Finally, the trade-off Pareto points attempt a balance between the two conflicting objectives. Here, most

					Y	70	10-40	-/0.4/0.8	Y/N	31	1	41%
						40	10-40	-/0.4/0.8	Y/N	39	0	35%

combinations have additionally in common to allow VfC, windows with the lowest U- and g-values, the best n50 levels and ShE. The WWR on the North and on the East-West façades varies depending on the case and location, highly determining the degree of compromise between the objectives. The final election of a best case among each Pareto front would depend on a complementary factor, such as the heating and cooling systems to be used, their efficiency, their energy source, its price, its primary energy factor, the costs of the design strategies, etc.

## CONCLUSIONS

It would be possible to highly diminish the heating and cooling demand of Chilean dwellings when tightening the envelope thermal transmittance and n50 values as the CSH proposes. Moreover, a high improvement potential remains beyond. In fact, the energy demand for space conditioning could approach to zero in all assessed locations when properly combining passive design strategies as the ones assessed in this study. However, attempting to minimize both demands are conflicting objectives and therefore, care should be taken to avoid shifting the heating savings into cooling demands or vice versa. Since some strategies attempt minimizing heating and others pursuit cooling reductions, a balance should be aimed and thus the interaction among strategies becomes highly relevant, which confirms the appropriateness of multi-objective analyses when searching for zero-energy buildings and the importance of the interaction between the design strategies when optimizing buildings' energy performance.

## ACKNOWLEDGEMENT

This study was undertaken as part of a doctoral study in the Building Physics Department of the Technische Universität Berlin, financed by the German Academic Exchange Office DAAD.

## **Pareto Optimality Analysis for Evaluating the Tradeoff between Visual Comfort and Energy Efficiency**

Maryam Hamidpour<sup>1\*</sup>, Vincent Blouin<sup>1</sup>

<sup>1</sup>Clemson University, Clemson, SC

*\*mhamidp@g.clemson.edu*

### **ABSTRACT**

Architectural designs are increasingly driven by both sustainability and health, which requires evaluating the tradeoff between visual comfort and energy consumption. Lack of daylight leads to poor visual comfort and health issues but reduces heat gains, while excessive daylight may lead to over-illumination, glare, and high heat gains. Identifying the tradeoff between multiple criteria is an intricate process that requires skill and experience, especially when dealing with complex phenomena such as visual comfort. In order to facilitate this process, this paper provides two contributions: (1) the description of a new single-valued visual comfort measure, and (2) the application of the Pareto optimality analysis method. Pareto optimality analysis consists of comparing different design options in terms of the tradeoff between multiple criteria, which is a method that is rarely used in architectural design albeit its many advantages. For the Pareto optimality analysis, single-valued performance metrics are required. The energy performance metrics such as annual heating and cooling loads are single-valued quantities that, nowadays, can be calculated and measured easily. Daylight performance, however, is a complex multi-dimensional phenomenon. While previously developed daylight and glare performance metrics have their merits, they are not readily applicable to Pareto analysis. In this work, a new light metric called Effective Glare and Light Measure (EGLM) is developed to address the current limitations. The EGLM metric is defined as a weighted sum of several normalized performance metrics to end up with a single-valued measure of visual comfort. Two software programs, DIVA-for-Rhino and EnergyPlus<sup>TM</sup>, are used to calculate the time-dependent visual performance data and energy consumption, respectively. A script is then used to post-process the data. Several case studies are presented to illustrate the method with various building orientations, window-to-wall ratios, overhang depths, and glass visibility transmittance.

### **KEYWORDS**

Pareto Optimality, Daylighting Analysis, Glare, Energy Efficiency

### **INTRODUCTION**

Daylight has consistently been an essential component of architecture and the primary source for illuminating the interior environment. The benefits of using daylight in buildings range from savings in energy consumption and enhancing occupant health and comfort to improving outside views, and design aesthetics (Reinhart, 2014). While admitting daylight within a building has many known benefits, there are some disadvantages associated with transferring too much light into a space. These problems include occupants' visual and thermal discomfort and waste of cooling energy. Careful design is required to adjust these effects. As such, it is beneficial to apply methods helping designers to predict the tradeoff between criteria as much as possible during early design stages. Using Pareto optimality analysis is a quantitative and rigorous way of predicting this tradeoff (Hunt et al., 2007). However, this method requires single-valued metrics for all design criteria. This explains why this method is extensively used in engineering design, which generally involves design criteria that are easily quantifiable.

Architectural design is a discipline that involves qualitative metrics, one of them being aesthetics, which explains the unpopular use of Pareto optimality analysis. The premise of this paper is to demonstrate that Pareto optimality analysis can be used in architectural design when dealing with quantifiable criteria such as visual comfort and energy consumption. The method is used to compare the performance of different design alternatives corresponding to variations of several design parameters including building orientation, window-to-wall ratio, overhang depth, and glass visibility transmittance.

Energy performance metrics are generally straightforward since they are based on annual heating and cooling loads, which can be added to provide the annual energy consumption as a single-valued quantity. Visual comfort, however, is a complex phenomenon quantified using various intricate performance metrics that evaluate the level of illuminance and glare (Reinhart, 2014). A number of metrics have been adapted to evaluate the sufficiency of illuminance within a space, including, Daylight Factor, Daylight Autonomy, and Useful Daylight Illuminance (Reinhart, 2014). These metrics, however, have a number of drawbacks as they are either climate-independent, excessively simple, or multi-valued. As for glare, a number of metrics have been developed, including, CIE Glare Index, Unified Glare Rating System, Daylight Glare Index, and Daylight Glare Probability (Wienold and Christoffersen, 2006). These metrics, however, are either only applicable to artificial lighting or are metrics that measure glare at a given time as opposed to during a period of time such as the whole year. Therefore, a new visual comfort metric, called the Effective Glare and Light Measure (EGLM) is developed specifically for the purpose of architectural design driven by the tradeoff between visual comfort and energy consumption.

Most studies that evaluate the performance of daylighting systems and shading devices such as blinds, overhangs, louvers, light shelves, and dynamic glass fall short of providing an effective approach to the tradeoff analysis when evaluating the building performance with multiple criteria. For instance many studies have evaluated the performance of electrochromic glass (Lee and Tavi, 2007) without quantitatively analyzing the tradeoff between light levels and energy efficiency. Similar work that focus on glazing and shading devices have the same limitation (Ochoa et al., 2012).

The paper includes three sections. The first section describes the development of the new visual comfort metric, some of its variations, and its application in the Pareto optimality analysis method using a single office room with a window on the South façade as a case study. The performance of a given design in terms of visual comfort and energy consumption is quantified using the simulation software DIVA-for-Rhino (Solemma, 2017) and EnergyPlus™ (DOE and NREL, 2017). The second section presents results of practical applications of the method on the case study problem for various design alternatives corresponding to various values of building orientation, window-to-wall ratio, overhang depth, and visibility transmittance. The method is compared to the traditional way of comparing alternatives without the Pareto optimality analysis to illustrate its practicality. The third section includes a discussion of the method, its limitations, and the design opportunities that it provides.

## METHODS

The Pareto optimality analysis method consists of visualizing the performance criteria of different design alternatives on a two- or three-dimensional graph when dealing with two or three criteria, respectively. In this paper, the first criterion consists of minimizing the annual energy consumption of the building of interest as the annual heating and cooling loads. The

annual energy consumption is a single-valued quantity measured in mega-Joules (MJ). The second criterion consists of maximizing visual comfort in a room of interest.

### Development of the Effective Glare and Light Measure (EGLM)

The EGLM metric is defined as a weighted sum of two additional metrics. i.e., the Effective Light Measure (ELM) and the Effective Glare Measure (EGM), as follows:

$$\text{EGLM} = \beta \text{ELM} + (1 - \beta) \text{EGM}$$

where  $\beta$  is a user-defined weight between 0 and 1.

### Development of the Effective Light Measure (ELM)

Illuminance, measured in lux, is the amount of light that falls on a given surface area (Lechner, 2008). The Illuminating Engineering Society of North America (IESNA) recommends target values of illuminance for various tasks, including for instance, an average of 400 lux for office tasks and 1000 lux for laboratory work (Rea and IESNA, 2000). These target values are then converted into target ranges, such as 300 to 500 lux for office tasks. An illuminance below or above these recommended ranges puts unnecessary strain on the eyes and induces fatigue, among other issues. Unlike artificial lighting, daylighting varies constantly during the day as it depends significantly on the climate, seasons, and the weather. As a result, maintaining the desired illuminance level at all times is virtually impossible, and the goal is then to maximize the number of hours in the recommended range. In this paper, the illuminance spectrum is divided into five ranges defined as follows: Range 1 between 0 and 100 lux is undesirable, Range 2 between 100 and 300 lux is acceptable, Range 3 between 300 and 500 lux is desirable, Range 4 between 500 and 1000 lux is acceptable, and Range 5 above 1000 lux is undesirable. Using five ranges, as opposed to only three, provides the increased resolution needed to capture the difference between architectural design alternatives. Using five ranges, the Effective Light Measure (ELM) is defined as a weighted sum of the normalized numbers of hours when the illuminance is within a predefined range, which can be written as follows:  $\text{ELM} = \sum_{i=1}^5 \alpha_i \frac{N_i}{N_{\text{total}}}$ ,

where  $\alpha_i$  is a user-defined weight for range  $i$ , with  $\sum_{i=1}^5 \alpha_i = 1$ ,  $N_i$  is the number of hours in range  $i$ , and  $N_{\text{total}}$  is the total number of working hours in a year. The user-defined weights,  $\alpha_i$ , are subjective and are currently defined as 0.1, 0.2, 0.4, 0.2, and 0.1 for ranges 1 to 5, respectively.

### Development of the Effective Glare Measure (EGM)

Glare depicts the contrast in brightness between different objects in one's field of vision and one way to quantify it is with the instantaneous measure called the Daylight Glare Probability (DGP). The DGP defines the probability that a person is disturbed by brightness distribution throughout the space (Wienold and Christoffersen, 2006). The DGP is a number between 0 and 1 to be minimized. Wienold (2009) proposes several ranges as follows. Range 1 corresponds to imperceptible glare with a DGP below 0.35, Range 2 is perceptible glare between 0.35 and 0.40, Range 3 is disturbing glare between 0.40 and 0.45, and Range 4 is intolerable glare above 0.45. The Effective Glare Measure (EGM) is defined as a weighted sum of the normalized numbers of hours when the DGP is within a predefined range, which can be written as follows:  $\text{EGM} = \sum_{j=1}^4 \gamma_j \frac{N_j}{N_{\text{total}}}$  where  $\gamma_j$  is a user-defined weight for range  $j$ , with  $\sum_{j=1}^4 \gamma_j = 1$ ,  $N_j$  is the number of hours in range  $j$ , and  $N_{\text{total}}$  is the total number of working hours in a year. The user-defined weights,  $\gamma_j$ , are subjective and are currently defined as 0.5, 0.3, 0.15, and 0.05 for ranges 1 to 4, respectively.

### Pareto optimality analysis

It is assumed that a set of design alternatives are analyzed in terms of visual comfort and energy consumption. The Pareto optimality analysis corresponds to plotting the corresponding values of all design alternatives on the two-dimensional graph. In this paper, the horizontal axis is the annual energy consumption to be minimized and the vertical axis is visual comfort to be maximized. As a result, the best design alternatives are those closest to the top-left corner of the graph.

### Case study

As shown in Figure 1, the room of interest is a rectangular office, 4.26-m long, 3.35-m wide, and 3.00-m floor-to-ceiling height with a window. The work table is placed at the middle of the room such that the user is facing the window. The baseline design of the office has the window on the South façade, a window-to-wall ratio of 50%, no overhang, and a glass visibility transmittance of 80%. The point where horizontal illuminance is simulated is at the center of the table. The glare sensor is located 1.4 meters from the floor facing the window to represent the position and orientation of the person sitting at the desk. The weather of Anderson, South Carolina is used for all simulations, which corresponds to a mild climate with approximately equal heating and cooling loads. A standard heat-pump HVAC system is considered for heating and cooling the building with lower and upper setpoint temperatures of 24°C and 22°C. The R-values of the exterior wall and window are 17 and 3.5, respectively, and the interior walls, floor, and ceiling are considered adiabatic to represent the effect of an interior office of a multi-story building. DIVA-for-Rhino and EnergyPlus<sup>TM</sup> are used to simulate the illuminance, glare, and energy consumption over the entire year, 10 hours per day from 8:00AM to 6:00PM.

Figure 1. a) Plan of view of the room of interest with window oriented towards South, table at the center of the room, b) Rendering of the room as simulated by DIVA-for-Rhino.

## RESULTS

### Effect of building orientation

Five different building orientations are considered, i.e., East, South-East, South, South-West, and West. Figure 2 shows the results using the traditional method of visualization with three histograms, namely, the number of hours of illuminance in each of the five ranges, number of hours of glare in each of the four ranges, and energy consumption. The graphs include all necessary information to compare the five design alternatives. However, this method is fairly confusing and analyzing the tradeoff between alternatives in terms of visual comfort and energy consumption is virtually impossible.

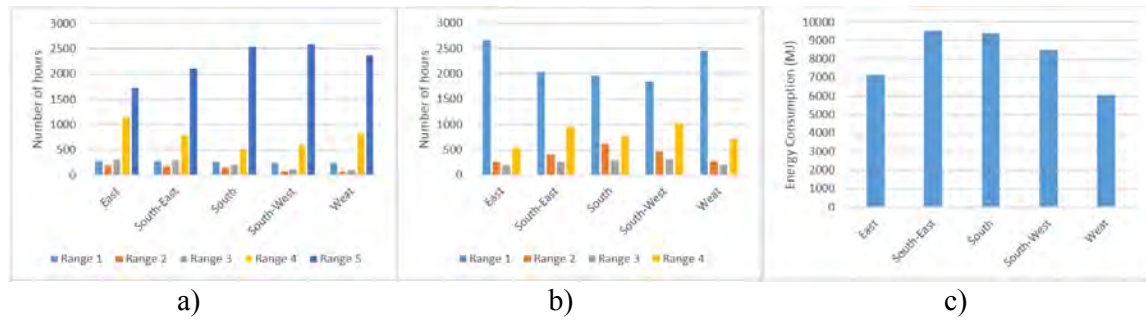

Figure 2. a) Number of hours of illuminance in each of the five ranges for each building orientation, b) Number of hours of glare in each of the five ranges for each building orientation, and c) Energy consumption for each building orientation.

Figure 3.a) shows the same results in a more compact manner by plotting the visual comfort metrics ELM, EGM, EGLM, and Energy on the same histogram. The information is easier to understand. However, the tradeoff is still difficult to extract. Finally, the same results are shown in Figure 3.b) using the Pareto optimality analysis method with the visual comfort metrics on the vertical axis and the energy consumption on the horizontal axis. Using this method, the tradeoff between the design alternatives can be easily identified since the best designs are those closest to the top left corner of the graph. Focusing on EGLM (grey curve), it is clear that the East and West orientation are significantly better than the other three building orientations. The selection of the final design alternative (either East or West) depends on the designer's preferences. The East orientation is best if visual comfort is preferred. The West orientation is best if energy consumption is preferred.

Figure 3. a) ELM, EGM, EGLM, and Energy (in MJ divided by 50,000 for scaling), b) ELM, EGM, EGLM versus Energy (MJ)

Figure 4 shows the Pareto curves corresponding to the variations of three other design parameters, i.e., window-to-wall ratio, dimension of overhang, and glass visibility transmittance. Analysing each curve allows identifying the best design in terms of tradeoff between criteria.

Figure 4. Pareto curves of three parametric studies: blue curve: WWR varies between 6% (lowest energy) and 40% (highest energy), orange curve: overhang depth varies between 0.5m (highest energy) and 1.4m (lowest energy), grey curve: glass visibility transmittance varies between 1% (lowest energy) and 60% (highest energy).

## CONCLUSIONS

This paper shows the advantages of using the Pareto optimality analysis method to identify the tradeoff between multiple criteria in architectural design. This method, however, requires the use of single-valued quantities. Since visual comfort is a complex phenomenon that is generally quantified using multi-valued quantities, a new single-valued metric was developed in order to be readily usable in Pareto optimality analysis. Several case studies are presented to illustrate the benefits of the method. The single-valued metric is based on a weighted sum of additional metric, which are also based on subjective user-defined weights. The effect of the subjectivity of these weights will be studied as future work. However, this disadvantage is somewhat negligible compared to the benefits of using the Pareto optimality analysis method.

### **ABSTRACT**

The increased frequency of heat waves around the world has prompted numerous studies to improve building resilience and maintain thermal comfort in the face of extreme conditions. However, previous studies rely on the assumption of steady-state conditions, including external temperature, which limits real-world applicability, demanding a more practical perspective. This paper presents the use of recorded heat wave temperatures for a specified location to simulate the effect of extreme temperatures on the interior temperature of buildings when air conditioning is not used. The objective of this study is to determine how a building becomes uninhabitable during extreme heat and to effectively compare the changes in internal temperature of different building types during heat waves and standard climatic conditions. Residential buildings were modeled using OpenStudio and simulated using EnergyPlus 8.7.0. for modified weather data files using recorded historical heat wave events. The results obtained provide a method for dynamic simulation of extreme events, establish a framework for policies supporting passive survivability in construction and consequently, reduce heat-related mortality.

### **KEYWORDS**

Heat waves, Passive survivability, Energy Simulation, Thermal Comfort

### **INTRODUCTION**

Heat waves are sometimes described as silent killers (Carroll, 2002) that often disproportionately affect vulnerable populations. To better understand and respond to such disasters, modeling and numerical simulations promise to identify critical thresholds, formulate parameters to estimate the damage, and evaluate possible design responses. In order to analyze the effect of a heat wave duration in the simulations carried out in this research, a heat wave will be defined as a period of at least three days, where the daily maximum temperature exceeds a threshold of the 97.5th percentile of the distribution of maximum temperatures observed in a given location (Meehl and Tebaldi, 2004).

### **Climate Change and Heat Waves**

Nearly all extreme weather events are exacerbated by climate change. A 2016 report notes that “If an extreme event truly is rare in the current climate, then almost by definition it required some unusual meteorological situation to be present, and the effect of climate change is a contributing factor (National Academies of Sciences, 2016).” The influence of global warming on heat waves is particularly direct. It is very likely that human influence has contributed to observed global scale changes in the frequency and intensity of daily temperature extremes since the mid-20th century, and likely that human influence has more than doubled the probability of occurrence of heat waves in some locations

(Intergovernmental Panel on Climate Change (IPCC), 2013). Heatwaves are a dangerous natural hazard, and one that requires increased attention (World Meteorological Organization and WHO, 2015), therefore a diverse body of prior research on heat waves includes exploring the risk and damage, providing recommendations for community adaptation, and identifying personal safety practices.

### **Overheating in Buildings**

Building HVAC systems are designed to provide conditions of acceptable human comfort. While a complex and nuanced field, indoor human thermal comfort is generally held to occur in a range of operative temperatures from 67°F (19°C) to 82°F (28°C), assuming low air velocities, < 40 fpm (0.2032 m/s), and moderate relative humidity (<65%) for sedentary subjects wearing western-style clothing (ASHRAE, 2017; ASHRAE, 2016). In older people, however, this range is narrower because their responses to changes in body temperature are altered (Güneş and Zaybak, 2008). Regardless of these standards, in buildings without mechanical cooling, or where systems are not functioning, indoor conditions can significantly exceed comfort conditions, rendering survivability—rather than comfort—the objective.

Researchers and policymakers are turning to energy simulation to understand the performance of buildings in extreme conditions, for example, to estimate how quickly indoor air temperature of buildings increase during extreme heat. Nahlik et al. (2017) simulated 39 building prototypes in Los Angeles and Phoenix and found that older buildings are more vulnerable to extreme heat than newer buildings because their interiors warm the fastest. Based on these data, the researchers proposed a new metric for building vulnerability to extreme outdoor heat called Building Heat Performance Index (BHPI). However, these results used a constant outdoor air temperature, which is not a good representation of actual exterior conditions. Using EnergyPlus to simulate the effectiveness building modifications to terrace houses in Greater London, UK, Porritt et al. (2012) showed that investments like insulation, solar controls, and ventilation could help reduce building overheating during heat waves.

### **METHODS**

This study uses dynamic meteorological conditions of Fresno, CA during a major historic heat wave as a case study to determine their impact on the interior temperature of buildings. Two typical, residential building prototypes were simulated with the EnergyPlus software. Clear differences were found between the effect of heat wave weather data and typical meteorological conditions on interior temperatures without air conditioning.

#### **Software**

Simulations were carried out using the EnergyPlus v8.7.0 (EnergyPlus, 2018)—an open-source, whole-building energy modeling engine developed by the US Department of Energy. Widely-used in research and practice, EnergyPlus performs dynamic thermal and building energy simulations to yield hourly results for a whole year or period thereof, in this case a heat wave. EnergyPlus simulates sub-hourly timesteps through an iterative calculation procedure to improve the accuracy of its results. Simulations were controlled, and input files were edited using the Open-studio plugin (OpenStudio, 2018) for Trimble SketchUp® (Trimble Sketchup, 2018) and the EnergyPlus IDF editor (EnergyPlus, 2018).

#### **Building Prototype**

To support replication, this study adapted residential prototype building models developed by the Pacific Northwest National Laboratory (PNNL) under the Department of Energy's

Building Energy Codes Program. The present study considers the single-family detached house (SF), and the multi-family (MF) low-rise apartment building, both illustrated in Figure 1.

The prototype building models are intended to be representative of homes in the state of California (PNNL, 2006). The material properties of the SF and MF buildings were defined with the assumption that the existing buildings during the 2006 heat wave considered in this research satisfies the 2006 version of the International Energy Conservation Code (IECC). Consequently, the minimum requirements given by the IECC for Fresno, located in Climate Zone 3B, were employed as the building construction properties in its entirety. Major features and characteristics are summarized in table 1.

Table 1. Comparison of major features of the building prototypes.

Feature	Single-Family	Multi-Family
Total floor area	148.6 m <sup>2</sup>	204.9 m <sup>2</sup>
Stories	1	2
Bedrooms	3	3
Wall R-Value	13 (hr °F ft <sup>2</sup> )/BTU	13 (hr °F ft <sup>2</sup> )/BTU
Ceiling R-Value	30 (hr °F ft <sup>2</sup> )/BTU	30 (hr °F ft <sup>2</sup> )/BTU
Window U-Value	0.65 BTU/(hr °F ft <sup>2</sup> )	0.65 BTU/(hr °F ft <sup>2</sup> )
HVAC	NA (turned off for study)	NA (turned off for study)

To support this research, the available prototype models were upgraded from EnergyPlus version 5.0.0 to version 8.7.0, and associated errors and warnings corrected. Finally, to represent the performance of a building without air conditioning during a heat-wave, HVAC schedules were set to prevent the equipment from operating.

Figure 1. 3D representations of the Single-family (SF) detached residential prototype (left) and the Multi-family (MF) low-rise apartment residential prototype (right).

#### Location and Climate data

This study uses Fresno California, and the 2006 heatwave, as a case study. Located in California's central valley, Fresno experiences a semi-arid climate (ASHRAE Zone 3B, CA climate zone 13). Climate data from Fresno Yosemite International Airport (36.7758° N, 119.7181° W, elevation 102 meters) was used. Energy plus uses data files in the EnergyPlus Weather (EPW) file format to represent exterior conditions. Each prototype was simulated with two different weather files: one representing the Typical Meteorological Year (TMY) for Fresno; and the second based one consisting of measured extreme weather in this location. The base TMY weather file was produced by the National Renewable Energy Laboratory's

(NREL's) Analytic Studies Division for the TMY3 process, using selected hourly data to represent standard climatic conditions. The second weather file contains the record of meteorological data for 2006, a year when this area experienced a major, multi-day heat event, and was purchased from White Box Technologies. Of interest is the 2006 summer heat wave, covered using a run period of July 15<sup>th</sup> – 22<sup>nd</sup>.

## RESULTS

Dynamic thermal simulations were carried out for the two cases considered.

a)

b)

Figure 2. Outdoor Air Temperature and simulated indoor dry-bulb temperatures and deltas for the dates of the study period considering a) Typical conditions (TMY), and b) the 2006 heat wave. Diurnal patterns in absolute temperature are visible, as is the clear trend of increasing temperature in the heatwave, and the declining delta-T.

Figure 2 shows the effect of an extreme heat period lasting 8 days (July 15<sup>th</sup> – 22<sup>nd</sup>) on a single-family and multi-family residential building.

## DISCUSSION

Figure 2 shows that the natural, diurnal variation of outdoor air temperature is approximately 15°C in July from warmest (midday) to coolest (predawn). This is apparent and similar in magnitude in both the typical year and under a heat wave. Notably, the indoor temperature closely follows the pattern of varying outdoor dry bulb temperature. All windows were treated as non-operable, therefore the indoor temperature always remains above the outdoor dry bulb temperature, suggesting that skin conduction is always a neat heat loss, while internal and especially solar gains are responsible for the increased temperature. Further, the relatively low-mass of the prototype buildings does little to damp the diurnal oscillation from dynamic thermal simulation. The MF building exhibits longer lags and less variation, due to higher mass and a lower surface-to-volume ratio. In both cases, the rate of conductive heat loss to the exterior is of course dependent on the magnitude of the temperature difference between interior and exterior temperature. These behaviors are not well represented by assuming a constant/steady state outdoor temperature.

In both the TMY and 2006 extreme heat data, the largest magnitude of difference between interior and exterior temperatures ( $\Delta T$ ) typically occurs at night, because the outdoors cools down after sunset, but the house retains some heat. In the heat wave, that difference is smaller, in part because the nights are not cooling off as much, and because the entire system is warmer. The smaller  $\Delta T$  reduces the loss through envelope convection, so the home cannot shed heat as quickly and continues to grow warmer. Consequently, as the outdoor DB temperature increases with increasing severity of the heat wave, the 2006 Indoor SF and MF increases with decreasing  $\Delta T$ . This indicates that a more severe heat wave, produces a more uninhabitable building in the absence of mechanical cooling or other strategies.

While not primarily focused on the human physiological consequences, these temperatures are dangerous. The highest temperature observed was 51.96°C, in the Single-Family residential building under the 2006 heat wave, compared to a maximum of 47.15°C in a typical year. Both these thermal conditions are hazardous and potentially fatal to occupants because they exceed body temperature, precluding the body from shedding heat and leading to heat stroke or other heat-related illnesses. It is therefore necessary to have a method that presents an analysis of the indoor conditions of buildings using dynamic exterior conditions.

There are other system-scale effects that can affect heat gain and loss, such as urban heat island effect and the cooling effect from neighborhood vegetation, as well as other cooling strategies such as operable windows that would complicate these models and increase the accuracy of this approach.

## CONCLUSIONS

This paper applied dynamic building energy simulation techniques to analyze heat wave effects on the indoor thermal conditions of residential buildings. This is not a complete representation of the scope of the analysis, as site-scale conditions, possible window

operation, and other physiological factors such as relative humidity are not included. Additional work is needed to characterize the vulnerability of a building occupants to extreme heat in dynamic conditions, however, thanks to the widespread availability of recorded actual meteorological data, the approach demonstrated here can be applied to a study using dynamic simulation of extreme heat events in any city of interest.

### **ABSTRACT**

The present paper investigated the application of the daylighting analysis features of the Insight BIM plugin, comparatively to DIVA, a plugin for a 3D Nurbs modeling software. Considering the early phases of the design process, workflows, simulation results and processing times were analyzed, focusing on the prediction of static (illuminance level) and dynamic (sDA<sub>300,50%</sub>) metrics. Simulations on both tools were performed in the context of analyzing the daylight behavior in a deep office room model, with and without light shelves. Results indicate that Insight has limitations compared to DIVA, especially concerning input data configuration flexibility. Simulation results presented significant similarity between Insight and DIVA in most cases, being the direct sun case the one in which illuminance levels differed the most. Insight presented longer processing time for the static metric and similar average time for the dynamic metric. Work findings indicate that Insight has important potential to contribute to daylighting analysis on early phases of design process, and points out to barriers to its adoption and correct use. Authors expect this paper to benefit architects, engineers and students on the comprehension of both tools.

### **KEYWORDS**

Daylighting simulation; Building Information Modeling; Insight; DIVA; design process.

### **INTRODUCTION**

Different work indicates the need for a highly skilled and experienced workforce in the field of high complexity software to have reliability on the results obtained through computational simulation, besides the great financial and time investment (Korolija and Zhang, 2013). Such difficulties reflect on the habit pointed by Dogan and Reinhart (2013) in which computational simulation occurs mainly for code compliance evaluations on final phases of design process. The authors also cite the potential benefit of using simplified easy to use simulation tools at early stages of design process, in which computational analysis exert a great impact on the project's qualification. Furthermore, with the current emphasis on sustainability, including building's energy performance, the multi-disciplinary design solution became more important in initial design stages (Negendahl, 2015).

In this context, Building Information Modeling (BIM) is recognized as a collaborative and information exchange methodology that generates integrated computer models, providing a reliable basis for decision-making regarding the building's design, construction, maintenance and disassemble (Santos et al, 2017). Recent research approaches the use of BIM tools to perform energy and environmental analysis (Chong et al, 2017). According to USGA (2015) these tools have the ability to generate analytical models in an automated or semi-automated

way, creating a simpler process, as simulations can be conducted directly on the modeling program interface. Thus, it can be less prone to errors and demand minimized time and financial investments if compared to current practices.

Insight is a daylighting analysis plugin for Revit, that uses A360 cloud-based rendering service. The tool was designed to be operated by non-daylighting simulation experts professionals (Autodesk, 2015). It presents automated settings for some study types and for others there are customizable input options. Possible analysis includes illuminance levels, daylight autonomy – spatial daylight autonomy ( $sDA_{300,50\%}$ ), studies for LEED credits, and solar access. A360 uses bidirectional ray tracing with multidimensional light cuts algorithm along with secret/patented extensions. The simulation engine has been validated in comparison with Radiance results and measured data (Autodesk, 2017). Such technology has the potential to contribute to the greater adoption of computational simulation, considering that tools difficulty level is a factor of great influence for its adoption (Rogers, 1995). However, although it is possible to increase the accessibility to computational simulations, there is still little research regarding the workflow, results quality and processing time of simulations performed through this methodology, comparable with notably known engines.

Regarding the most used daylighting predictions tools, Radiance, a backward ray tracer simulation engine "enjoys the status of a *gold standard*" (Reinhart and Breton, 2009, p. 1514), being widely validated comparatively to measured data under different sky conditions and complexity of models. Radiance simulates daylighting conditions under one sky condition at a time, and the Radiance-based simulation tool Daysim allows the processing of dynamic simulations under various sky conditions. It is a freeware also extensively used and validated comparatively to measured data (Reinhart and Breton, 2009). Several works that developed Radiance validation studies since 1995 are presented in Reinhart and Anderson (2006).

Over the last years, the adoption of DIVA, a plugin that incorporates Radiance and Daysim into the 3D Nurbs modeling program Rhinoceros has been noticed. From this plug-in, it is possible to analyze the performance of different design options without manually exporting the architectural model to another software. International researches have been using DIVA for daylighting and energy consumption studies (Sharma et al. 2017, Tabadkan et al. 2018 and Villalba et al., 2018). DIVA was initially developed at the Graduate School of Harvard University and is now distributed and developed by Solemma LLC. Free use is available through educational licenses for students and educators (Solemma LCC, 2018). Due to its validated simulation engines and acceptance among the academic community, DIVA will be considered in this study as a reference program.

In the search for a better distribution of daylight in laterally daylit rooms, light redistribution elements such as light shelves and daylight harvesting louvers have been widely studied (Berardi et al. 2018, Villalba et al. 2018 and Tabadkan et al. 2018). This article aims then to investigate the plugin Insight, focusing on its application on daylighting simulations analysis during the early phases of a design process. For that, the daylight behavior in a deep office room model with a 1:2 proportion with and without light shelves was analyzed. Workflows, static (illuminance levels) and dynamic ( $sDA_{300,50\%}$ ) results and processing time were studied comparatively to DIVA.

## METHODS

The study was developed in two phases. In the first phase Insight and DIVA workflows were apprehended, and in the second one, the study focused on simulation results and processing

time. A design process was assumed within the context of analyzing daylight behavior in a deep office room model with a 1:2 proportion with and without light shelves. The model is not obstructed by neighbouring building and has a depth which corresponds to nearly 4 times the aperture height. Its internal dimensions are 5.0m x 9.9m; 3.0m height, with a 15° Azimuth. This office configuration is commonly found in commercial buildings in Belo Horizonte, Brazil as stated by Alves et al. (2017). Three design options were tested: the basic model (without light shelf) and two models with light shelves with varied inferior surface reflectance ( $\rho$ ) (Figure 1). A 0.2m wall thickness was assumed and the reflectance of interior walls, interior ceiling, interior floor and exterior ground was 50%, 80%, 20% and 20%, respectively. The outer frame represented a framing factor of 20% of the rough opening area of the window, which included a single glazing with a 90% direct visual transmittance.

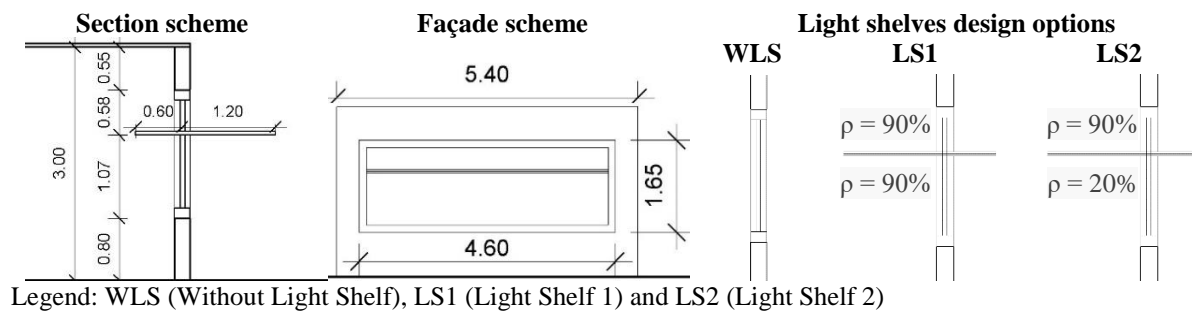

Figure 1. Schematic models description.

Daylighting simulations were performed with Insight (v. 3.0.0.1 for Revit 2018) and DIVA (v. 4.0 for Rhinoceros5.0) for Belo Horizonte (lat.: -19.85, long.: -43.95). Simulated metrics and parameters were: illuminance levels for winter solstice at 12:00h with analysis plan height of 0.75m and nodes distance of 0.35m; and sDA<sub>300,50%</sub> with 0.8m plan height and 0.6m node distance. For illuminance analysis the Perez sky model was used in both software, using weather data as sources for sky condition information. The one considered for Insight simulations was automatically assigned from the project location indication through a default city list, and for DIVA simulations a SWERA file was considered (Table 1). Table 2 presents DIVA advanced simulation parameters - at Insight, it is not possible to access such settings.

Table 1. Sky condition information.

	GHI <sup>1</sup>	DNI <sup>1</sup>	DHI <sup>1</sup>	Sky cover	Weather file
Insight	890Wh/m <sup>2</sup>	810Wh/m <sup>2</sup>	93Wh/m <sup>2</sup>	0%	GBS_04R20_299004
DIVA	623Wh/m <sup>2</sup>	616Wh/m <sup>2</sup>	179Wh/m <sup>2</sup>	5%	Belo Horizonte/Pampulha-SWERA

<sup>1</sup>GHI: Global Horizontal Irradiance, DNI: Direct Normal Irradiance, DHI: Diffuse Horizontal Irradiance.

Table 2. Advanced Radiance simulation parameters used in DIVA.

Model	ab	ad	as	ar	dt	ds
Without light shelf	5	1000	20	300	0	0
With light shelves (1 and 2)	7	1500	100	300	0	0

## RESULTS

Figure 2 displays workflows schemes of Insight and DIVA. Key aspects of Insight operation mode involve the use of a BIM model to perform cloud-based daylighting analysis and having the option to configure or not analysis parameters, as the tool presents default values for material, nodes and analysis information. DIVA uses a scene modeled in Rhinoceros and processes simulations on user's computer. There are also default parameters for numerous daylighting analysis, but nodes and materials properties must be configured manually.

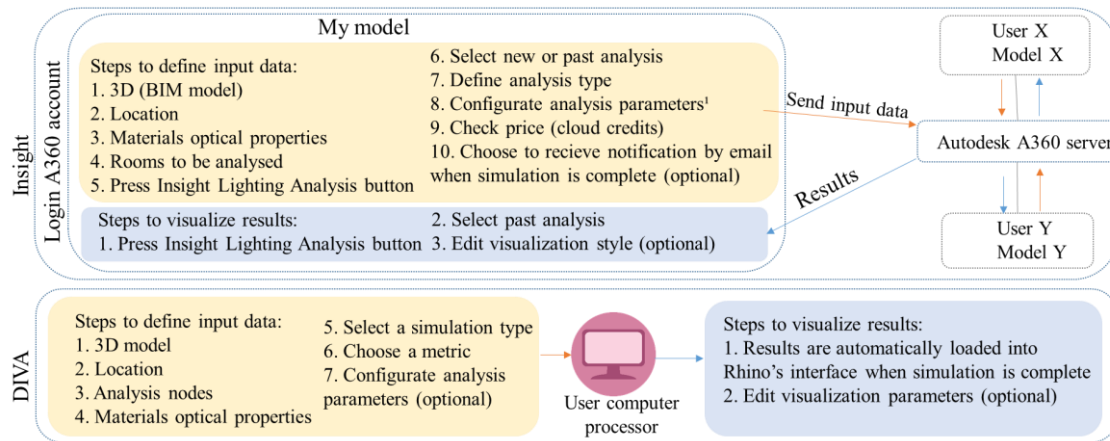

Figure 2. Schematic operating mode of Insight and DIVA.

Important workflow differences rely on material's optical properties configuration: on Insight it is set by color or by specific Red, Green and Blue (RGB) values, defined by equations presented in Autodesk (2017); while in DIVA it is set by a default list, which can be altered in a .rad file. In Insight it is viable to load past simulation results, as a simulation historic is stored in the A360 user account. Also, it provides users with design tips for lighting performance improvement. Both tools allow configuring result scale appearance, an important aspect of comparing design options. In Insight users can manually change color schemes and define intervals between the maximum and minimum thresholds, which are fixed on the scale; while in DIVA it is viable to choose between three color schemes and to define scale's maximum and minimum thresholds, but quantity and value of intermediate intervals are automatically set. Figure 3 presents both tools results and its processing time.

	Without light shelf (WLS)	With light shelf 1 (LS1)	With light shelf 2 (LS2)
<b>Insight</b>	 <p>Illuminance - Max.: 6,000lx / Min.: 214 lx Illuminance processing time: 3 minutes sDA<sub>300,50%</sub>: 68% / Processing time: 39 min.</p>	 <p>Illuminance - Max.: 6,000lx / Min.: 161 lx Illuminance processing time: 10 minutes sDA<sub>300,50%</sub>: 65% / Processing time: 9 min.</p>	 <p>Illuminance - Max.: 3,010lx / Min.: 173 lx Illuminance processing time: 1 minute sDA<sub>300,50%</sub>: 62% / Processing time: 3 min.</p>
<b>DIVA</b>	 <p>Illuminance: Max.: 53,700 lx / Min.: 358 lx Illuminance processing time: &lt; 1 minute sDA<sub>300,50%</sub>: 65% / Processing time: 20 min.</p>	 <p>Illuminance: Max.: 5,549lx / Min.: 179 lx Illuminance processing time: &lt; 1 minute sDA<sub>300,50%</sub>: 61% / Processing time: 13 min.</p>	 <p>Illuminance: Max.: 4,117 lx / Min.: 179 lx Illuminance processing time: &lt; 1 minute sDA<sub>300,50%</sub>: 60% / Processing time: 14 min.</p>

Figure 3. Results and processing time of Insight and DIVA simulations.

Maximum and minimum resulting illuminance levels were similar on both tools in the cases of light shelves use (LS1 and LS2). Most discrepant illuminance result was in the case with direct sun exposure (WLS), being the maximum level in DIVA approximately 9 times higher than in Insight. In what concerns the three design options, both tools demonstrated decreasing illuminance levels in the area next to the opening and more uniform daylight distribution when WLS, LS1 and LS2 were tested, respectively. Medium illuminance simulation time in Insight was 4.7 minutes, while in DIVA it was less than 1 minute. In what concerns the  $sDA_{300,50\%}$ , both tools presented similar results in all cases, being the bigger difference in case LS1 (4%). Medium  $sDA_{300,50\%}$  simulation time was 17 minutes for Insight and 15.7 minutes for DIVA. Authors point out that there were occasions when Insight simulations were impaired due to connection problems with Autodesk's server.

## DISCUSSIONS

With the workflows study, characteristics that can favour Insight adoption on early phases of design process were noticed. Firstly, there is the possibility to use a BIM model to perform daylighting analysis, for all benefits of BIM design process cited by Santos et al (2017). Secondly, the indication of design tips can assist the development of project solutions. Thirdly, default values configured for material properties, analysis nodes and metrics parameters enables simulations execution by nonexperts professionals, in congruence with Insight developers objectives, as stated in Autodesk (2015). As indicated by Rogers (1995) those simplifications can contribute to the tools higher adoption. Also, the storage of simulation historic facilitates results comparison between design options. On the other hand, with the experience of this work, authors encountered aspects that can be considered barriers to Insights adoption and correct use. Among them, there is the occurrence of errors with Autodesk's server connection. Also, when consulting the design tips, which was based on studies developed in the USA, users should attempt to their specific project climate characteristics. Further, fixed input values encountered in Insight may represent an obstacle for more detailed analysis. An example is the impossibility to specify the desired weather file and although it is possible to inform GHI, DNI and DHI values for illuminance analysis, it is not viable to inform a sky cover percentage. Additionally, the configuration process of the desired material reflectivity or visible transmittance is unintuitive compared to DIVA's, due to the necessity of informing the RGB values. Since calculated values presented in Autodesk (2017) are not available in Revit or Insight interfaces, users must search for this reference.

Illuminance levels and  $sDA_{300,50\%}$  results of both tools presented similarity, mostly in cases with a predominance of diffuse light, when LS1 and LS2 were used. The case with direct sun exposure (WLS) presented illuminance significant discrepancy among both tools, and based on weather files sky condition information, authors infer this was due to Insight's maximum threshold specification. Authors could not confirm this hypothesis because this configuration could not be accessed. Still, transposing this results to a design process practice, such difference may not imply great prejudice, for illuminance levels in both cases were above comfortable desired levels if a 3,000lx limit is considered - so both of them indicated the necessity to develop sun protection solutions. In this study, illuminance simulation processing time was notably shorter when using DIVA than when using Insight, and this may be caused by the low computing capacity necessary for such static metric along with the low complexity of the model. The average processing time for  $sDA_{300,50\%}$ , in its turn, was similar in both tools.

## CONCLUSIONS

This work investigated the application of Insight daylighting features on design process, comparatively to DIVA. Workflows, simulation results and processing time were analyzed.

Results indicate that Insight has limitations, mostly on what concerns input data configuration flexibility, but it still has significant similarity in results with DIVA, mainly in cases with a predominance of diffuse daylighting. Findings demonstrate Insight has important potential for contributing to daylighting analysis on early phases of design process, assisting A&E professionals on developing more based solutions in conjunction with the use of a BIM platform. Authors intend this paper to benefit architects, engineers and students on the better comprehension of both studied tools. Future research could approach simulations with other metrics, model complexities, and the use of DIVA along with Rhinoceros BIM plugins.

## ACKNOWLEDGEMENT

The work reported in this paper was supported by Capes and CNPq.

# Existing Energy Performance and The Potential of Simulation in School Buildings – A Review

Ming Hu<sup>1</sup>

<sup>1</sup>University of Maryland, College Park, Maryland

\*Corresponding email: mhu2008@umd.edu

## Abstract:

The objective of this paper is to present finding of existing building performance assessment for educational buildings and related energy simulation tools with a focus on K-12 buildings. First, the paper examines the current status of energy performance in educational buildings and existing simulation tools used in building energy retrofit. Then, the paper summarizes the obstacles to conducting energy simulation for school buildings, gaps and weaknesses in existing tools will be summarized, and potential opportunities for a comprehensive tool will be outlined. Last, the paper identifies the particular needs of educational buildings, and a set of criteria and requirements for future tools will be proposed based on the particular needs for educational building.

## KEYWORD

educational buildings, K-12, energy simulation tools

## INTRODUCTION

In the United States, educational buildings account for 12% of total commercial building energy consumption, with K-12 schools accounting for 8% (EIA 2012). All together, educational buildings are the third largest energy consumers in the commercial building sector, following office buildings and mercantile buildings. K-12 schools account for 10% of total commercial building floor area and other educational buildings account for 4% (EIA 2012).

Figure 1 commercial building energy use

Figure 2 commercial building floor area

K-12 school buildings in U.S spend more than \$8 billion each year on energy—more than they spend on computers and textbooks combined (EPA 2011). Most occupy older buildings that often have poor operational performance—more than 30% of schools were built before 1960. 53% of public schools need to spend money on repairs, renovations, and modernization to ensure that the schools buildings are in good overall condition. And among public schools with permanent buildings, the environmental factors in these permanent buildings have been rated as unsatisfactory or very unsatisfactory in 5% to 17% of schools (DOE 2012). The average age of a school is about 42 years—which is nearly the expected serviceable lifespan of the building (McGraw Hill 2011).

Improving the energy performance of school buildings could result in the direct benefit of reduced utility costs, and

improving the indoor quality could improve the learning environment for students. Research also suggests that aging school facilities and inefficient equipment have a detrimental effect on academic performance that can be reversed when schools are upgraded. Several studies have linked better lighting, thermal comfort, and air quality to higher test scores (Chan et al, 1979; Earthman et al. 1998; Phillips et al. 1997). Another benefit of improving the energy efficiency of education buildings is the potential increase in market value through recognition of green building practice and labelling such as that of a net zero energy building. In addition, because of their educational function, high-performance or energy-efficient buildings are particularly valuable for institution clients and local government. More and more high-performance buildings, net zero energy buildings, and positive energy buildings serve as living laboratories for educational purposes. Currently, educational/institutional buildings represent the largest portion of NZE (Net Zero Energy) projects. Educational buildings comprise 36% of all net zero buildings, according to a 2014 National New Building Institute report. Of the 58 net zero energy educational buildings, 32 are used for kindergarten through 12th grade (K-12), 21 for higher education, and five for general education (NBI 2014).

### EXISTING ENERGY PERFORMANCE OF K-12 BUILDING

For this study, first author compared three different database: Building Performance Database, EIA's (Energy Information Administration) Commercial Building Energy Consumption Survey (CBECS), and Building Energy Data Book. BPD was chosen because of its size and non-biased sources. BPD is the United States largest dataset of information about the energy-related characteristics of commercial and residential buildings. This database is sponsored by Department of Energy and raw data come from variety sources includes federal, state and local government data, as well as utility companies and other energy efficiency programs. In BPD, there are 8883 school buildings. In the CBECS, there are 389 education buildings include elementary, middle school, high school, college and other types of adult education and vocational training facilities. CBECS is much smaller dataset than BPD. Building Energy Data Book does not list the original raw data quantity, so it is hard evaluating its' reliability.

Figure 3 Age of school buildings in U.S.

Figure 4 Current energy performance (EUI) of school

Among the 8883 school buildings in BPD, 10.71% was built between 1960-1965, 10% was built between 2005-2010, 9.29% was built between 1965-1970, and 2000-2005 (refer to figure 3). 545 buildings have site EUI of 10-20KBtu/sf/yr, 1791 buildings have site EUI of 20-30KBtu/sf/yr, 2151 buildings have site EUI of 30-40KBtu/sf/yr, 1828 buildings have site EUI of 40-50KBtu/sf/yr, 1314 buildings have site EUI of 50-60KBtu/sf/yr, 673 buildings have site EUI of 60-70KBtu/sf/yr. Majority K-12 school buildings have a site EUI between 30-40 KBtu/sf/yr which is indeed smaller than what is extracted from CBECS and later on used in Energy Start Portfolio Manager tool (refer to figure 4).

The energy performance of K-12 buildings is primarily affected by three impact factors: site/climate condition; building total area; and very significantly by occupancy rate. *The first impact factor* in education building energy performance is the external environment conditions. In the U.S., based on BPD data there is a clear correlation between cold climate zone and overall energy consumption. Buildings in hot climate zone have better performance than those in cold climate, as illustrated in Figure 5. From data obtained in Europe, studies also indicated that the energy usage intensity (EUI) is typically higher in regions with a harsh and cold climate than in those with relatively pleasant climate conditions.

Figure 5 Correlation between climate zone and energy efficiency

*The second factor* is the overall area of the buildings. First, author has ruled out the impact from construction year. Building ages is not the key issue affecting the energy performance, the newer buildings particularly built around 1990s to 2000s have higher EUJ number than those built before 1980s. This could be due to the larger plug load in newer schools. When we look at the building total area, smaller buildings tend to have higher energy intensity compared to larger buildings which is the same across different climate zones and building ages (refer to figure 6).

Figure 7 Correlation between building area and energy efficiency

Figure 6 Correlation between building age and energy efficiency

*The third factor* is occupancy rate. Data shows lower occupancy density is correlated to the higher EUI (refer to figure 8), which suggest fewer people consume more energy due to the behavior change. This could be interpreted by the occupant's behaviors. In the United States, historically low energy prices have contributed to building occupants engaging in relatively energy-intensive behaviors (Climate Policy Initiative Report 2013). In other countries due to the conscious mind of energy conservation, we have seen close correlation between building operational characteristic of the buildings as a result of how they affect the actions taken by students or teachers to control their internal environment (Theodosiou et al 2014).

Figure 8 Correlation between occupancy density and energy efficiency

### EXISTING SIMULATION TOOLS USED IN BUILDING ENERGY ANALYSIS

Realizing the energy efficient design is a two-steps concept: first is to reduce energy consumption, and the second is to increase the energy generated on site through renewable energy. The different steps require different simulation tools. The first set of tools (energy consumption simulation tool) is utilized to predict the future energy consumption based on sufficient parameters with the aim to make sure the energy demand could be reduced to minimal. This type of tool has been in development since the past 50 years, and typically requires experienced professionals from the building community. The second set of tools (energy generation simulation tool) is used to predict the energy generated onsite, which could depend on the site and geographic condition. Most tools also require certain professional training and knowledge in the utilization of these tools. More and more whole building simulation software is starting to include the potential energy generation on-site combined with predicted energy consumption on-site so that the design team can view the energy balance result in one interface.

In energy consumption simulation tools, the core tools in the building energy efficiency field are the whole-building energy simulation programs. Those programs can take a large number of building parameters into consideration such as building geometry, massing, orientation, wall-window ratio, temperature, humidity, energy use and demand, and costs. Large bodies of research and surveys have been conducted to compare different energy simulation tools.

Among those surveys and studies, two research projects have the most impact. In 2006, a team of research from U.S DOE and Scotland studied twenty major building energy consumption simulation programs and concluded that even among the ‘mature’ tools, there was not a common language to describe what the tools could do, and solely relying on a single tool might not be productive (Crawley et al 2008). In 2010, researchers from Ireland and Denmark studied 37 tools in collaboration with the tool developers or recommended points of contact. This study provides a review of different computer tools that can be used to analyse the integration of renewable energy generation (Connolly et al 2010). Among the 37 tools studied, four programs are applicable to single-building, group of buildings, or a community. Those four programs are BCHP Screening Tool, HOMER, and TRNSYS16. Between those two studies, there is only one overlap (Trnsys16). In this session, the author chose 10 of the most used and most invested whole-building simulation programs and illustrated their characteristics based on a high number of users from the previous studies. Table 1 illustrate those major tools.

Table 1 Major Characteristic of Energy Simulation Tools

#### GAPS AND POTENTIAL OPPORTUNITIES FOR EDUCATIONAL BUILDING ENERGY SIMULATION

Currently, most whole-building simulation tools generally focus on commercial and residential buildings. According to the most recent Commercial Building Energy Consumption Survey (CBECS), conducted in 2012, space heating demanded the greatest overall energy use (25%), followed by lighting, refrigeration, ventilation, and cooling. In residential buildings, space heating demanded the greatest overall energy use (45%), followed by water heating (18%) and space cooling (9%). School buildings have a unique energy profile that does not align with that of typical commercial buildings. In school buildings, space heating accounts for 47% of the overall energy consumption, followed by lighting (14%) and cooling (10%). The energy behavior of schools is more similar to that of a residential building than that of a commercial building. This could be due to the operational schedule of schools; in particular, primary and secondary schools are largely different from regular commercial buildings that operate on a 12 months per year schedule. Further research could be conducted to obtain a better understanding of school building energy behavior. Using a typical commercial energy simulation model setting for school buildings could create inaccurate results. There is a potential gap and need for integrated simulation tools that are created and suitable for school building design. In most existing schools, the building system does not have smart sensors that can automatically control the lighting, so one can often observe that sun shades and blinds are pulled down during the day to avoid glare while the electric lights are all turned on because of the reduced daylight level. Hence, the users’ energy behavior management requires a cultural shift, which could take a long time, and we should simulate the energy consumption caused by the relatively high-intensity energy behavior in schools. A future energy simulation tool should accommodate a wide range of operation schedules and users’ behavior could lead to more accurate results. Illustrating the direct savings from behavior change could create a positive environment to expedite the behavior paradigm shift.

## CONCLUSION

Educational buildings in the U.S. consume large amounts of energy, representing immense opportunities for energy savings. K-12 schools offer unique opportunities for deep, cost-effective energy-efficiency improvements. According to the EPA, the modification of a pre-existing school building for energy efficiency can save a typical 100,000-square-foot school building between \$10,000 and \$16,000 annually. Future building performance will not be generic and will vary according to the buildings' operational character, local context, and user behaviors. The overall goal of future buildings, including educational buildings, may be "net zero" or "net positive". The intent of reviewing the current energy performance status of K-12 buildings is to identify the gaps and opportunities for improvement of K-12 building performance.

### **ABSTRACT**

The precise daylighting simulation in buildings can potentially contribute to designers' and occupants' smart utilization of it. The traditional method of employing sky models was indicated with noticeable errors in transient lighting simulation for complex fenestration systems (CFS), due to the mismatch between the real sky and standard sky models. This paper evaluates the performance of a calibrated embedded photometric device based on sky luminance monitoring, capable of real-time on-board lighting computing. Daylighting experiments for external Venetian blinds (EVB) were conducted in a lighting test module to demonstrate its accuracy in the simulation of horizontal work-plane illuminance. The BTDF of the EVB was generated for two different tilt angles of slats respectively. With partly cloudy skies, the photometric device was validated with improved accuracy in simulating the work-plane illuminance distribution compared with a common practice employing the Perez all-weather sky model.

BTDF, HDR, Workplane illuminance, Venetian blinds, Transient Simulation

### **INTRODUCTION**

Lighting constitutes about 15 - 30% energy consumption in non-residential buildings (ul Haq et al., 2014). The utilization of daylight, as a free source, can potentially mitigate the energy consumption of buildings at a considerable scale and, at the same time, contributes to occupants' health condition and working performance (Mills et al., 2007). However, excessive penetration of daylight into buildings can increase the cooling load and glare probability for occupants. To overcome this issue, shading devices or electrochromic glazing is commonly applied in commercial and residential buildings for the regulation of daylight provision and the prevention of glare. Despite of their merits in tuning daylighting, the complexity of their architecture, with curved profile or micro structures, makes it difficult for designers to pre-plan the room or to dynamically control the daylight precisely.

The bi-directional transmittance distribution function (BTDF) describes the light transmittance behaviour of a certain material or a complex fenestration system (CFS). The function is defined by the ratio of directional exiting radiance over the incident irradiance on a surface (Dereniak et al., 1982). The BTDF is a five-dimensional quantity, with two sets of spherical coordinates for incident and exiting directions respectively as well as the wavelength of light. In the context

of photometric scope, the variable of wavelength can be cancelled by the integration with the luminosity function  $V(\lambda)$  over the wavelength. Over the past decades, multiple angular basis has been defined, which discretize the BTDF with a finite number of incident and exiting directions, including the Tregenza and Klems basis (Tregenza, 1987; Klems and Warner, 1995). Together with the ray-tracing techniques, the BTDF of a CFS can be used to calculate the daylight provisions and assess glare risks in buildings, however, the BTDF of a CFS is limited by a number of factors in daylighting application: firstly, the approximated BTDF commonly neglects the spatial variation over different positions on the incident surface plane, which takes the average over a periodic section; secondly, although the BTDF can be either generated by using simulation software, with the defined surface properties and geometry, or monitored by a Gonio-photometer, the cost and time can be considerable for a CFS with multiple states; last but not the least, the resolution of the BTDF has to balance between the computation load and accuracy in lighting simulation.

For dynamic regulation of daylighting, the accuracy of transient lighting simulation is constrained by the mismatch between the standard sky models and the real sky. The standard sky models can hardly reproduce the real sky for a specific location and moment, because they are based on averages over a range of sky types, including the CIE standard sky model and Perez all-weather sky model (Perez et al., 1993). In addition, a limited number of input weather data is not sufficient to reconstruct the reality, since the sampling frequency of inputs were not over two times the maximum spatial frequency of the sky, according to the Shannon sampling theory (Shannon, 1949). Especially for partly cloudy skies with scattered high contrast sky patches, the discrepancy between the standard sky models, with smooth luminance distribution, and the reality can be pronounced, contributing to substantial error in transient lighting simulation from the simplified source of daylighting.

In this paper, an embedded photometric device (Wu et al., 2017b,a), integrating the sky luminance monitoring and on-board lighting computing, is validated experimentally in the horizontal work-plane illuminance simulation for external Venetian blinds (EVB) in a daylighting testbed. The device, employing high dynamic range (HDR) imaging techniques, is able to monitor the luminance of the sun orb, the sky and landscape during the day with high resolution mapping, which can potentially reproduce the real sky more accurately than the standard sky models. The BTDF was generated for the EVB at various tilt angles and employed in the daylighting simulation.

## METHODOLOGY AND EXPERIMENTS

One EVB, with a sinusoidal profile, was installed in a lighting test module, as illustrated in Figure 1 a). The profile of the EVB was modelled with the identical geometry in RADIANCE (Larson and Shakespeare, 2004), an open source lighting simulation software employing ray-tracing techniques. To improve the accuracy in lighting simulation, the reflectance of the surface material of the EVB at both sides were measured by a chromameter (MINOLTA CR-220) and its specular component was monitored by a gloss meter (MINOLTA GM-060), characterizing the specular component at 60° incident angle to approximate the specularity. As various tilt angles of its slats correspond to different light transmittance properties, a group of BTDF for the EVB was computed by the 'genBSDF', a sub-program of RADIANCE, at 5° interval of tilt angles respectively. In the scope of this paper, two tilt angles were evaluated at 72° and 32° respectively to the vertical plane, directing downward. Their BTDF was generated employing the Klems angu-

lar basis, with 145 incident and exiting directions respectively. During the lighting simulation, the EVB was defined as the 'BSDF material' with proxy geometry in the RADIANCE. In this way, the direct tracing rays interact with the modelled geometry of the EVB, while the indirect rays, with multi-reflections, use the BTDF to compute lighting, reducing the computation load for ambient calculation.

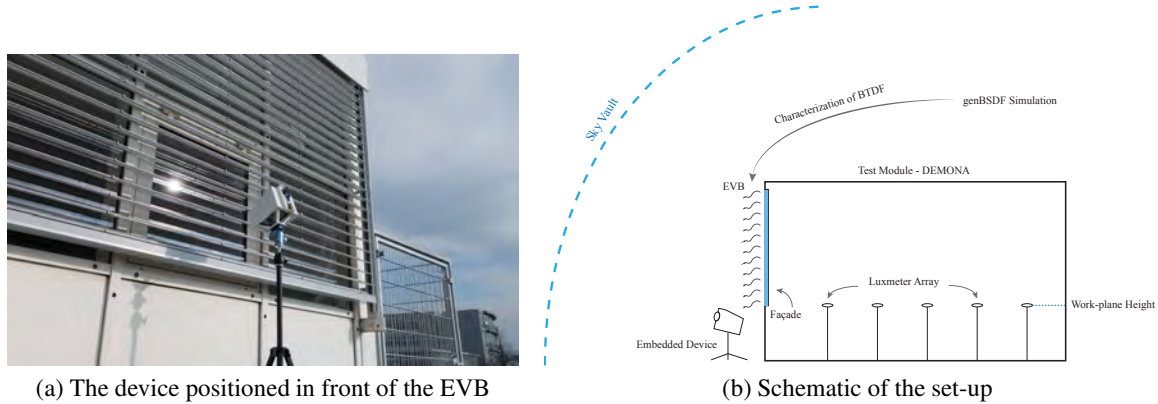

Fig. 1. The experimental set-up for testing the embedded photometric device

To validate the daylighting simulation of the embedded photometric device, 'in situ' experiments were conducted in a retrofitted test module (interior size:  $6.4 \times 2.9 \times 2.6 \text{ m}^3$ ), equipped with a unilateral façade reaching a 0.62 window-to-wall ratio and with the EVB. This module was modelled at 1:1 scale with surface material properties monitored by the chromameter and gloss meter, including the wall, ceiling, floor, and surfaces of each furniture. The photometric device was positioned in front of the EVB with its lens targeting toward the sky vault, as shown in Figure 1 a). The modelled scene was embedded into the device with its on-board RADIANCE software operating for quasi real-time lighting simulation. The embedded photometric device, as a compact platform, calculated the horizontal work-plane illuminance distribution at 1 m, 2 m, 3 m, 3.9 m, and 4.7 m distance to the façade. To assess its accuracy, an array of lux-meters was positioned at identical positions inside the module to monitor the work-plane illuminance as reference, illustrated in Figure 1 b). Each lux-meter was connected to a data logger, recording the illuminance simultaneously. For comparison, both the embedded device and lux-meters were synchronized to simulate and monitor the work-plane illuminance respectively every 15 min. Furthermore, the direct normal and diffuse horizontal irradiance were monitored by a pyranometer at the rooftop for contrasting the performance employing the Perez all-weather sky model.

## RESULTS

For a partly cloudy day, the slats of the EVB were fully stretched and directed downward at  $32^\circ$  to the vertical plane. The horizontal work-plane illuminance simulated by the embedded photometric device from 9:00 to 18:00, based on HDR imaging techniques, is illustrated in Figure 2 a), with green data points and curves. The five curves stacked from up to bottom represent the five sensors at different distance to the façade respectively. The monitored illuminance values by using the lux-meters are denoted by grey dotted lines stacked similarly as reference. In comparison, the illuminance simulated by using the Perez all-weather model was illustrated in Figure 2 b) by stacked green lines. According to the two figures, the simulated illuminance by

using the embedded device is closer to the monitored value than that employing the Perez all-weather sky model. The relative error, as shown in Figure 3, further illustrates the merits of the HDR imaging techniques in reconstructing the sky. The Perez sky model is not well performing in simulating relatively dim skies and tend to have pronounced error, when the sky has scattered high contrast patches. The average relative error for work-plane illuminance by the embedded device at the five positions is 18.7%, 19.1%, 22.7%, 24.7%, and 27.2% respectively, while that by employing the Perez all-weather model is 169.1%, 166.0%, 144.1%, 133.4%, and 134.1% respectively.

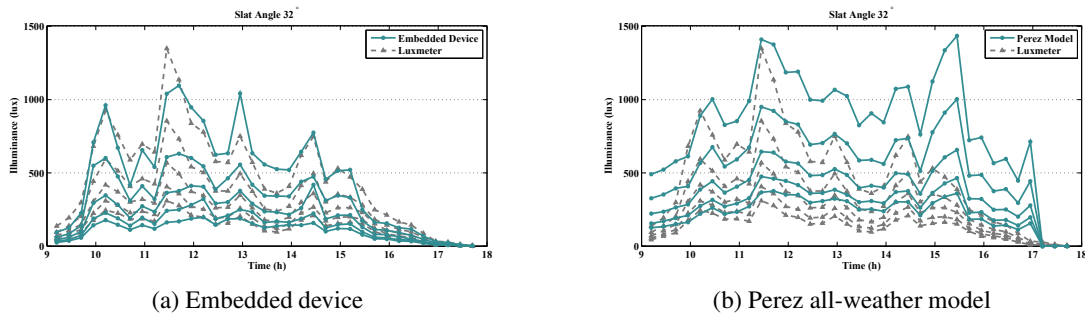

Fig. 2. Simulated horizontal work-plane illuminance by using the two approaches to reproduce the sky ( $32^\circ$  tilt angle)

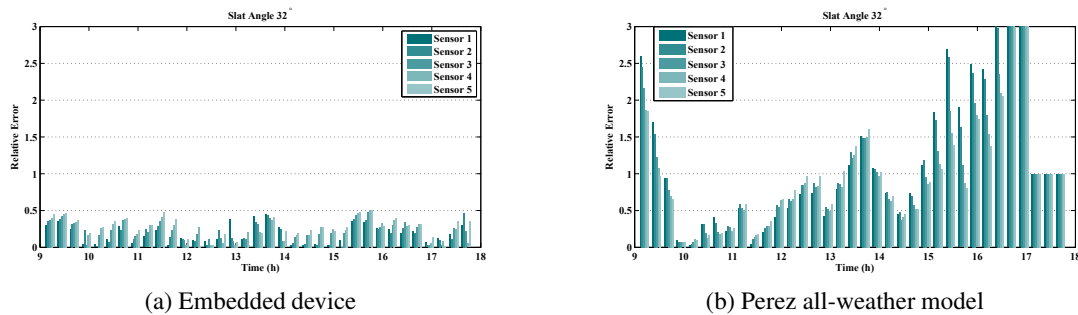

Fig. 3. Relative error in the simulated horizontal work-plane illuminance by using the two approaches ( $32^\circ$  tilt angle)

For the tilt angle of slats at  $72^\circ$  to the vertical plane, the simulated work-plane illuminance and its relative error are illustrated in Figure 4 and Figure 5 respectively. The embedded photometric device out-performs the Perez sky model in transient simulation, especially for relatively dim skies with thick clouds and with high contrast sky patches. The spikes of error bars at mid-day were possibly due to the exposure of the lux-meters to the sun disk through the spacing of the EVB slats. For clear illustration and comparison, the error bar is not scaled to include the maximum peaks. The average relative error at the five positions through out the day for the embedded device is 35.8%, 33.8%, 42.1%, 34.9%, and 24.8%, while that for the common practice employing Perez all-weather model is 659.6%, 538.7%, 401.2%, 378.9%, and 400.0%.

Fig. 4. Simulated horizontal work-plane illuminance by using the two approaches to reproduce the sky (72° tilt angle)

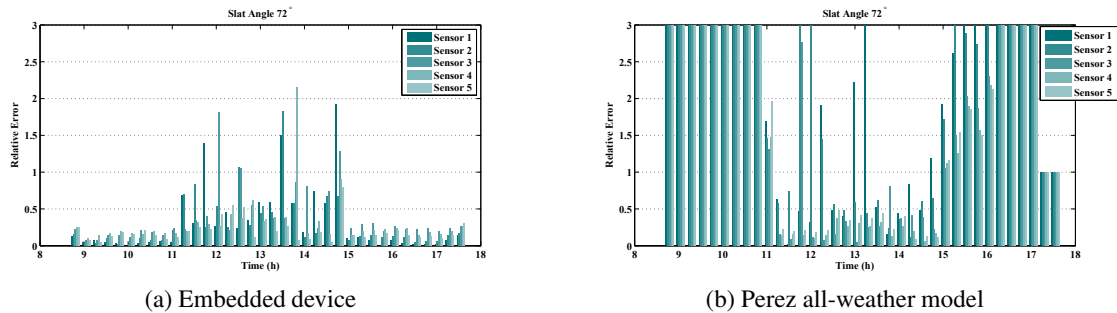

Fig. 5. Relative error in the simulated horizontal work-plane illuminance by using the two approaches (72° tilt angle)

## CONCLUSIONS

Daylighting simulation is contingent on the mismatch between the modelled sky and real sky particularly for transient analysis. This paper demonstrates an embedded photometric device, integrating the HDR sky luminance monitoring and on-board lighting computing, in the daylighting simulation of horizontal work-plane illuminance for an EVB with a sinusoidal profile. Experiments were conducted for the EVB in a lighting test module. The BTDF of the EVB at tilt angle 32° and 72° was generated by the genBSDF program respectively. Employing the BTDF and geometry of EVB in the daylighting simulation, the experimental results show the embedded photometric device, based on HDR sky luminance monitoring, improves the accuracy in simulating the transient work-plane illuminance than the common practice employing the Perez all-weather sky model, especially for partly cloudy skies with high contrast sky patches. Despite of its merits in annual lighting analysis, the Perez model may have pronounced mismatch with the real sky for a specific location and moment.

Although the embedded photometric device, based on HDR sky luminance mapping, reproduces the sky more accurately than sky models, its computation load and bulky input data can limit its application in annual daylighting analysis, including daylight autonomy. The device is advantageous in applications sensitive to the accuracy of daylighting simulation, including dynamic shading control and building retrofitting. Its accuracy can be potentially improved further by the BTDF with higher resolution, which will be studied in the future.

## ACKNOWLEDGEMENT

The authors would like to thank the Commission for Technology and Innovation of Switzerland for funding Swiss Competence Center for Energy Research (SCCER), Future Energy Efficiency Buildings and District (FEEB&D).

### ABSTRACT

Two major causes of energy yield reduction in PV systems are partial shading and high operating temperatures. Both issues are particularly critical for BIPV systems. The correct assessment of the BIPV contribution to the built environment depends, therefore, on the accurate prediction of PV temperature and on the possibility of simulating shading effects. This paper describes the development of a multi-physics model for a naturally ventilated façade BIPV system within the openIDEAS environment for building and district energy simulations. The PV electrical model used here follows a physics-based approach that takes into account solar intensity and temperature spatial variations within the PV module, enabling the simulation of shading effects both at cell and module level. A detailed thermal model has been developed and coupled to the electrical model to estimate the PV temperature. Four case studies illustrate the importance of temperature and shading effects on the PV power output. The model has been validated using data from an experimental BIPV setup deployed in Belgium. The results indicate that the model is able to predict both the PV surface temperature and the power production, given the correct boundary conditions are applied.

### KEYWORDS

Building Integrated PhotoVoltaics (BIPV), partial shading, Building Energy Simulation (BES), Modelica, openIDEAS.

### INTRODUCTION

The effort to mitigate climate change is driving a revolutionary transformation in the energy system. Worldwide, nations have established strategic plans aiming at the reduction of greenhouse gas emissions. Responsible for a large percent of energy consumption and CO<sub>2</sub> emissions, the building sector is key to comply with such challenging guidelines. In view of the potential to increase the share of renewable energy in the built environment and reduce the related CO<sub>2</sub> emissions, building integrated photovoltaics (BIPV) systems have currently been considered the backbone of the 2020 zero energy buildings target in the European Union.

Building energy simulation (BES) tools can be used to assess the BIPV performance at building level. This paper addresses three main aspects regarding BIPV modelling in BES programs. TRNSYS, EnergyPlus and ESPr are considered here. The first aspect concerns the limited range of BIPV applications currently available in these programs. TRNSYS only offers a mechanically ventilated BIPV component (TRNSYS, 2018), while in EnergyPlus only a naturally ventilated variant is available (EnergyPlus Documentation, 2017). The development and validation of a mechanically ventilated façade BIPV model in ESPr has been reported by Clarke et al. (1997).

Secondly, the traditional BES tools, including the three considered here, are typically based on imperative language, which makes the code hard to maintain and restricts the inclusion of

new models (Wetter et al., 2016). Integrating new models in these tools requires not only a great effort from the user but also a high level of specific knowledge that may not be equally shared by all BIPV stakeholders. The ability of such tools to follow the development of new technologies and support the implementation of new systems is consequently limited, which is a major drawback for building and district energy simulation programs.

Finally, the third aspect focuses on the PV electrical model. All three tools considered here assume that (1) the performance of an array of identical modules is linear with the number of modules in series and parallel, and (2) all modules within the array operate always at maximum power point (MPP). This means that module and cell mismatch losses are not taken into account. While the assumption that all PV modules operate at the same conditions might be representative for roof installations, where partial shading effects are less important, this is not the case for façade BIPV applications. To allow the simulation of shading events, this work follows a physics-based approach that takes into account solar intensity and temperature spatial variations within the PV module. Although this approach has been extensively validated for different PV module topologies and varying weather conditions (Goverde et al., 2017; Goverde, 2016), to the best of the authors' knowledge, it has not been applied to BIPV systems, nor implemented in BES tools.

The following section introduces the methodology. First, the modelling approach is described. Next, four case studies are defined to illustrate the impact of the PV temperature and shading effects on the PV power output. An overview of the experimental BIPV setup used for the models validation is then presented. The third section brings the results. Finally, the last two sections discuss and elaborate on the results, and indicate the direction of future work.

## METHODOLOGY

### Modelling approach

The BIPV model was developed within the IDEAS environment, an open-source framework for building and district energy simulations based on Modelica language (Jorissen et al., 2018). Modelica is a general-purpose language for modelling complex and multi-domain systems. In particular, its equation-based object-oriented nature brings on the flexibility required to cover the wide range of BIPV applications and provides autonomy to the user to include new models or modify existing ones.

Figure 1 (left) illustrates the object-oriented approach: the PV elements represent the electrical model while the BIPV elements represent the thermal model. Each PV element corresponds to one PV cell, and has a different temperature and solar irradiation intensity as input, allowing for temperature and shading spatial variations. The temperature-dependent one-diode model based on Goverde (2016) represents the PV electrical behaviour at cell level. Each PV element is combined to one thermal element (explained below). The airflow circulating inside the BIPV element interconnects the thermal elements. The electric-thermal coupling between PV and thermal elements is achieved by using the PV temperature obtained from the thermal model to calculate the power output in the electrical model, which is in turn imposed as a heat sink to the PV thermal layer. A multi-step solver with a tolerance of 0.0001 resolves the equations iteratively. The PV controller limits the maximum time step to 10 s.

The thermal model is detailed in Figure 1 (right). The airflow rate results from the balance between the local and friction losses (calculated as in Langmans et al., 2015) and the driving pressure (wind and buoyancy). Buoyancy-driven pressure depends on the density difference

between the air inside the cavity and the ambient air. The wind-driven pressure is calculated according to Saelens and Hens (2011). Correlations available in the literature are used to model the convective heat transfer inside the cavity and at the exterior BIPV surface (Churchill and Chu, 1975; Montazeri and Blocken, 2017). Radiative heat transfer follows the Stefan Boltzmann's law. Long-wave losses to the ground and the sky are modelled separately.

Figure 1. Schematics of (left) electric-thermal couplings, and (right) thermal model.

### PV electrical model: case studies

To demonstrate the effect of temperature and shading on the PV power production, four cases were simulated. In Case 1, the temperature of all PV cells within the module was taken equal to 25 °C, which represent the standard test conditions (STC) for PV systems. Case 2 uses the surface temperature measured at cell level as an input to the model. Cases 1 and 2 are compared to the measured PV power output. In Case 3, shading is simulated at cell level, with 3 out of 9 cells within the PV module receiving 50% less irradiation. Case 4 represents the shading at module level, where all 9 cells receive the same amount of equivalent solar irradiation (83.3%). Case 3 characterizes the spatial approach used in this work while Case 4 represents the approach available in TRNSYS and EnergyPlus (spatial variations within the PV module are not included). Cases 3 and 4 are compared to non-shading conditions.

### Experimental setup: overview

A schematic representation of the BIPV experimental setup used in this work is presented in Figure 1 (left). Lehmann et al. (2017) and Goverde et al. (2017) provide detailed information and experimental results for this setup. The BIPV element (1.3 x 0.6 x 0.14 m) is composed of two PV modules connected to a naturally ventilated cavity (width: 0.14 m; openings: 0.05 x 0.6 m). Each module consists of nine monocrystalline silicon PV cells connected in series and assembled in a glass-glass panel. The setup was integrated into the south-west façade of the Vliet test building in Leuven, Belgium. The instrumentation provides the BIPV surface and air temperature at relevant locations, PV power generation, and weather conditions, including the solar irradiation on the façade.

## RESULTS

### PV electrical model: case studies

The results presented here focus on two consecutive sunny days in May 2017. Weather conditions recorded on-site and measured PV surface temperatures are inputs to the simulations. On the left side of Figure 2, the comparison of Cases 1 and 2 against the measured values demonstrates the effect of the PV temperature on the power output. Assuming that the PV cells are at 25 °C overestimates the PV output by 14% at peak solar

irradiation. Provide the temperature of each PV cell is correct (Case 2), the results also indicate that the one-diode electrical model is able to predict the PV power output. Slightly larger deviations are observed in the beginning of the day. The right side of Figure 2 focuses on shading events. Case 3 shows that considering solar intensity variation at cell level leads to power reduction of more than 40% at peak solar irradiation compared to non-shading situations. The difference of 32% at peak solar conditions between cases 3 and 4 corresponds to the impact of the PV electrical modelling approach used in this work compared to the existing implementation in BES tools.

Figure 2. Results for two sunny days in May 2017: (left) Cases 1 and 2 are compared to measured power production, (right) Cases 2 and 3 compared to no shading conditions.

#### Experimental validation: multi-physics BIPV model

Simulations were performed for the fully coupled multi-physics model using weather data measured on-site from June to August 2017. Saelens et al. (2004) demonstrate that the assumption of an inlet air temperature equal to the exterior temperature may not be valid for ventilated façades. Thus, the air temperature measured at the cavity bottom is used as inlet temperature in the model. The heat flux through the building wall was measured at the middle of the wall and imposed to all thermal elements in the model as a boundary condition. Now, the coupled model predicts the PV temperature, instead of using measured PV temperatures as input to the model, as done previously for the case studies.

In Figure 3, on the left side, the results are presented for the same two days in May 2017. It has been demonstrated previously (Cases 1 and 2) that the PV electrical behavior is highly dependent on the PV temperature. Figure 3 (left) shows that the coupled model is capable of well predicting the average PV temperature and, therefore, is equally able to estimate the power output accurately. The absolute monthly energy yield error shown in Figure 3 (right) varies from less than 2.5% in June to 4% in July. The error has been calculated for power output above 2 W, which corresponds approximately to the period between 7h30-20h.

#### DISCUSSION

This paper has demonstrated the importance of considering temperature and shading effects to model BIPV systems. For the monocrystalline silicon cells used in this work, the power temperature coefficient is about  $-0.5\%/K$  (Goverde, 2016), which leads to a power reduction of 15% for a temperature 30K above STC. Such temperature conditions are observed in Figure 3 (left). Note that the BIPV configuration investigated in this paper corresponds to a fairly well ventilated system. The temperature influence is expected to be more important for BIPV concepts with limited heat dissipation. These results indicate that assessing BIPV systems based on the temperature at STC may not be a suitable approximation, which corroborates the need for more detailed BIPV thermal models.

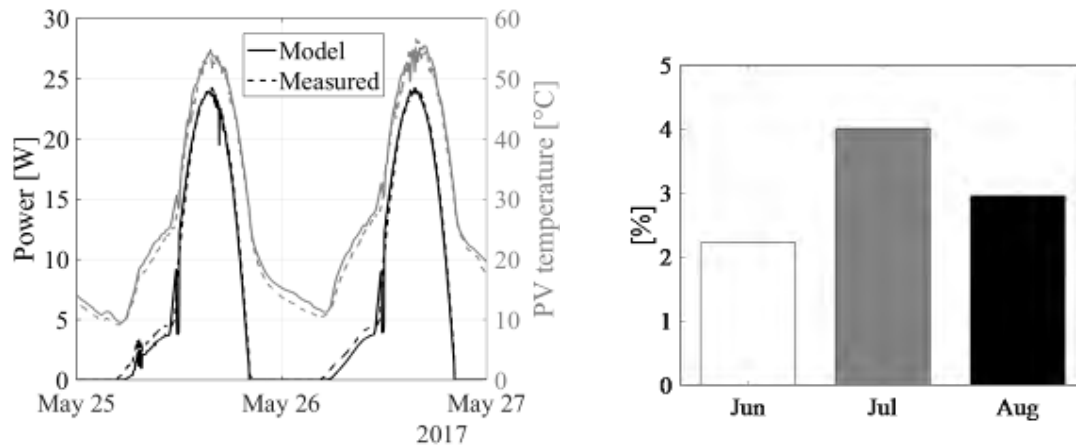

Figure 3. Left: results for two sunny days in May 2017. Right: monthly energy yield error.

As for shading effects, the results show that including solar intensity spatial variation at cell level within the PV module leads to a significant power reduction. This occurs because the PV module performance is bounded to the worst performing cell, a consequence of current mismatch between cells connected in series. The same applies to an array of PV modules in series, in which the worst performing module will dictate the array overall performance. Although a constant shading profile (throughout the day) might not represent real conditions, the results presented here are also quantitatively valid if shading occurs during peak solar irradiation, since larger differences in power production occur at high irradiation conditions.

The fully coupled BIPV model described in this paper is able to predict the BIPV temperature and, therefore, its power production. Possible causes for the power deviations in the beginning of the day are the following: 1) different pyranometer and PV response to the solar irradiation; 2) use of parameters not optimized for low irradiation conditions (Goverde, 2016); 3) use of one-diode model at low irradiation conditions (Chin et al., 2015). These aspects will be investigated in the future. Finally, the error difference from one month to the other indicates that the model is sensitive to weather conditions, in agreement with Goverde (2016).

Although this paper focused on naturally ventilated BIPV systems, which is more challenging from the modelling point-of-view, the flexibility of object-oriented models allows for easily adapting the model to a mechanically ventilated or unventilated variant. Validating the model for different BIPV concepts, including unventilated and real-size setups, is part of ongoing effort. Modelling the airflow behind the PV modules has also proven to be a challenging task. Future work will focus on computational flow dynamic methods and experimental techniques to better understand the airflow inside the cavity and improve the model accordingly.

## CONCLUSIONS

This paper focused on the experimental validation of a naturally ventilated façade BIPV model. The modelling approach proposed here comprehends (1) a detailed multi-physics BIPV model; (2) the use of the equation-based object-oriented Modelica language; (3) the use of hydraulic network to model the airflow; (4) the individual modelling of wind and buoyancy effects; (4) a physics-based model to represent the PV electrical behaviour under non-uniform spatial conditions (temperature and solar irradiation). Thereby, mismatch losses between cells and modules are taken into account, and both shading and temperature effects can be simulated. This approach further provides detailed BIPV and building models within the same simulation environment.

This paper has demonstrated that, for a BIPV system, temperature effects may reduce the PV power output by 15% at peak solar irradiation compared to STC. Shading effects may be even more important with power reduction up to 40%. Although the air temperature measured at the bottom of the cavity was taken as the air inlet temperature for validation purposes, the authors recognize the importance of accurately modelling the inlet conditions. Nevertheless, provide that correct cavity flow characteristics and boundary conditions are used, the model presented in this paper is able to predict the performance of naturally ventilated BIPV systems with monthly energy yield error inferior to 4%.

## **Numerical analysis of the influencing factors on the performance of a pipe-embedded window operated in summer**

Sihang Jiang, Chong Shen and Xianting Li\*

### **ABSTRACT**

The pipe-embedded window is a double window structure with pipes embedded inside the cavity to adjust the temperature. The preliminary studies showed that it can significantly reduce the cooling load of buildings with natural cooling sources such as the water from cooling towers in summer. However, the research on the influencing factors of the pipe-embedded window is insufficient. In this paper, the numerical calculation models are established for a pipe-embedded window and a traditional window. The influence of climatic factors, such as the natural cooling source temperature and outdoor air temperature on the thermal performance of the pipe-embedded window are studied. Based on these, the building energy efficiency is analysed. The results show that the thermal resistance of the pipe-embedded window is basically constant. A linear relationship has been found between the inner surface heat flux, pipe heat flux, interlayer mean air temperature and the outdoor air temperature, mean water temperature or solar radiation intensity. The solar radiation intensity, water temperature, outdoor air temperature is ranked from most to least influence. The location of pipe has little effect on the temperature field and heat transfer of a pipe-embedded window. In summer, the difference between inner-glass and outer-glass insulation is small.

### **KEYWORDS**

Space cooling, Pipe-embedded window, CFD, Cooling load, Building energy efficiency

### **INTRODUCTION**

It is crucial to reduce the cooling load caused by glass envelope. Double Skin Façade (DSF) is able to utilize the dry bulb temperature of outdoor air to improve its own thermal performance, so it has a very large energy-saving potential. However, some problems of the DSF have been exposed with the research and application going in deep. As the two main problems, under summer solar radiation, it is prone to the interlayer greenhouse effect because of the interlayer overheat (Gratia and De Herde, 2007); in winter, strengthening insulation can only be achieved by closing the passageway. The external environment is underutilized in regulating temperature as in summer.

To further reduce the cooling load from window, Shen and Li (2016a) proposed a system that embedding water pipes in the venetian blinds of a double glass window utilizing cooling water and studied the system performance under the design condition. Their results showed the effectiveness of the pipe-embedded window. However, the system performance under different weather conditions and water temperatures wasn't studied; Shen and Li (2016b) also studied the performance of the pipe-embedded window they proposed applying it to different regions and orientations. It showed that the above pipe-embedded window had a great energy saving potential in most climatic regions of China. However, the influence of different types of window structures wasn't considered. Overall, at present, the influencing factors on the heat transfer of this kind of window are rarely studied. The analysis of the relevant energy

efficiency and heat transfer mechanism is also insufficient, which also restricts the popularization and application of this kind of window to a certain extent.

In this paper, a numerical model is built for a pipe-embedded window. The influences of the climatic influencing parameters, such as the natural cooling source temperature, outdoor air temperature and solar radiation intensity, as well as the geometrical influencing parameters, such as the pipe and insulating layer location on the thermal performance of this kind of window are systematically studied in order to provide reference for engineering practice.

## METHODS

### Physical model

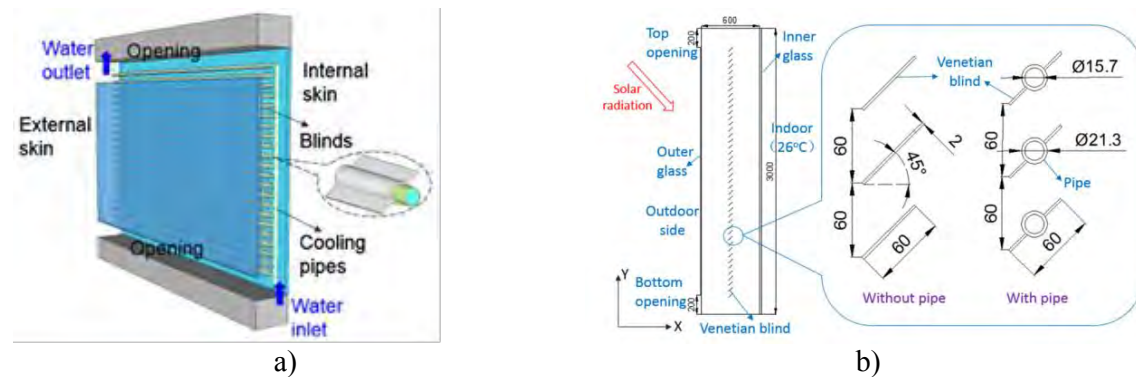

Figure 1. Pipe-embedded double window system. a) Structures, b) Dimensions

Fig. 1 provides the structures and dimensions of a pipe-embedded double window system. Water pipes are embedded into the venetian blinds of the double window. Actually, the differences between the traditional window and the pipe-embedded window only exist in sunshade structures. The dimensions of the studied pipe-embedded window are 3 m (height, Y)  $\times$  0.6 m (width, X). In total, 44 cooling pipes are embedded into the venetian blinds with an interval of 60 mm. The outside diameter of each cooling pipe is 21.3 mm. The thermal parameters of materials are determined by referring to the references (Iyi et al. 2014; Zeng et al. 2012). The working conditions about the climatic influencing factors in this paper are divided into three groups: Different water temperatures (A); Different outdoor air temperatures (B); Different solar radiation intensities (C). The working conditions about the geometrical influencing factors are divided into two groups: Different pipe locations (D); Different insulating layer locations (E). The details are summarized in Table 1 and Table 2.

Table 1. The settings of the working conditions (Climatic influencing factors)

Working condition	Water temperature(°C)	Outdoor temperature(°C)	Solar radiation(W/m <sup>2</sup> )
A	24/26/28/30	34	500
B	28	32/34/36/38	500
C	28	34	125/250/375/500

\*The pipes are located in the middle of interlayer. The insulating layer closes to the indoor side.

Table 2. The settings of the working conditions (Geometrical influencing factors)

Working Condition	Water temperature(°C)	Pipe location	Insulating layer location
D	28	left/middle/right	right
E	22/26/30	middle	left/right

\*The outdoor air temperature is 34 °C. The solar radiation intensity is 500W/m<sup>2</sup>.

### Numerical method

A CFD model is established in this paper. The  $\kappa$ - $\varepsilon$  turbulence model is adopted in this paper (Iyi et al, 2014). A two-dimensional simplification is adopted in this paper (Manz, 2004; Saelens et al, 2008). The heat transfer is considered to be a steady process. Discrete ordinate (DO) method is adopted for simulating the radiation heat transfer. The commercial CFD software ANSYS Fluent is employed to solve all the numerical equations in this paper. Structured quadratic meshes are divided in the main domain except for a small part near venetian blinds; the mesh with 35,000 cells is eventually employed. The numerical simulation methods in this section have been validated successfully (Shen and Li, 2016b).

### Energy efficiency analysis method

The electricity consumption of delivery for a pipe-embedded window system ( $P_{pipe}$ , W/m<sup>2</sup>) is made up of the electricity consumption of indoor pumps and outdoor heat rejection equipment (such as cooling tower), it can be calculated as:

$$P_{pipe} = \frac{Q_{pipe}}{WTF_{pipe}} + \frac{Q_{pipe}}{EER_{out}} \quad (1)$$

where  $Q_{pipe}$  is the heat flux of water pipes, W/m<sup>2</sup>.  $WTF_{pipe}$  is the transport factor (ratio of transferred heat energy to the electricity consumption of pumps) of the pipe-embedded water system.  $EER_{out}$  is the energy efficiency ratio of outdoor unit, the NDRC (2008) recommends the values.

The electricity consumption of delivery for a traditional air conditioning system ( $P_{room}$ , W/m<sup>2</sup>) is made up of the electricity consumption of indoor pumps, outdoor heat rejection equipment and indoor heat exchangers (such as fan-coil unit), it can be calculated as:

$$P_{room} = \frac{Q_{room}}{WTF_{room}} + \frac{Q_{room}}{EER_{in}} + \frac{Q_{room}}{EER_{out}} \quad (2)$$

where  $Q_{room}$  is the indoor air conditioning load caused by the window (equal to the inner surface heat flux), W/m<sup>2</sup>.  $WTF_{room}$  is the transport factor of the indoor air conditioning water system.  $EER_{in}$  is the energy efficiency ratio of indoor unit, the NDRC (2008) recommends the values.

The electricity consumption of the traditional air conditioning system ( $E_{trad}$ , W/m<sup>2</sup>) can be calculated as:

$$E_{trad} = \frac{Q_{room}}{COP} + P_{room} \quad (3)$$

where  $COP$  is the coefficient of performance of the chiller system.

## RESULTS AND DISCUSSIONS

### Influences of the climatic influencing factors

By calculating the inner surface heat flux, pipe heat flux, interlayer mean air temperature in every case, the relevant fitting formulas can be obtained ( $R^2 \approx 1$ ):

$$Q_{room} = 0.9964 \cdot t_{air} + 3.3456 \cdot t_{water} + 0.07889 \cdot R_{solar} - 86.25 \quad (4)$$

$$Q_{pipe} = 4.7091 \cdot t_{air} - 9.5898 \cdot t_{water} + 0.60877 \cdot R_{solar} + 60.22 \quad (5)$$

$$t_{aver} = 0.1954 \cdot t_{air} + 0.6761 \cdot t_{water} + 0.00413 \cdot R_{solar} + 3.18 \quad (6)$$

where  $T_{aver}$  is the interlayer mean air temperature, °C.  $t_{air}$  is the outdoor air temperature, °C, and  $t_{water}$  is the water temperature, °C.  $R_{solar}$  is the solar radiation intensity, W/m<sup>2</sup>.

The above formulas with a very high linearity show that the thermal resistance of the pipe-embedded window will be basically constant if the structure of a pipe-embedded is defined. The convective and radiant heat transfer coefficients are basically unaffected by the climatic influencing parameters such as outdoor air temperature. The influence of the water temperature on the inner surface heat flux is significantly higher than that of the outdoor air temperature. However, the pipe heat flux will increase by  $50 \text{ W/m}^2$  if the solar radiation intensity increases by  $60 \text{ W/m}^2$ . The fluctuation range of the solar radiation intensity in one day is often at the order of several hundred  $\text{W/m}^2$ , so the solar radiation intensity is the most significant influencing factor. The water with a higher temperature can also take away effectively solar radiation heat energy because of the solar radiation heating source with a very high temperature, so the influence of the water temperature is slightly smaller.

Fig 2 and Fig 3 show the influences of the outdoor air temperature, water temperature and solar radiation intensity on the cooling load reduction rate of the embedded window (compared with the traditional DSF) and electricity consumption.

Figure 2. Influences of outdoor air and water temperature. a) Outdoor air temperature, b) Water temperature

Figure 3. Influence of solar radiation intensity

It can be seen that all the influence relations are approximately linear. The load reduction rate increases with the outdoor temperature and solar radiation intensity, decreases with the water temperature. The water temperature has a greater influence than the outdoor air temperature. It shows that when the outdoor air temperature or solar radiation intensity rise or the water temperature reduces, the pipes can take away not only more heat energy but also a greater proportion of heat energy because of the increase of difference between the water temperature and solar-air temperature. When the outdoor air temperature is  $38 \text{ }^\circ\text{C}$ , the inner surface heat flux is  $84.7 \text{ W/m}^2$  and the load reduction rate is up to 44%; when the water temperature is  $24 \text{ }^\circ\text{C}$ , the inner surface heat flux is  $67.4 \text{ W/m}^2$  and the load reduction rate is up to 49%; when the

solar radiation intensity is  $125 \text{ W/m}^2$ , the inner surface heat flux is  $80.7 \text{ W/m}^2$  and the load reduction rate is up to 40%. The electricity consumption increases with the outdoor air temperature, water temperature and solar radiation intensity. However, it doesn't change much around  $38 \text{ W/m}^2$  when the outdoor air temperature and water temperature change. The solar radiation intensity has the most significant impact on electricity consumption. When the solar radiation intensity is  $125 \text{ W/m}^2$ , the electricity consumption reduction rate is up to 25%.

### Influences of the geometrical influencing factors

Fig 4 shows the comparison of the temperature fields with different pipe locations. It can be seen that the temperature fields are basically the same. When the pipes are near the indoor side, the overall air temperature between the pipes and outer glass is slightly higher because of more direct radiation hitting the bottom surface. The pipe location almost has no effect on the electricity consumption (around  $39 \text{ W/m}^2$ ) and the heat transfer of the window.

Figure 4. Comparison of the temperature fields with different pipe locations (The left boundary direct contacts with the outdoor environment). a) Right, b) Middle, c) Left

Figure 5. Influences of insulating layer with different locations

Figure 5 shows the influences of insulating layer with different locations. It can be seen that the weights between the inner surface and pipe heat flux with different insulating layer locations are different. When the insulating layer is located near the indoor side, the heat flux passing the inner surface is very little but the heat flux passing the pipe wall is very much. On the contrary, when the insulating layer is located near the outdoor side, the no-water interlayer air temperature is higher, the inner surface heat flux will increase and pipe heat flux will decrease with the decrease of the difference between the interlayer air temperature and water temperature. When the insulating layer location changes, the change range of the pipe heat

flux is about 2.5 times that of the inner surface heat flux. In other words, if the cooling efficiency of the pipes is 2.5 times higher than that of indoor heat exchangers, the way of inner-glass insulation will be more energy-saving. However, the pipes are mainly used to remove the solar radiation energy instead of the thermal conduction and convection in summer. Besides, the difference between the water temperature and outdoor air temperature is usually little, so the difference of the electricity consumption between the inner-glass and outer-glass insulation is very small.

## CONCLUSIONS

A linear relationship was found between the inner surface heat flux, pipe heat flux, interlayer mean air temperature and the outdoor air temperature, mean water temperature or solar radiation intensity. The solar radiation intensity, water temperature, outdoor air temperature is ranked from most to least influence.

The cooling effect of the pipe-embedded window is significant even if the water temperature is higher than the indoor air temperature. For example, When the water temperature is 28 °C, the interlayer mean air temperature of the pipe-embedded window is 5.5 °C lower than that of traditional DSF. The inner surface heat flux of the pipe-embedded window is 52.7 W/m<sup>2</sup> lower than that of tradition DSF, the load reduction rate is nearly 40%; when the water temperature is equal to the indoor air temperature, the load reduction rate can be up to 45%.

In summer, the pipe location almost has no effect on the temperature field and heat transfer of the pipe-embedded window. The performance of glass is not the decisive factor in the overall performance of the pipe-embedded window. The difference between inner-glass and outer-glass insulation is small.

### ABSTRACT

This paper compares a simplified method to calculate the daylight factor and the annual daylight contribution in a space to the output of dynamic daylighting simulations. The simplified calculation method is the one implemented in the European Standard EN 15193 for the calculation of the energy demand for lighting in buildings, while the tool for dynamic simulations is Daysim (managed through DIVA-for-Rhino). The analysis was carried out by applying the two approaches to a reference office room, which was assumed to be located in different sites and having different window areas, with different orientations, both in the absence and in the presence of a mobile shade. The presence of an obstructing building was also considered. A total number of 108 cases was considered for the comparison.

The results showed a very good correlation between the analytical method and the Daysim simulations to calculate the daylight factor ( $R^2=0.99$ , with an absolute average difference of 11%). The correlation was lower for the calculation of the annual daylight contribution ( $R^2=0.86$ , with an absolute average difference of 35%), due to the complexity of variables included (climate, orientation, presence of a moveable shade). Among the variables, the higher differences between the analytical and simulation results were observed for the climate and the absence/presence of a shade.

### KEYWORDS

Daylight supply estimation, simplified calculation method, Daylight Factor, DIVA-for-Rhino simulations, EN15193-1 standard.

### INTRODUCTION

The standard EN 15193-1 (2017) belongs to a set of standards that were developed to support the implementation of the Energy Performance of Buildings Directives. In the standard, the metric LENI (Lighting Energy Numeric Indicator) was introduced to quantify the energy demand for lighting for a building. Consistently, an analytical calculation method was also supplied. This includes all the main factors that affect the energy consumption for electric lighting: power of the lighting systems, daylight contribution into an indoor space, type of lighting control and building usage. The “core” of the calculation method is the estimation of the daylight contribution through the daylight dependency factor ( $F_D$ ). This depends on other two factors: the *daylight supply factor*,  $F_{D,S}$ , to estimate the “daylight autonomy” of the space under consideration; the *lighting control factor*,  $F_{D,C}$ , to account for the effectiveness of the type of lighting control system in exploiting daylight. To calculate  $F_D$ , the building is divided into ‘Daylit Areas -  $A_D$ ’, which receive daylight, and ‘Non-Daylit Areas -  $A_{ND}$ ’ for which  $F_D$  is assumed equal to 1 (no significant daylight contribution).

The calculation method introduced in the original standard (2007) was deeply revised in the present version (2017), with regard to both  $F_{D,S}$  and  $F_{D,C}$ . The analytical procedure adopted in the new version of the standard relies on a parametric study, whose basic principles are described in the EN 15193-2 (2017) and in the ISO 10916 (2014).

Focusing on  $F_{D,S}$ , this is the result of a two-step calculation. Firstly the daylight factor for the opening (D) is calculated as a function of external obstructions, room sizes and characteristics of the apertures (such as window size, glazing visible transmittance and maintenance, and frame factor). Secondly, the annual daylight supply factor of the considered space ( $F_{D,S}$ ) is determined as a function of D, of the climate, of the orientation of the windows, of the absence/presence of a shading system for thermal and/or glare control, and of the target illuminance. Except for the illuminance, the other factors of step *two* of the calculation method were not included in the original version of the standard (2007). In the new standard, the climate is taken into account through the *luminous exposure*  $H_{dir}/H_{glob}$ , i.e. the ratio of the direct horizontal illuminance to the global horizontal illuminance, each being calculated by summing up the illuminances in the hour range 8-17 throughout a year. To account for the presence of mobile shading systems,  $F_{D,S}$  is determined with reference to two different façade states, i.e. with systems activated ( $F_{D,S,SA}$ ) and with systems non-activated ( $F_{D,S,SNA}$ ).  $F_{D,S}$  is calculated as a weighted average of  $F_{D,S,SA}$  and  $F_{D,S,SNA}$ , using the annual relative time of usage or non-usage of the shading system as weighting factors.

Figure 1 shows a schematic representation of the flow chart to calculate  $F_D$  and of the space segmentation into Daylit and Non-Daylit Areas.

More information about the calculation method of the EN15193 standard can be found in Tian and Su (2014), Zinzi and Mangione (2015), and in Aghemo et al. (2016).

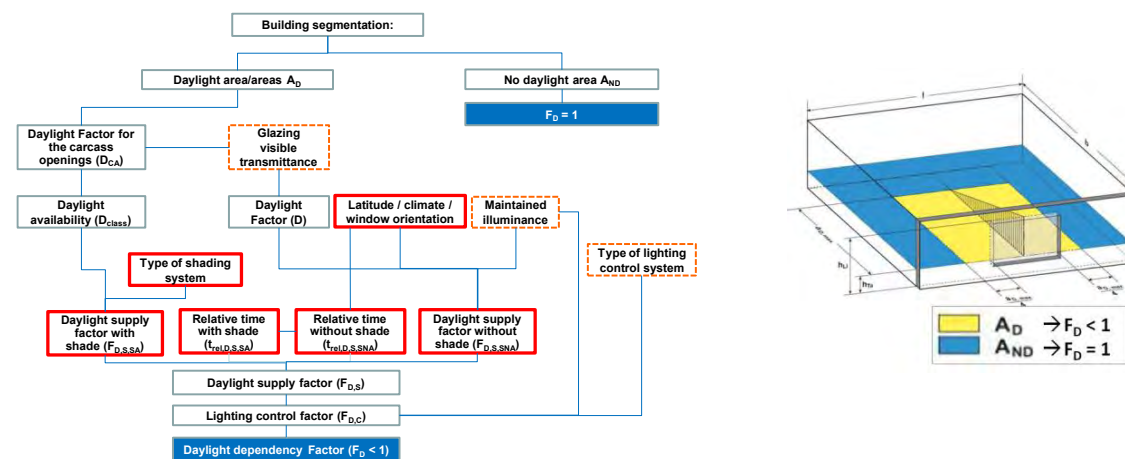

Figure 1. Flow chart to calculate the daylight dependency factor  $F_D$  for  $A_D$  and  $A_{ND}$ .

With the new standard, building practitioners are supplied with an analytical method, which accounts also for climate conditions, orientations and movable shadings, to calculate the daylight contribution in a space and therefore the LENI, without any simulations. The method is tabular, and the influencing factors are considered in a simplified way through discrete ranges. Compared to a dynamic simulation, the analytical method has a lower level of detail. Within this frame, this paper presents a comparison of the daylight contribution in a space as calculated through the analytical method of the standard and through a dynamic simulation tool. The validated Radiance-based daylight simulation method DAYSIM was used for this purpose (Reinhart and Walkenhorst, 2001). This combines the concept of the daylight coefficients and the Perez sky model to run annual simulations to determine the daylighting and the energy demand for lighting in a space.

## METHODS

A set of case studies was defined for the analysis of the daylight supplied in a room, calculated both through the analytical method and advanced simulation. The analytical

method was carried out in accordance with the Standard EN 15193-1 through a purpose-developed Excel spreadsheet, while the program DIVA-for-Rhino was used to manage Daysim annual daylighting simulations (a time-step of 1h was used). The Energy Plus climate files were used, both as input for the Daysim simulations and to calculate the *luminous exposure*  $H_{dir}/H_{glob}$ , which in turn was then used as input for the analytical calculation of  $F_{D,S}$ . A reference room was chosen, whose plan sizes are 6 m x 6 m, with a floor-to-ceiling distance of 3 m. The room has a single vertical opening (with a lintel height of 2.70 m and a sill height of 1 m above the floor), equipped with a glazing with a visible transmittance of 0.70. The room was meant to be used as a cellular office, with a target illuminance of 500 lx and with an occupancy profile 8:00 through 17:00, Monday through Friday, as specified in Standard EN 15193-1. A series of variables were parametrically modified to obtain a meaningful number of cases for which to compare the daylight contribution determined analytically and from simulations. The cases were defined so as to determine different daylight amounts in the room (poor, medium, high) under different climates to test the two methods.

For each case,  $D$  and  $F_{D,S}$  values were calculated analytically following the standard, while through the Daysim simulations two climate-based daylight metrics were determined: the continuous Daylight Autonomy  $DA_{con}$  and the Daylight Autonomy  $DA$ . Conceptually, the  $DA_{con}$  appears as the most consistent metric to be compared to  $F_{D,S}$ , based on how  $F_{D,S}$  is defined and calculated in the EN 15193-2 (2017). Considering that the  $DA$  is a more widely used metric to calculate the daylighting in a space, this was also determined and compared to the  $F_{D,S}$ . For the simulations, a grid of sensors was positioned over the workplane (0.8 m above the floor), with a spacing of 50 cm, covering the whole room area except a peripheral stripe of 50 cm. Annual  $DA$  and  $DA_{con}$  values were calculated for each point of the grid, then computing their average value to be compared to  $F_{D,S}$ .

The parameters that were modified were: site (3), size of the openings (3), type of shading (2), presence of a building ahead that produces a frontal obstruction (obstruction angle of 45°) (2), and orientation (3) (see Table 1). Each variable was parametrically combined with all the other variables, resulting in a database of 108 cases for the comparative analyses.

Table 1. Variables of the reference room that were changed for the comparative analysis.

Position (3)	London - L = 52.3°N ( $H_{dir}/H_{glob} = 0.37$ )	Turin - L = 51.5°N ( $H_{dir}/H_{glob} = 0.43$ )	Palermo - L = 38.1°N ( $H_{dir}/H_{glob} = 0.50$ )
Window area (3)	1 m x 1.7 m (WWR = 0.09) (carcass area 1.70 m <sup>2</sup> )	6 m x 1.7 m (WWR = 0.57) (carcass area 10.2 m <sup>2</sup> )	6 m x 3 m (WWR = 1) (carcass area 18 m <sup>2</sup> )
Shading (2)	No glare protection	Blind for glare protection	
Obstruction angle (2)	0°	45° (Building with a visible reflectance of 25%)	
Orientation (3)	South	West	North

## RESULTS

### Comparison of the *daylight factor* calculated analytically and through simulations

Figure 2 shows the daylight factor results (analytical and from simulations) for the entire database. For the analytical method, the  $D$  value is the area weighted average value of the two  $D$  values for  $A_D$  and  $A_{ND}$ . Plotting the analytical  $D$  values (standard) versus the  $DF$  values from Daysim simulations (Fig. 2a) shows a robust correlation ( $R^2=0.99$ ). In spite of this, a difference in the estimate is observed: the relative difference between the daylight factor values through the two approaches for all the cases analyzed is in the range -18.7% ÷ +9.9%, with an average difference of -5.2% (Fig. 2b). It seems therefore that the analytical method on average tends to underestimate the daylight amount compared to the simulation results.

Figure 2. D values (analytical method of the standard) versus DF values from simulations: a) absolute values, b) relative percent difference.

### Comparison of the *daylight supply* calculated analytically and through simulations

The daylight contribution in the spaces analyzed through the analytical method ( $F_{D,S}$ ) was compared to two climate-based daylight metrics from DIVA simulations (Fig. 3): the continuous Daylight Autonomy  $DA_{con}$  (Fig. 3a) and the Daylight Autonomy  $DA$  (Fig. 3b).  $F_{D,S}$  is calculated as area weighted average value of the two  $F_{D,S}$  values for  $A_D$  and  $A_{ND}$ .

Figure 3. Comparison of the daylight supply: a)  $F_{D,S}$  vs.  $DA_{con}$ , b)  $F_{D,S}$  vs.  $DA$ .

The correlation between analytical and simulation results is similar when using the  $DA_{con}$  metric ( $R^2=0.86$ ) or the  $DA$  metric ( $R^2=0.85$ ). In spite of this, the comparison  $F_{D,S}$ - $DA$  shows a gap for the lower values, in a way that  $F_{D,S}$  values in the range 7%-23% correspond to a  $DA$  of around 0% (such gap was not observed using the  $DA_{con}$ ).

Figure 4 shows the relative percent differences between analytical and simulation results.

Based on the results shown in Figure 4, the following considerations can be drawn:

- **range of relative differences:** the range was  $-115\% \div +22\%$ , with an average difference of  $-32.4\%$ . Consistently with what observed for the daylight factor but to a greater extent, the comparison between  $DA_{con}$  and  $F_{D,S}$  values shows that the analytical method on average tends to underestimate the daylight supply in a room compared to Daysim simulations
- **effect of climate:** the highest differences between analytical and simulation results were observed for Palermo, then for Turin and for London (average difference:  $-60\%$ ,  $-29\%$ , and  $-17\%$ , respectively). The way the climate is taken into consideration in the standard approach and in simulations plays therefore a crucial role on the final result: the standard accounts for the climate through the *luminous exposure*  $H_{dir}/H_{glob}$ , which synthetizes the climatic variation during the course of a year through a single value that expresses the annual presence of direct radiation compared to the global radiation. Differently, an annual

simulation calculates the daylighting into a space with a time-step of 1 hour, i.e. accounting for a specific sky condition that takes place every hour

- *effect of obstruction*: the relative difference values between the analytical and the simulations results for cases without and cases with obstruction were found to be of the same magnitude (average difference: -35.4% and -28.8%, respectively)
- *effect of orientation*: the three orientations considered showed differences between analytical and simulations results of the same magnitude (average difference: -37.2% for South, -29.1% for West, and -30.1% for North; again, the analytical results tend to underestimate the simulation results). Another aspect to mention is that the analytical approach assumes the same tabular coefficients for East and West orientations, which means that the same  $D$  and  $F_{D,S}$  values are obtained for the same space facing East or West. Besides, in the presence of the blinds, the  $DA_{con}$  values obtained with DIVA for the same space with the window West and East oriented were quite different: the relative differences of  $DA_{con\_W}$  and  $DA_{con\_E}$  values were in the range  $-56\% \div +8\%$ . These differences are due to the calculation algorithm implemented in Daysim to model the blinds: once glare is detected, the blind is pulled down and left in that position for the rest of day, so an East-facing space remains shaded for longer periods compared to the same space facing West.

Figure 4. Relative percent differences of the results for the daylight supply.

## DISCUSSIONS

The paper presented the results of a study on the effectiveness of a simplified analytical method, adopted in the European standard EN 15193-1, to calculate the daylight supply in buildings, compared to the results from dynamic simulations with a commercially available tool (DIVA-for-Rhino, which uses Daysim). The study was focused on the analysis of two of the parameters included in the simplified calculation procedure: the daylight factor ( $D$ ) and the daylight supply factor ( $F_{D,S}$ ). The first one is representative of the daylight provision under an overcast sky condition and in the absence of shading devices; the second one is descriptive of the daylight supply calculated taking into account the actual climate conditions, the window orientation, the presence of movable shadings and the required target illuminance.

The results of the study demonstrated that there is a very good correlation between the analytical method and the dynamic simulations with Daysim for what concerns the calculation of  $D$  ( $R^2 = 0.99$ , with an absolute average percent difference of 11%), while the correlation is lower when  $F_{D,S}$  is considered ( $R^2 = 0.86$ ). The daylight supply factor  $F_{D,S}$  was compared to the  $DA_{con}$ , as these two parameters have the same conceptual meaning. The results showed an average difference of -32.4%, ranging between -115% and +22%. Such lower correspondence for the global daylight supply ( $F_{D,S}$  and  $DA_{con}$ ) with respect to the daylight factors is in line

with the greater complexity of the factors affecting  $F_{D,S}$  and  $DA_{con}$ . The way the climate and movable shading systems are considered in the two estimation approaches particularly seem to be responsible for the greatest gaps observed between the results: the average difference is higher for Palermo (-60%), intermediate for Torino (-29%) and lower for London (-17%), and it is higher for cases with moveable shading devices than without shadings (-41% vs. -29%). The great difference between  $F_{D,S}$  and  $DA_{con}$  for Palermo is probably due to the very simplified approach used in the standard to account for climate conditions. Very few climate conditions (expressed in terms of  $H_{dir}/H_{glob}$ ) are reported in the tables of the standard and, while Torino and London show a  $H_{dir}/H_{glob}$  very close to the values used in the tables, the  $H_{dir}/H_{glob}$  for Palermo is almost halfway through the values reported in the standard. A linear interpolation was used to calculate the daylight supply factor to overcome this problem.

## CONCLUSIONS

The evaluation of the daylight contribution to indoor lighting is a key factor for the estimation of the energy performance of buildings. The availability of simplified calculation methods could be of help to take this aspect into account since the beginning of the design process.

The results of this study confirmed a good correlation between the parameters to estimate the daylight supply in buildings used in the simplified calculation method proposed by the European standard EN 15193 and in the dynamic simulation software DIVA-for-Rhino (which uses Daysim). Nonetheless, the differences between the results, especially for what concerns the  $F_{D,S}$  compared to the  $DA_{con}$ , are sometimes relevant, particularly for climate conditions that deviate from the data reported in the standard.

As a future work, the database will be expanded (new weather conditions and types of shading) and the energy demand for lighting will be calculated. The study shall provide useful information and data to optimize and implement the standard, particularly for what concerns the impact of climate and movable shading devices.

### ABSTRACT

Hygrothermal performance of building envelopes based on three different building materials (solid brick, high performance concrete, aerated autoclaved concrete) is assessed under climatic conditions of Prague and Atlantic City. Main objective of the paper is to evaluate the influence of cumulative damage, which was induced by means of natural weathering in 2012-2015 period, on the long-term performance. The performance is assessed using various measures, namely time-of-wetness function, number of freeze/thaw cycles, and annual amount of energy transmitted through the envelope. The results show that thermal performance of the envelopes gets mostly better after weathering as the annual amount of energy is decreased by ~3.5% in average. On the other hand, time-of-wetness function and number of freeze/thaw cycles increase by ~24.1% and ~22.0%, respectively. Based on the results summary it can be concluded, that cumulative damage of materials has an indisputable influence on the hygrothermal performance of building envelopes which might be either negative or positive. A detailed computational assessment is therefore necessary, incorporating not only reference, but also weather-affected material properties.

### KEYWORDS

Cumulative damage, computational modelling, hygrothermal performance, weathering, building envelope.

### INTRODUCTION

Possibilities of predicting hygrothermal performance of building envelopes are generally known, exploiting capabilities of computational techniques (Oladokun *et al.*, 2017). Such an approach provides relatively fast results without necessity of a construction to be built. Therefore, it is mostly used by building designers or building material producers. However, all computational models are strongly dependent on the quality of input data, the material properties in particular (Goffart *et al.*, 2017). An acquisition of material characteristics is therefore essential and advanced experimental techniques have been developed for this purpose so far, being more or less precise and demanding on time or costs. Unfortunately, it has been mostly ignored that material properties may change upon exposure to environmental conditions. The reason of ignoring this phenomenon, even if it is clear, might be found in the fact that such a kind of experimental investigations is extremely time-demanding and requires considerable storage space which makes it inconceivable for many research groups or departments. The vast majority of computational simulations in the field of building physics is therefore performed using reference material data that remain unchanged during the simulated period (Lakatos, 2017). However, having an indisputable impact on hygrothermal performance of materials, these changes should be included in all serious damage assessment analyses or simulations of hygrothermal performance.

The main objective of this research is to point at the differences in hygrothermal performance of building materials/envelopes that might occur when reference or weather affected data is used within the computational simulations. For this purpose, solid brick, high performance concrete, and autoclaved aerated concrete have been selected as representative load-bearing materials. They had been exposed to natural weathering and induced changes of their hygric and thermal transport and storage parameters were studied. Using computational modelling of coupled heat and moisture transport, subsequent long-term analyses of hygrothermal performance of building envelopes were carried out using reference and weather-affected material parameters in order to emphasize the possible differences.

## MATERIALS AND METHODS

### Materials

Solid brick (SB), high performance concrete (HPC), and autoclaved aerated concrete (AAC) have been selected as objects of study, representing typical building materials. The material characterization was carried out in the reference state and then after three years of natural weathering between 2012 and 2015. The weather characteristics of this period were continuously recorded using Davis Vantage Pro 2 weather station. The summary of selected weather parameters is given in Table 1, being compared to reference weather parameters of Prague, Czech Republic and Atlantic City, NJ. Climatic conditions of these locations were further considered as the exterior boundary conditions of the simulated walls. The abbreviations used in Table 1 have following meanings: Nov – November, Dec – December, Jan – January, Feb – February, Real – real weather data that were the materials exposed to, TRY – Test Reference Year, PRG – Prague (Czech Republic), ATC – Atlantic City (NJ).

Table 1. Comparison of selected weather parameters.

The material characteristics of the studied materials were determined following the procedure described by Černý (2013). The results are summarized in Table 2 (Maděra *et al.*, 2017; Kočí *et al.*, 2017; Kočí *et al.*, 2018b). The meaning of used symbols is as follows:  $\rho$  – bulk density

( $\text{kg}\cdot\text{m}^{-3}$ ),  $\psi$  – total porosity (%),  $\mu$  – water vapor diffusion resistance factor (measured using dry cup and wet cup methods) (-),  $\kappa_{\text{app}}$  – apparent moisture diffusivity ( $\text{m}^2\cdot\text{s}^{-1}$ ),  $c$  – specific heat capacity (in dry and water saturated state) ( $\text{J}\cdot\text{kg}^{-1}\cdot\text{K}^{-1}$ ),  $\lambda$  – thermal conductivity (in dry and water saturated state) ( $\text{W}\cdot\text{m}^{-1}\cdot\text{K}^{-1}$ ).

### Computational modelling

The computational modelling of one-dimensional heat and moisture transport was applied to assess the hygrothermal performance of studied materials when exposed to different weather conditions. Comparing the results obtained using reference and weather-affected material properties, one can evaluate the influence of weathering on long-term hygrothermal performance of the investigated building materials.

The computations were performed using the computer code HM Transport (Kočí *et al.*, 2018a) which works on the basis of the general finite element package SIFEL (Kruis *et al.*, 2010). The coupled transport processes were described using a diffusion type mathematical model derived from the Kunzel's original formulation (Madera *et al.*, 2017), as it requires only a tight set of input parameters while sufficiently precise results are provided. Besides the mathematical model and material properties, also boundary conditions, discretization mesh and time controller of the simulations are required. Within this paper, a 500 mm thick wall was assumed being exposed to dynamic climatic conditions of Prague and Atlantic City from the exterior side and to constant conditions (21 °C, 55 % RH) from the interior side (see Fig. 1). While Prague is typical with its continental climate, Atlantic City has the oceanic climate as it is located on the east coast of the USA. The weather conditions were applied in the form of TRY which contains long-term average hourly values of temperature, relative humidity, rainfalls, wind direction and orientation, and several kinds of sun radiation. The simulations took 10 years which is long enough to reach a certain kind of dynamic equilibrium.

Figure 1. Scheme of the analysed construction detail.

The hygrothermal performance of the wall was assessed by means of time-of-wetness function (ToW) and the number of freeze/thaw (FT) cycles (Koci *et al.*, 2014). These measures were applied to the whole construction detail. Additionally, thermal performance was evaluated by means of quantification of the annual amount of energy transported through  $1 \text{ m}^2$  of the particular envelopes (further denoted as Annual EB). It was calculated as

$$Q = \int_{1.\text{Jan}}^{31.\text{Dec}} q(t) dt, \quad (1)$$

where

$$q(t) = \lambda(w, t) \frac{\Delta T(t)}{\Delta x} \quad (2)$$

In Eq. (2),  $\lambda(w, t)$  is the moisture dependent thermal conductivity as a function of time ( $\text{W} \cdot \text{m}^{-1} \cdot \text{K}^{-1}$ ),  $\Delta T(t)$  the temperature difference (K) between two nodes defining the boundary element and  $\Delta x$  is their distance (m). The hourly values of  $\lambda(w, t)$  and  $T(t)$  were obtained as the results of computational modelling.

## RESULTS AND DISCUSSION

The results of computational simulations revealed that the hygrothermal performance of studied materials is definitely affected by their weathering. However, the influence may be positive as well as negative, depending on the material, climatic data and the measure investigated. The summary of hygric and hygrothermal performance is given in Table 3.

Table 3. Summary of hygric/hygrothermal performance.

		Prague		Atlantic City	
		ToW (h)	FT cycles (-)	ToW (h)	FT cycles (-)
SB	reference	350.02	30	3380.64	38
	3y-weathering	406.22	35	3478.49	42
HPC	reference	155.06	8	850.70	7
	3y-weathering	197.06	14	1240.70	8
AAC	reference	76.08	9	651.74	13
	3y-weathering	93.10	9	847.73	15

The hygric performance measure, ToW function, determines the sum of time when liquid moisture is present in any of nodes of the computational mesh (see Fig. 1). For this sake, the decisive value of relative humidity was considered to be 95 %. Approximately 8 times higher values in average were obtained when the weather conditions of Atlantic City were assumed. This finding agrees with the weather parameters presented in Table 1 showing much higher amount of rainfalls in Atlantic City than in Prague. However, more interesting is the fact that ToW values got higher after weathering in all the investigated cases. For instance, ToW of solid brick increased by ~16 % under climatic conditions of Prague and by ~27 % and ~22 % in case of high performance concrete and aerated autoclaved concrete, respectively. Except for solid brick, the relative increase of ToW was even higher under Atlantic City weather conditions. In case of high performance concrete, the ToW changed from 850.70 to 1240.7 h which represented an increase of about 45 %.

Figure 2. Comparison of moisture profiles: HPC, Atlantic City, Aug 10, 15:00

These changes can be explained mostly by the decrease of moisture diffusivity of studied materials, which led to retaining moisture for longer periods. The changes of hygric performance can also be demonstrated by a comparison of moisture profile before and after weathering. In Fig. 2 the moisture profiles of HPC under Atlantic City's climatic conditions as of August 10 are captured. The differences in this case reached more than 5 % of RH.

Closely related to hygric performance of materials is a risk of creation of freeze/thaw cycles that might cause a serious damage. The possibility of creation of FT cycles appears only when moisture is contained in the liquid phase and, at the same time, the temperature drops below zero. The principles of ice formation in real porous structures are, of course, more complex, incorporating other aspects such as pore characteristic, freezing temperature and duration, mechanical straining, or presence of chemical compounds. However, this measure serves well as a comparative indicator. Alongside with worsening of ToW values, also the number of FT cycles increased as it is shown in Table 3. It can be therefore concluded, that weathering of materials negatively affects their hygrothermal performance and thus might have also a negative impact on their durability. The rate of worsening depends on the type of material, as well as on specifics of the climatic conditions.

Table 4. Summary of thermal performance.

		Prague		Atlantic City	
		Average thermal conductivity ( $\text{W}\cdot\text{m}^{-1}\cdot\text{K}^{-1}$ )	Annual energy balance ( $\text{kWh}\cdot\text{m}^{-2}$ )	Average thermal conductivity ( $\text{W}\cdot\text{m}^{-1}\cdot\text{K}^{-1}$ )	Annual energy balance ( $\text{kWh}\cdot\text{m}^{-2}$ )
SB	reference	0.59253	98.66	0.59309	81.78
	3y-weathering	0.54811	92.34	0.54932	76.60
HPC	reference	2.12483	250.55	2.12764	207.41
	3y-weathering	2.15129	253.05	2.15426	209.49
AAC	reference	0.07276	13.98	0.07359	11.72
	3y-weathering	0.06908	13.29	0.06983	11.12

Unlike hygric performance, the thermal performance of studied materials got mostly better after weathering. It can be ascribed to the increase of porosity due to formation of microcracks which subsequently contribute to decrease of thermal conductivity. The opposite phenomenon can be observed in the case of high performance concrete, of which porosity decreased most likely due to secondary hydration processes. However, more sophisticated method such as SEM or XRD would be necessary to provide a detailed explanation. The summary of thermal conductivity changes is provided in Table 4: the annual energy balance of brick and aerated concrete was improved by ~6.4 % and by ~5.0 %, respectively. On the other hand, the energy transmitted through  $1 \text{ m}^2$  of high performance concrete got higher by ~1.0 %. All these findings correlate with the changes of thermal conductivity.

## CONCLUSIONS

A study of the influence of weathering on the hygrothermal performance of selected building envelopes was presented in this paper. In the first step, the samples made of solid brick, high performance concrete, and aerated autoclaved concrete were exposed to natural weathering and the weather-induced changes of their material properties were investigated. Subsequently, computational analyses of coupled heat and moisture transport of walls made of these materials were carried out in order to assess the impact of weathering on their long-term hygrothermal performance.

The natural weathering of materials led to changes in microstructure which was reflected also in their transport and storage parameters and thus in their hygrothermal performance. While the hygric performance got worse, being proved by an increase of ToW and FT values, the thermal performance got slightly better. As the formation of microcracks contributed to the increase of porosity, the lower thermal conductivity resulted in better thermal insulating properties of the studied materials except for HPC of which porosity decreased due to secondary hydration processes.

Based on the results presented in this paper it can be concluded, that weathering of materials and cumulative damage of theirs have indisputable influence on their long-term hygrothermal performance. Since the effects can be positive as well as negative, depending on the specific measure and climatic conditions, the cumulative damage should be included in computational simulations that are supposed to provide precise results.

### ABSTRACT

The aim of this paper is to evaluate the impact of thermal inertia of the substrate of a vegetative roof on its thermal behaviour. Thermal inertia of the substrate was incorporated in two existing thermal models of vegetative (green) roof systems, the Sailor (2008) and Tabares and Srebric (2012) models. The predicted temperatures across the substrate, with and without inertia, were compared with experimental data obtained on a real vegetated roof located in a semiarid climate. The study shows the absolute need to consider the thermal inertia of the substrate to accurately predict the temperatures within the substrate and thus the heat flux through the roof. When taking into consideration the thermal mass, substrate temperatures predicted by both models agree well with experimental data, with a Root-Mean-Square Deviation of about 1°C at a depth of 10 cm. For the analysed period and investigated vegetative roof, the Tabares and Srebric model outperforms the Sailor model.

### KEYWORDS

Vegetative roof substrate, thermal inertia, thermal models, substrate temperature.

### INTRODUCTION

At global level, buildings are responsible for one third of greenhouse gases and around 32% of energy consumption. Consequently, the energy efficiency of buildings represents a key factor in limiting global warming and mitigating the impacts of climate change. Therefore, improving the energy performance of the building envelope is one of the main objectives to achieve. In this context, vegetative roofs (VRs), usually called green roofs, offer a technological solution that contributes, through an appropriate design, to the reduction of the energy consumption of buildings (Berardi et al. 2014; Castleton et al. 2010; Fioretti et al. 2010; Tabares-Velasco, 2009; Vera et al. 2017).

The impacts of VRs on the energy performance of buildings have been widely studied. Table 1 summarizes the main heat and mass transfer mechanisms occurring in the VRs that might contribute to the reduction of the building energy consumption. Several heat and mass transfer models of VRs have been developed since 1982. Currently, Sailor model (2008) is the only one incorporated in the building simulation tool *EnergyPlus*, whereas Tabares and Srebric model (2012) is currently being included in the same tool. However, none of these two VR models incorporates thermal inertia of the substrate, which can influence the heat transfer through the roof and the energy consumption of buildings.

The objective of this study is to incorporate thermal inertia of the substrate in the vegetative roofs models developed by Sailor (2008) and Tabares and Srebric (2012) in order to evaluate

its impact on the predictions of both models. These two thermal models were first programmed in Matlab without any substrate thermal inertia and then thermal inertia was incorporated by finite differences method. The predicted temperatures across the substrate with and without thermal inertia were compared with experimental data of a real vegetated roof located in Santiago of Chile at the Laboratory of Vegetated Infrastructure of Buildings at Pontificia Universidad Católica de Chile, location that is characterized by a semiarid climate.

Table 1. Heat and mass transfer mechanisms in VRs (Vera et al. 2015).

Heat and mass transfer mechanisms	Description
Substrate evaporation and vegetation transpiration	This is known as evapotranspiration or latent heat transfer. It is a combined effect of water evaporation from the substrate and transpiration of plants. Evapotranspiration is the main contributor to counterbalance the incident solar radiation on the roof.
Shading provided by the canopy	The foliage reduces the amount of solar radiation that reaches the outer roof surface. This reduces the roof surface temperature in comparison with a traditional roof. Thus, heat flux into the roof also decreases.
Thermal inertia provided by substrate	The growing media contributes with thermal mass that helps to stabilize indoor temperature.
Additional insulation provided by substrate	The substrate adds thermal resistance to the roof, which helps to reduce heat losses through the roof and heat gains into the roof.

## METHODS

### Brief description of the Sailor (2008) and Tabares and Srebric (2012) vegetative roof models

The VR model developed by Sailor (2008) is based on the Fast All-season Soil STrenght (Frankenstein and Koenig, 2004a, 2004b), the Biosphere Atmosphere Transfer Scheme (Dickinson et al. 1993) and the Simple Biosphere (Sellers et al. 1986) models. This model is currently the only model implemented in the building energy simulation tool *EnergyPlus* (Crawley et al. 2001, 2004). The VR model developed by Tabares and Srebric (2012) can consider partially-covered VRs. This model has been validated using laboratory and field data (Tabares-Velasco et al. 2012).

Both VR models are similar in the way they present the energy balance and the components they consider and neglect. In fact, both models assume one-dimensional heat transfer, a single vegetation layer located above the surface of the substrate layer. The differences that exist are only evidenced in the way both models calculate each of the components of the energy balance. For both the substrate and foliage layers, the energy balances equations consider the absorbed short-wave solar radiation ( $R_{sh,abs}$ ), the absorbed infrared radiation from the sky ( $Q_{ir}$ ), the radiation heat transfer between the foliage and substrate surface layers ( $Q_{ir,s-f}$ ), the latent (L) and sensible (H) heat transfer and the conduction heat transfer from the substrate surface going downwards ( $Q_{cond}$ ) (only for the substrate layer). The net heat fluxes to the foliage  $F_f$  and to the substrate  $F_s$  are given by Equations 1 and 2, respectively:

$$F_f = R_{sh,abs,f} + Q_{ir,f} + Q_{ir,s-f} + H_f + L_f \quad (1)$$

$$F_s = R_{sh,abs,s} + Q_{ir,s} - Q_{ir,s-f} + H_s + L_s - Q_{cond} \quad (2)$$

### Implementation of the thermal inertia in the models

Both VR models were implemented in Matlab, including the thermal inertia of the substrate. While some simulation tools use conduction transfer functions to propagate the heat fluxes to the interior of the building, the VR models in Matlab use the finite difference approach. The original assumption that says that the canopy has a neglectable thermal mass was maintained. Assuming a vertical direction for the heat flux through the roof, the thermal behaviour of the VR can be approximated using the finite difference method with a discretization of the layers as shown in Figure 1, and can be represented by Equation 3.

Figure 1. Discretization of the different layers of the VR (Brown and grey layers correspond to the substrate and concrete slab structure, respectively)

$$C_p \rho \Delta x \frac{T_i^{j+1} - T_i^j}{\Delta t} = k_{i+1} \frac{(T_{i+1}^{j+1} - T_i^{j+1})}{\Delta x} + k_{i-1} \frac{(T_{i-1}^{j+1} - T_i^{j+1})}{\Delta x} \quad (3)$$

where  $k_i = k(T_i^{j+1}, VWC_i^{j+1})$  is the thermal conductivity that depends on the temperature  $T$  and volumetric water content  $VWC$ ;  $T_i^j$  the temperature of node  $i$  at time  $j$ ;  $\Delta t$  the time step;  $\Delta x$  the finite-difference layer thickness; and  $C_p$  and  $\rho$  the specific heat and the density of the material.

In this study, 16 layers were defined (8 for substrate and 8 for concrete slab). To model the substrate without thermal inertia, parameters  $C_p$  and  $\rho$  were set to very negligible values, leading to a steady state solution to the energy balance.

### Experimental dataset

The experimental data was collected in the city of Santiago, Chile (33°26'S, 70°39'W) and corresponds to measurements performed on a real vegetated roof system installed in a test facility called 'Laboratory of Vegetative Infrastructure of Buildings' (LIVE, for its acronym in Spanish). The experimental data considered in this study was measured during 10 days in September 2017 (end of the winter period). Santiago is characterized by a typical dry Mediterranean climate (semiarid) and has a warm temperate climate with dry summers (Peel et al. 2007). The average annual temperature is 14.6°C and the mean annual precipitation is 313 mm, with 25-30 rainy days per year (DGAC, 2015). The LIVE consists of 4 testing modules of 2 m height, with high level of thermal insulation in their walls and floors. Three of the modules are 25 m² each while one is 35 m². This facility allows testing up to 18 different specimens of VRs, each of one has an area of about 1.8m x 1.8m (see Figure 2) (Reyes et al. 2016).

This paper presents the results obtained on only one vegetated roof installed on one of the four testing modules. It is composed by the following layers (from top to bottom): (1) a vegetation layer (grass); (2) a 15 cm thick substrate composed by 1/3 part of humus, 1/3 part of garden soil and 1/3 part of perlite (measures in volume); (3) a filter layer; (4) a root barrier; (5) a drainage layer; (6) a waterproofing layer and (6) a support structure (a 15 cm thick concrete slab).

Measured data included the weather data conditions, the temperatures at different depths in the substrate (at the surface and at a depth of 5 cm and 10 cm), the heat flux across the substrate, the vegetation and substrate properties and the volumetric water content of the substrate.

Figure 2. Photo of the four specimens of the investigated vegetated roof in the LIVE.

### Analysis method

In order to assess the level of agreement between the model results and the measured data, the metric ‘Root-mean-square deviation’ (RMSD) was used. It is a measure of the average value of the absolute deviation between the simulation results and the experimental data, and it is calculated according to Equation 4.

$$RMSD = \sqrt{\frac{\sum_{t=1}^n (x_{1,t} - x_{2,t})^2}{n}} \quad (4)$$

where  $x_{1,t}$  is the simulated substrate temperature (°C) at time step  $t$ ,  $x_{2,t}$  is the measured substrate temperature (°C) at time step  $t$  and  $n$  is the quantity of data compared.

### RESULTS AND DISCUSSIONS

Figures 3 and 4 shows the comparison of the simulated and measured values of the surface temperature and at 10 cm depth of the VR substrate for the Sailor and Tabares models, with and without thermal mass. All data points that were measured and simulated during the considered period (10 days in September 2017), with a time step of 5 minutes, are plotted in the graphs. Table 2 shows the RMSD-values between the simulated and measured temperatures at different.

Table 2. RMSD for the different models investigated

	With Thermal Inertia		Without thermal inertia	
	Tabares	Sailor	Tabares	Sailor
Surface	1.12	2.18	1.41	4.38
5 cm depth	1.13	1.74	1.88	4.19
10 cm depth	0.76	1.25	1.80	3.39

These results evidence vegetative roof models that consider thermal inertia perform significantly better than the same models without thermal inertia. These results show a good agreement between the measured temperatures at different depths in the substrate and the ones predicted with both models – the Tabares model and the Sailor model – when thermal mass is taken into account. For the considered period and investigated vegetative roof, the Tabares and Srebric model is performing slightly better, showing lower RMSD-values around 1°C when thermal inertia is considered.

On the other hand, models that do not consider thermal inertia significantly overpredict the temperatures within the substrate. They present RMSD-values of 1.3 to 2.7 times higher than those that do consider thermal inertia. In particular the Sailor model without thermal inertia shows very high RMSD-values around 4°C, which is not acceptable for a correct estimation of the heat flow through the roof.

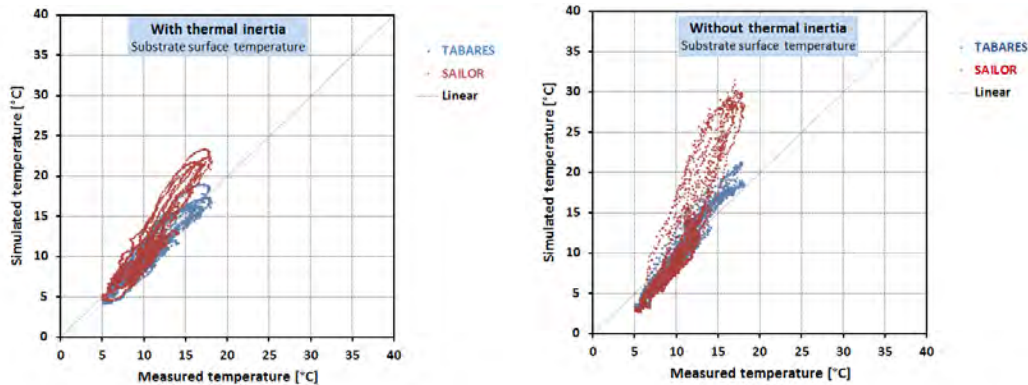

Figure 3. Simulated vs Measured surface temperatures of the substrate for models with and without thermal mass.

Figure 4. Simulated vs Measured substrate temperatures at a depth of 10 cm for models with and without thermal mass.

## CONCLUSIONS

This paper discusses the impact of the thermal inertia of the substrate on the thermal behaviour of a vegetative (green) roof system. Two thermal models – the Sailor (2008) and the Tabares and Srebric (2012) models - were implemented in Matlab and the thermal inertia was implemented in them by using the finite difference approach. Substrate temperatures simulated by the two models were then compared with experimental data during 10 days at the end of the winter period, first without considering the thermal inertia of the substrate and secondly by taking it into account. The results clearly evidence the importance of considering thermal inertia of the substrate to accurately predict the temperatures within the substrate. When thermal mass of the substrate is taken into consideration, both investigated VR models are capable of accurately predicting the substrate temperature, with a RMSD about 1°C at 10 cm of depth. For the analysed period and investigated vegetative roof, the Tabares model outperforms the Sailor model. The future work of this study should include other periods of evaluation such as summer and mid-seasons and different climates and vegetation species.

## New algorithm for water leakages flow through rain screen deficiencies

Lars Olsson<sup>1,2,\*</sup>, Carl-Eric Hagentoft<sup>2</sup>

<sup>1</sup>RISE Research Institute of Sweden, Division Built Environment, Sweden

<sup>2</sup>Chalmers University of Technology, Division of Building Technology, Sweden

### ABSTRACT

There is a need of more knowledge about the mechanisms of water leakage through façades exposed to driving rain to make reliable risk analyses. Therefore, we have studied it in more detail and the outcome include inter alia a new algorithm. The algorithm is developed for calculation of water leakages through rain screen deficiencies. The algorithm is based on empirical values from many measurements according to standardized test method and validation. Even though the leakage process is very complicated, simple correlations have been shown. The leakages flow rate through deficiencies are mainly limited by the runoff rate and the catch area above the hole and around the hole with dam. Apart from wind pressure as a driving force, the inlet of the holes is often on a higher level than the outlet at the rear of the façade, which creates significant hydrostatic pressure, which can be elevated by impoundment at the obstacle. This is the main reasons to comprehensive water leakages through façades without any wind pressure (pressure equalized façades).

If precise information about defects data is not available, there are extensive measurements supporting the following assumption – a realistic leakage flow for a small or invisible spot leakage at a façade detail is presumed to be 0.5 to 2% of the runoff rate per meter of façade width. If there are multiple penetrations or obvious defects in the façade design in combination with the dams, a significantly higher proportion of the runoff flow can leak in.

### KEYWORDS

Rain intrusion, runoff, catch area, mechanisms of water leakage, façade details

### INTRODUCTION

The latest research in Sweden confirms the statements in ASHRAE Standard 160, which state that façades are normally not completely rainproof (ASHRAE, 2016) and should be considered in moisture calculations (Olsson, 2017b). In addition, there is no reliable theoretical risk analysis tool to assess the moisture resistance of new façade solutions and of renovation solutions (Bednar & Hagentoft, 2015). If you rely solely on today's theoretical analyses, you end up underestimating water intrusion with consequences such as moisture-related damage, interior environment problems, and failure to meet energy efficiency requirements. Among other things, there is a lack of input data for driving rain intrusion to enable sufficiently relevant analyses. Several studies have therefore been conducted in recent years to investigate rain resistance due to driving rain and leakage flow in full scale with different solutions and different mounted details in Sweden (Olsson, 2017a).

One significant conclusion from the studies is that leakage at cracks and joints between façades and façade details and details are more the rule than the exception, regardless of façade type, material, ventilated vs unventilated, etc. Similar conclusions are drawn in other similar studies (Lacasse, 2003, Straube, 1998). Furthermore, (Olsson, 2016) has shown that significant leakage can be expected even in extremely small and invisible penetrations,

making it difficult or practically impossible to visually assess whether attachment details have been mounted tight. It is a matter of spot leakage flows of 0.01–0.05 l/min,m during a heavy driving rain load for rain-exposed multi story façades or 0.5–2% of the runoff rate per meter of façade width (Olsson, 2017a) for small or invisible penetrations. These results correlate well with an earlier study (Sahal & Lacasse, 2004), where a function was developed to describe the connection between applied quantity and leakage flow. The percentage of leakage in the study was 1.2–2.5% of the runoff rate per meter of façade width. It penetrated via a 50 mm elastic joint that was missing sealant between a mounting plate and the façade (in connection to a ventilation lead-through in the façade with a 15 mm protrusion). A study of a field experiment that was published relatively recently (Ngudjiharto, 2015) showed that the percentage of leakage flow was 1.5% of the runoff rate at a window detail with a 90 mm long penetration (without dam). Naturally, greater leakage can occur with noticeable penetrations, multiple penetrations in close proximity, façade details that both dam and lead in water, and extreme loads (Van Den Bossche, 2013, Lacasse, 2003).

The outcome of several of these studies and a newly study, (Olsson & Hagentoft, 2018) to be submitted 2018, which this paper is mainly based on has increased the understanding, both practical and theoretical, of driving rain intrusion and its mechanisms, and to present a modelling theory.

## METHODS

Many targeted experiments with different vertical surfaces (fibre cement and polycarbonate board) and different hole geometry and dam sizes were conducted. The results of the measurement and linear regression analysis serve as the basis for the empirically-determined values. As in previous studies (Olsson, 2017a), a standardized method, EN 12865, (SIS, 2001) was used. Additionally, theory from literature and simple phenomenological experiments performed prior served as the basis for describing the water's behaviour on a vertical surface and with different types of defects.

## THEORY

A theoretical description of the most dominated factors and forces involved that are of practical significance to the inward leakage process follows.

### Amount of water that can reach the defect

If the façade is capillary saturated or non-moisture-absorbing, then all the driving rain that lands on the façade surface will run downwards and be added along the vertical façade surface. The greatest runoff rate thus occurs at the bottom of the façade provided there are no water-diverting details. The water quantity that loads a penetration,  $G_{max}$  (kg/s), is based on the area (catch area) above the penetration, defined by height,  $H$ , (m) and width,  $D$  or  $W$ , (m), see equation (1) and Figure 1(a). The width of the catch area is made up of either the width of the hole ( $D$ ) or the width of the dam ( $W$ ). The dam can direct in more water from surfaces next to and above the hole. Designations for the geometry of the dam are also provided in Figure 1(a) and (b). The driving rain intensity is denoted  $g_{DR}$  (kg/(m<sup>2</sup>s))

$$G_{max} = H \cdot D \cdot g_{DR} \quad \text{or} \quad H \cdot W \cdot g_{DR} \quad (1)$$

The water leakage rate through the defect is denoted  $G$  (kg/s). We define a factor  $\eta$  (-) describing how efficiently the caught water is actually leaking in through the façade layer, see equation (2).

**Figure 1.** (a) Catch area as regards hole width ( $D$ ) or dam width ( $W$ ) plus façade height ( $H$ ). The assumed catch area is shown within the two vertical lines. (b) The figure shows a dam located at the bottom edge of a hole in a polycarbonate board. The dimension of the protrusion is given by ( $L$ ). (c) Wall section with spraying water with different holes and a dam. The height difference ( $h$ ) between the highest and the lowest point of the water across the hole constitutes the hydrostatic pressure. The figure shows how the water penetrates through a horizontal hole, downward-sloping hole and a hole with underlying dam.

### Hydrostatic pressure

The hydrostatic pressure  $P_h$  (Pa) is determined by water depth  $h$  (m), gravity  $g$  ( $\text{m/s}^2$ ) and the water's density  $\rho$  ( $\text{kg/m}^3$ ); see equation (3) and Figure 1 (c). The highest pressure thus occurs at the bottom of a pool of water or at the bottom edge of a hole filled with water. Increased hydrostatic pressure may therefore occur at protruding details in façades that cause dams.

$$P_h = \rho \cdot g \cdot h \quad (3)$$

### Wind pressure

In addition to the hydrostatic pressure described earlier, wind pressure is an essential driver for water leakage into façades due to air pressure difference across the façade layer. Assuming that the façade constitutes the dominant air pressure differences across the wall, the façade is subjected to the current wind pressure. The wind pressure  $P_w$  (Pa) across the façade layer can be estimated using the following formula, where wind velocity is denoted  $v$  (m/s) and  $f(-)$  is a form factor with a value somewhere between 0 and 1 depending primarily on wind direction in relation to the façade:

$$P_w = f \cdot \frac{\rho \cdot v^2}{2} \quad (4)$$

### Capillarity and surface tension

The surface properties of the materials have a bearing on how water acts on material surfaces. Even if the material is not capillary absorbing, the water may act differently on a surface depending on the surface energy of the material, or as it is also called the surface tension. Water has a lower surface tension than e.g. hydrophilic materials like steel, aluminium, glass and stone. For this reason, the water tends to flow out over such material surfaces (De Gennes et al., 2004). Conversely, water has a higher surface tension than hydrophobic materials, such as many plastics. The water surface tension coefficient is denoted  $\gamma$ , for water at 20 °C is

equal to 72,8 mN/m. The meniscus that is formed on the backside of the rain screen is resulting in a counteracting pressure, with a radius  $r$  (m) and contact angle  $\theta$  we get:

$$P_{men} = \frac{2\pi \cdot r \cdot \gamma}{\pi \cdot r^2} = \frac{2\gamma}{r} \quad (5)$$

### MODEL

We assume that the total pressure will be an important factor to include in an algorithm for estimated leakage flow. Thus, the estimated value of the leakage factor can be expressed as:

$$\eta_{est} = f(P_{tot}) \quad (6)$$

The total pressure for a non-absorbing surface is obtained through:

$$P_{tot} = P_w + P_h - P_{men} \quad (7)$$

The counterpressure in the meniscus that forms on the rear counteracts leakage, while the pressure from the water column and the wind helps to increase the leakage. For an absorbing surface, a counteracting meniscus does not form on the rear in the same systematic way and  $P_{men}$  is set to zero otherwise given by (5).

### VALIDATION OF MODEL

The measured leakage flow was examined in relation to the hole width or dam width and the actual runoff rate as per equation (2). We found that the dam width has a significant impact. If the hole is small in relation to the dam, maximal leakage efficiency of  $\eta=0.5$  is obtained as a rough target value. The maximal leakage efficiency of  $\eta=1$  is obtained at higher wind pressure as a rough target value.

The following formula, with linear relation to the total pressure, for leakage factor  $\eta_{est}$  was adopted:

$$\eta_{est} = \eta_0 + \alpha \cdot P_{tot} + \beta \cdot \frac{D}{W} + \gamma \cdot \frac{D}{L} \quad (8)$$

A large number of measurements were performed (Olsson&Hagentoft to be submitted 2018) and the constants in equation (8) were determined using linear regression, see Table 1. The wind pressure used in equation (4) relates to the maximum pressure that occurs under each wind pressure cycle. According to method EN 12865, the wind pressure during one-third of each cycle is zero,  $P_w/2$  and  $P_w$  respectively. The average pressure over the cycle is thus  $P_w/2$ . The total pressure  $P_{tot}$ , used in equation (8) is set to zero if negative.  $\eta_{est}$  is limited to stay in the range of zero to one.

Table 1. Constants determined for equation (8) for a number of experimental cases.  $R^2$  is a determination coefficient. The table applies for different runoff rates see column Runoff and different D width, see column Case.

Case	$\eta_0$	$\alpha$	$\beta$	$\gamma$	$R^2$	Runoff (l/min,m)
Fiber cem. with hole (2/4/8 mm)	0.19	0.0011	-	-	0.71	2.9
(-//-)	0.16	0.0010	-	-	0.69	1.1
Fiber cem.-hole with dam (1/4 mm)	-0.039	0.00035	1.36	-0.044	0.85	2.9
(-//-)	0.012	0.00044	0.92	-0.055	0.71	1.1
Polycarbonate with hole (4 mm)	0.065	0.0013	-	-	0.88	2.9
(-//-)	0.19	0.0014	-	-	0.36	1.1
Polycarb. hole with dam (1/4 mm)	-0.011	0.00054	1.30	0.040	0.73	2.9
(-//-)	0.029	0.00042	0.77	-0.043	0.47	1.1

### Comments for validation

The results of linear regression in Table 1 show in most cases  $R^2 > 0.7$ , which indicates that there are more or less clear correlations even though the water forms stochastically on surfaces to varying degrees. In some cases with low runoff rate, rivulets or small hole equal to 1 mm, there were no clear correlations for holes without dam.

We can establish that constants was not changed very much with different runoff rates, see Table 1. This indicates that the algorithm is applicable for different runoff rates with moisture-absorbing façades. Accordingly, equation (8) suits this best as a uniform water film is formed on the façade surface, resulting in a smaller spread in the repeated experiments. For non-absorbing materials, rivulets instead occur, particularly at low runoff rates, which move more stochastically across the surface.

### USE OF ALGORITHM – AN EXAMPLE

An example of how the algorithm, equation (2), can be used is presented here. The driving rain load in, for example, Gothenburg for the most exposed compass direction is assumed to be 250 liters/year,  $m^2$ . For a pressure-equalized façade with a three-meter high façade (capillary saturated), the runoff rate that can strike a hole in the lower part of the façade is 750 liters/year,m. For a small, downward-sloping ( $h=60$  mm) hole with e.g. a 3 mm diameter and with a dam of 60 mm ( $W$ ) and 30 mm ( $L$ ), ( $\eta_{est} = 0.24$ ) as per equation (8) based on the constants for fibercement board (holes with dam) indicates a spot leakage of 11 liters/year (equivalent to 1.5% of the total runoff rate per meter of façade width), which is significant.

### DISCUSSION AND COMMENTS

The algorithm was based on our own newly made studies and validated against measurement results from our own earlier studies and the studies of others (Olsson & Hagentoft, 2018), and seems to fall relatively well in line.

If precise data is not available, there are extensive measurements supporting the following assumption – a realistic leakage flow for a small or invisible spot leakage at a façade detail is presumed to be up to a few percent of the flow rate per meter of façade width. If there are multiple penetrations or obvious defects in the façade design in combination with the dams, a significantly higher proportion of the runoff rate can leak in. Exactly how the spread of the leakage in the wall appears, needs to be known or investigated, alternatively that the worst case scenario (the whole leakage is placed concentrated and in the most critical point) is applied.

## CONCLUSION

A new calculation algorithm, using equation (2) and (8) was developed as an expression based on runoff rates that strike the width of the hole or dam, plus a factor  $\eta_{est}$ . The constants in equation (8) are based on empirical values. The new knowledge increases the ability to make more accurate calculations of expected leakage flows. However, there must be exact data on factors such as geometry and the dimensions of holes and dams. Furthermore, the constants in Table 1 must be selected with respect to representative of the façade material.

### **ABSTRACT**

This paper reports the results of a genetic optimisation based numerical analysis of a PV-PCM system integrated into a double skin façade. The aim of the research activity was to develop and test the performance of a proposed simulation approach to identify the optimal configuration of the PCM layer, in terms of temperature transition range, and thickness, to assure the best energy performance of the façade system.

Furthermore, because of the intimate relationship between the PCM's features and the ventilated cavity to define the performance of the façade system, the domain of exploration included as variable the airflow rate and ventilation schedule.

The evaluation of the performances of the PV-PCM glazed facade is carried through an on-purpose developed, transient 1-D (with finite difference method) heat transfer model, which integrates a suitable representation of the PCM's system (through the so-called enthalpy method) to include the thermophysical behaviour of such a type of materials. This numerical model is implemented in MATLAB and coupled to TRNSYS in order to calculate the dynamic thermal energy profiles of a fictitious building equipped with such a façade.

The subsequent single objective optimization is based on a genetic algorithm, which looks for the best PCM type and schedule of ventilation in order to optimize the summer thermal energy performance in two case-study cities, Venice and Chicago.

The results show how the proposed genetic optimisation algorithm is capable of identifying the most suitable configuration (that differs in each climate) after a relatively small number of generations (ca. 25). Furthermore, the optimisation approach used in this study leads to the identification of configurations capable of assuring a reduction in the cooling energy need (objective function) in the range 28% to 19 %, when compared to non-optimal configurations, for the two case-study cities.

### **KEYWORDS**

Simulation based optimization, PV-PCM modules, PCM type, Buildings energy savings.

### **INTRODUCTION**

Designers often use dynamic thermal simulation programs to analyse thermal and energy behaviours of a building and to achieve specific targets, e.g. reducing energy consumption, environmental impacts or improving indoor thermal environment (Garber, 2009). Two approaches are commonly considered at the simulation process. The first is the parametric method, which consists of changing the input of one variable at a time to evaluate the effect on the design objectives, while all other variables are kept unchanged. It is often time-consuming and it only results in partial improvement because such an approach cannot fully consider the complex and non-linear interactions of different variables in the simulation (Nguyen et al,

2014). The second approach is the simulation-based optimization and it usually achieved through iterative methods, which construct infinite sequences of progressively better approximations to an “optimal” solution, i.e. a point in the domain of possible values that satisfies an optimality condition (Wetter, 2009). The optimization of Phase change materials (PCMs) technology implementation has been the centre of attention of many researchers due to its exclusive assets for thermal regulation of buildings (Cascone et al. 2018 and Soares et al., 2014). Huang et al. (2014) performed an optimisation of the thermal properties of an envelope in an energy-saving renovation of existing public buildings. They concluded that the performance parameters for the renovation of existing buildings should be determined for each orientation. Ascione et al. (2014) carried out a study on the retrofitting of an office building in which they added a PCM plasterboard to the inner side of its exterior envelope. It was found that a refurbishment, by means of PCM wallboards, seemed to be more appropriate for a semi-arid climate. Ramakrishnan et al. (2016) performed a parametric optimization for the retrofitting of a typical Australian residential building by installing bio-PCM mats on the ceiling. The investigated variables included, the phase transition temperature, the thickness of the PCM layer and the night ventilation rate that guaranteed the best indoor thermal comfort. It was found that depending on the climatic condition, the optimal phase change temperature was about 3–5 °C higher than the average outdoor air temperature. Furthermore, selection of a proper PCM thickness and night ventilation are important to maximise PCM efficiency and minimise costs. Saffari et al. (2017) have investigated optimum PCM melting temperature of a wallboard integrated into a residential building envelope. It has been concluded that the proper selection of PCM enhanced gypsum technology as integrated passive system into the building envelopes. Soares et al. (2014) have concluded that 10% to 62% savings in energy consumption can be achieved utilizing PCM passive technology through building prototypes located in warm temperate climates. However, few of the available modelling studies concerning the implementation of PCM-PV systems make use of simulation-based optimization.

The present simulation based optimization is an extension of previous works (Elarga et al., 2017). Optimizations were automated by coupling between the dynamic building simulation model, the PV-PCM façade module and the optimization engine. A library of 18 PCM types containing the specifications and thermal characteristics of these materials (obtained from Rubitherm) has been integrated in the algorithm and the optimization has run for two cities Venice and Chicago.

## METHODS

The optimization numerical approach consists of two steps: the pre-processing phases and the optimization phases.

- The Pre-processing step included the following elements.

The definition of a fictitious double skin façade that integrates a PV-PCM system where the façade consists of outer clear glass layer ( $g_1$ ) with a thickness of 8 mm and U value of 5.3(W/m<sup>2</sup>K), middle and inner glass layers ( $g_2$  &  $g_3$ ) with a thickness of 4mm and U value of 5.6(W/m<sup>2</sup>K). The applied Cavity ventilation technique is outside to outside and the considered PV-PCM area equals 70m<sup>2</sup> which is 100% from the overall façade area, a future study will address the optimum façade composition percentage, scheme is illustrated in Figure 1a.

- The modelling and the definition of the design conditions of a double glazed skin, ventilated facade office zone area of 80m<sup>2</sup> was carried out with TRNSYS software (Klien et al. 2004).
- Since TRNSYS does not include a defined TYPE to model a glazed PV-PCM facades, it was necessary to separately model the PV-PCM façade in MATLAB. This model is based on a finite difference method scheme (based on a grid with 15 fixed nodes grid as shown in Figure 1b. Each glass layer has been represented by 2 nodes and for the PCM layer a sensitivity analysis has been carried out to estimate the required nodes number i.e. 5 nodes, combined

with the enthalpy method (Voller, 1997) in order to model the non-linear behaviour of the PCM layer. For more details, refer to (Elarga et al., 2016). The governing equations are:

$$C^A = \frac{dH}{dT} = \begin{cases} c_s & T \leq T_{m-\epsilon} \\ \left[ \frac{c_s + c_l}{2} + \frac{L}{2\epsilon} \right] & T_{m+\epsilon} < T < T_{m-\epsilon} \\ c_l & T \geq T_{m+\epsilon} \end{cases} \quad (1)$$

Where:

$\epsilon$ : is an arbitrarily small value representing half the phase change temperature interval.

$c_s$ : Solid specific heat capacity

$c_l$ : Liquid specific heat capacity

$H$ : Enthalpy

$$\sum a_{nb} T_{nb} - (a_p + \rho C^A) T_p^n = a_p \rho C^A T_p^{n-1} - \rho \cdot \frac{v}{\Delta\tau} [H_p^\circ - H_p^{n-1}] \quad (2)$$

Where:

$H_p^\circ$ : Enthalpy node value of the previous time step

$H_p^{n-1}$ : Enthalpy node value of iteration n-1

$T_p$ : Nodal temperature value

$a_{nb}$ : Nodal coefficients of neighbor nodes to control volume P

$\tau$ : Time Step

$T_{nb}$ : Nodal Temperature of neighbour nodes to control volume P

Figure 1: a) Sketch of the glazed PV-PCM façade; b) PV-PCM façade with fixed nodal grid

The integration between the MATLAB model and the TRNSYS model has been carried out using TYPE155 from TRNYS library, which reads external codes executed by MATLAB. The numerical algorithm starts by linking the required weather condition from TYPE16 to both the MATLAB and the zone built in TRNbld TYPE-56. Generally, it is mandatory to link the weather to TYPE-56 in order to operate the simulation model. On the other hand, for each listed inner zone on TYPE-56, there is availability to set its input data and boundary conditions as a user defined option. The PV-PCM 1D numerical code estimates the temperature and transmitted solar radiation for each of the fixed grid nodes including the last node which represents the inner surface layer temperature i.e. node 15. However, the transient interface between TRNSYS and MATLAB models occurs in air node 13. Climatic data of the Test Reference Year (TRY) are then used. For the case study presented in this paper, TMY for Chicago and Venice were adopted. The Optimization step included the following elements:

- Setting the objective function: the objective function is the reduction of required thermal energy for cooling purpose during summer season. However, in the present study, the simulation has run for the entire year to assure PCM thermal storage and transition consistency.
- Selecting and setting independent (design) variables that are part of the domain of search: *i)* PCM layer thickness, *ii)* schedule and starting hour of cavity ventilation, *iii)* PCM type selected from the integrated 18 PCM types library on-purpose developed for this study. The technical data of the PCM list are shown in Table1:

Table 1 List of properties of 18 commercial-grade PCMs (source: Rubitherm GmbH)

Type	temp/ storage cap.	Type	temp/ storage cap.	Type	temp/ storage cap.
PCM-1	21°C /155kJ/Kg	PCM-7	25°C /180kJ/Kg	PCM-13	43°C /250kJ/Kg
PCM-2	21°C / 190kJ/Kg	PCM-8	28°C /250kJ/Kg	PCM-14	46°C /165kJ/Kg
PCM-3	22 °C/190kJ/Kg	PCM-9	31°C /165kJ/Kg	PCM-15	49°C /160kJ/Kg
PCM-4	24°C /160kJ/Kg	PCM-10	33°C /160kJ/Kg	PCM-16	54°C/200kJ/Kg
PCM-5	25 °C/170kJ/Kg	PCM-11	35°C /240kJ/Kg	PCM-17	55°C /170kJ/Kg
PCM-6	25°C /230kJ/Kg	PCM-12	41°C/165kJ/Kg	PCM-18	60 °C/160kJ/Kg

- Selecting an appropriate optimization algorithm and its settings: the adopted optimization algorithm was the mono-objective (MATLAB-GA) and it was set to consider 6 design variables (mass flows of cavity 1 and 2, PCM type, PCM thickness and ventilation schedule in terms of starting hour and duration). The imposed lower and upper boundaries represent the space of exploration of the design variables, as reported in Table 2. The population consists of 20 individuals and the analysis run for 50 generations.

## RESULTS

### Optimization solutions evolution through generations

The mono-objective optimizations ran for 50 generation and succeeded in archiving an improvement for both the considered cities. The convergence trends show some similarities, with an important decrease of thermal load approx. (-16% for Chicago, -40% for Venice) reached around the 5th generation. After this, the optimization further improves the thermal performances by small steps. Finally, the overall decrease in thermal load is 17% for Chicago and about 43% for Venice.

### Analysis of best solution

The best solution for each city is defined by the set of variables that led the minimum required thermal loads. For Venice city, the best individual was: PCM type-16 with melting temperature of 54°C and a storage capacity of 200 kJ/Kg; a PCM thickness of 0.03m; a ventilation duration of 18 hrs. The ventilation schedule has allowed an efficient PCM melting/solidification cycle to be exploited in order to take advantage of higher values of the material heat storage capacity occurred only during this transition. Seasonal cooling thermal loads have reached in this case 2793 kW h. Optimization of PCM dimensions was important to be investigated: the expected weight for this PCM layer in Venice case is about 0.072kg for a PV module area of (2m x 1.5m). On the other hand, in Chicago, the optimum solution was found to be: PCM Type 17 of 55°C melting temperature and 170 kJ/Kg storage capacity; PCM thickness of 5mm. With a ventilation

schedule of 18 hrs, cooling thermal loads have reached 2622 kW h and the layer weight equals 0.012kg for PV module area of (2m x 1.5m).

Table 2: Optimization upper and lower bounds

	cav1 kg/s	cav2 kg/s	PCM type	PCM thick m	Vent. start hr	Vent. duration hrs
Lb	60	60	1	0.001	12:00am	0
Ub	360	360	18	0.1	11:45am	5

Table 3: Best solution of variables

City	cav1 kg/s	cav2 kg/s	PCM type	PCM thick m	Vent. start hr	Vent. duration hrs
Venice	0.2	0.09	16	0.03	9:00am	10
Chicago	0.15	0.10	17	0.005	10:00am	9

## DISCUSSIONS

The influence of the PCM type on the building configuration has been highlighted through a parametric study its only variable is the PCM type. While, the best solutions achieved through the optimization process remains constant (Table 2). In Venice, for the same indoor air operative temperature, seasonal thermal loads of the best configuration,  $2.0 \text{ kW h m}^{-2}$  (PCM-16), are increased up to  $2.6 \text{ kW h m}^{-2}$  by implementing a non-optimized type (PCM- 8), see Figure 3a. Furthermore, the energy savings for the overall season is 28% if the optimized (PCM-16) and non-optimized solution (PCM-8) are compared. In a similar way, the daily cooling energy consumption in Chicago ( $1.5 \text{ kW h m}^{-2}$  in the best case) is increased up to  $1.8 \text{ kW h m}^{-2}$  when a different type is adopted (PCM-6) (Figure 3b) and the seasonal energy savings are 19% when the optimal solution is compared to a non-optimal one.

Figure 2: Daily thermal loads and operative air temperature profile a) Venice, b) Chicago

## CONCLUSIONS

The ventilation schedule, proper selection of the type and layer thickness of PCM are among the fundamental design parameters to achieve an efficient implementation of the latent heat storage technology in buildings. The present mono objective algorithm has focused on minimizing the cooling energy requirements of an office building at Venice and Chicago. The

optimized solutions have been analysed varying only the PCM type through a parametric study. It has been shown that thermal energy savings could be achieved by selecting the proper PCM type. However, designers may also need to evaluate different trade-off settings, taking into consideration multidisciplinary aspects and their interactions in order to identify the best, suitable, solutions. Accordingly, the present optimization algorithm might be increased in comprehensiveness to include more objectives such as the indoor comfort, the PV electrical performance, the cost of the material and the electrical consumption of the ventilation system; façade composition leading to a multi-objective optimisation process, where the complexity lies in the definition of the optimisation function.

## **Stochastic modelling of hygrothermal performance of highly insulated wood framed walls**

Lin Wang<sup>1,\*</sup>, Hua Ge<sup>1</sup>

<sup>1</sup>Concordia University, Montreal, Canada

*\*Corresponding email: forestwang2013@gmail.com*

### **ABSTRACT**

Recent years, the majority of building codes in North America require an energy efficient envelope to improve the building energy efficiency. There are different design strategies to achieve a higher insulation level of the wood framed building envelope, such as increasing the depth of stud cavity to accommodate thicker insulation or adding an exterior insulation while keeping the depth of stud cavity unchanged. However, the highly insulated walls may lead to a higher risk of moisture problems. The deep cavity walls will reduce the temperature of the wood sheathing, which may increase the potential for condensation and mold growth. The exterior insulated walls may result in a low drying capacity of the wood sheathing if the exterior insulation has a low vapour permeance. Although hygrothermal simulations have been widely used to investigate the moisture performance of wood framed walls, the uncertainty of the input parameters may lead to discrepancies between simulation results and real performance of the walls. This paper investigates the hygrothermal performance of highly insulated wood framed walls- deep cavity wall and exterior insulated wall using a stochastic simulation approach. The uncertainties of the input parameters including the material properties, air leakage and rain leakage rates are taken into account in stochastic modelling. The mold growth risks of the walls are evaluated based on the stochastic simulation results.

### **KEYWORDS**

Highly Insulated Wood Framed Wall, Hygrothermal Simulation, Stochastic Modelling

### **INTRODUCTION**

Recent years, the majority of building codes in North America require an energy efficient envelope to improve the building energy efficiency. There are different design strategies to achieve a higher insulation level of wood framed building envelope, such as increasing the depth of the stud cavity to accommodate a thicker insulation or adding an exterior insulation while keeping the depth of stud cavity unchanged. However, the highly insulated walls may lead to a higher risk of moisture problems. Hygrothermal simulations have been widely used to investigate the hygrothermal performance of highly insulated walls (Maref et al., 2010; Arena et al., 2013; Parsons and Lieburn, 2013; Smegal et al., 2013; Craven and Garber-Slaght, 2014; Glass et al., 2015). However, the uncertainties of the input parameters may lead to discrepancies between simulation results and real performance of the walls. Stochastic approach has been applied to investigate the uncertainties of the input parameters and their influence, but the stochastic variables were often limited to material properties and surface transfer coefficients (Salonvaara et al., 2001; Holm and Kunzel, 2002; Zhao et al., 2011; Defraeye et al., 2013). The moisture loads such as air leakage and rain leakage were not taken into account in previous studies.

To investigate the air leakage effect on the hygrothermal performance of highly insulated wood framed walls, field measurements were conducted for three types of walls: 2x6 framed wall with fiber glass insulation, deep cavity walls and exterior insulated walls in Southern

Ontario Canada (Fox, 2014). Hygrothermal models using the mean values of the input parameters have been created and validated with the field measurements (Fox, 2014). In this paper, a stochastic approach is applied to investigate the influence of the uncertainties of input parameters including material properties, air leakage and rain leakage rates. Stochastic simulations are carried out using DELPHIN on four walls tested: 2x6 framed wall with fiberglass insulation, I-joist framed deep cavity wall with cellulose fiber insulation, polyisocyanurate exterior insulated wall and mineral wool exterior insulated wall. The mold growth risks are evaluated under the air leakage and rain leakage based on the stochastic results.

## STOCHASTIC MODELING

### Material properties and boundary conditions

Figure 1 shows the configuration of the walls under investigation. The material properties and their uncertainties are determined from several sources (Kumaran et al., 2003; Mukhopadhyaya et al., 2007). The hygric properties (saturation water content, vapor resistance factor and moisture diffusivity) of the OSB sheathing and insulations are considered as stochastic variables since the moisture content of OSB is used for performance evaluation.

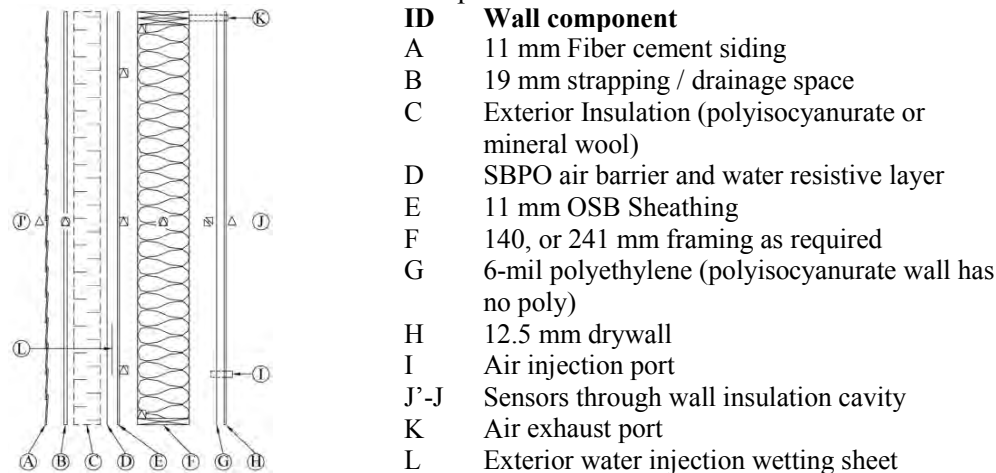

Figure 1 General section view of the highly insulated walls and the wall components (adapted from Fox, 2014)

The surface transfer coefficients are considered as deterministic parameters since these parameters have no significant influence on hygrothermal performance of wood framed walls (Zhao et al., 2011). The rain deposition factor is considered as stochastic variable to reflect the variability of wind-driven rain load on façade, thus, rain leakage rate. The monitored on-site weather data is used to generate the customized weather data files for DELPHIN. The indoor climate file is also generated based on the monitored indoor temperature and relative humidity, which was maintained at 20°C and 40%RH.

### Air leakage and rain leakage

The impact of air leakage is simulated using the air infiltration method (Kunzel, 2012). By using this method, a moisture source that is equivalent to the condensing rate caused by air leakage is deposited on the interior surface of OSB sheathing. The air leakage rate ( $5.0 \pm 3.7 \text{ m}^3/\text{h} \cdot \text{m}^2$  under 75Pa pressure difference for walls with air barrier) is determined based on the air leakage database developed by Emmerich and Persily (2014), and converted to those under 5Pa pressure difference. Details of modeling air leakage can be found in (Wang and Ge, 2017). The rain leakage is simulated by depositing 1% of wind-driven rain on the exterior surface of OSB sheathing. The rain deposition factor is from 0.35 to 1 as prescribed in ASHRAE 160 (2016).

### Generation of stochastic models

The material properties and air leakage rate are assumed to follow normal distribution to obtain the stochastic values, while the rain deposition factor is assumed to follow a uniform distribution. The stochastic models are generated for three scenarios: 1) only material properties are considered as stochastic variables; 2) material properties and air leakage rate are considered as stochastic variables; and 3) material properties and rain deposition factor are considered as stochastic variables. For each scenario, 100 stochastic models are generated using Latin Hypercube Sampling technique. Simulations are performed for five years starting from Oct. 2012.

## STOCHASTIC RESULTS

### Influence of material properties

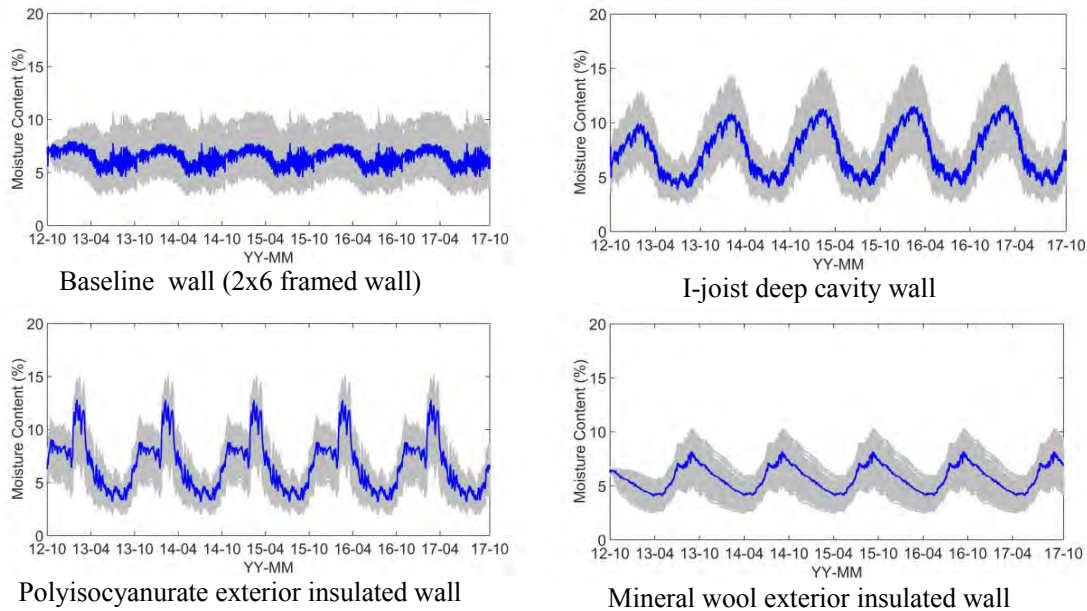

Figure 2 Stochastic results of MC with variation of material properties\_south

Figure 2 shows the stochastic results of OSB moisture content of the south-facing walls with only the material properties are treated as stochastic variables. The blue curve is the base case, which uses the mean values of the input parameters. The grey curves are the stochastic results. The highly insulated walls generally have higher MC level and more significant seasonal variation (increasing in winter and decreasing in summer) than the baseline wall except for mineral wool exterior insulated wall, which has similar MC level to the baseline wall but different seasonal variations (increasing from spring to summer but decreasing starting from fall to winter). The MC of I-joist wall has an upward trend with a highest value of  $12 \pm 4\%$ , which is slightly higher than the polyisocyanurate insulated wall. The highest MC of the baseline wall is  $8 \pm 3\%$ , which is similar to the mineral wool exterior insulated wall. The highest moisture content is below 20% for all the walls.

### Influence of air leakage

There is no condensation caused by air leakage for the exterior insulated walls and the MC profiles of OSB are the same as those presented in Figure 2, therefore, only the results of south facing baseline wall and I-joist wall are presented. It can be observed from Figure 3 that the influence of air leakage is more significant for the baseline wall than for the I-joist wall. The highest MC of baseline wall is  $23 \pm 17\%$ , which is much higher than that of I-joist wall  $17 \pm 8\%$ .

For the baseline wall, 75% of the stochastic cases have highest MC exceeding 20%, but only 35% of stochastic cases of I-joist wall have highest MC exceeding 20%. The I-joist wall performs better than the baseline wall because the cellulose fiber in I-joist wall has a higher moisture storage capacity than fiberglass in the baseline wall, and the cellulose fiber is able to absorb the moisture carried by the air leakage and reduces the amount of moisture reached the OSB sheathing.

Figure 3 Stochastic results of MC with variation of material properties and air leakage rate\_south

### Influence of rain leakage

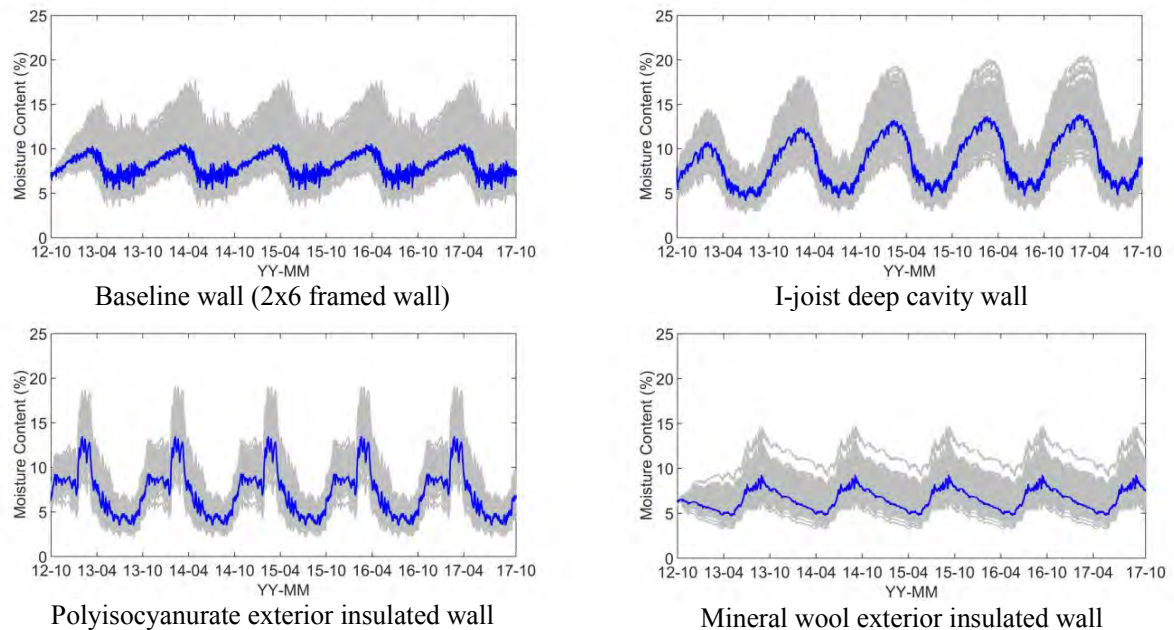

Figure 4 Stochastic results of MC with variation of material properties and rain factor\_south

Since the south orientation receives higher wind-driven rain than the north orientation, the results for south oriented walls are presented in Figure 4. It can be seen that the impact of rain leakage is less significant than air leakage. The highest MC of the baseline wall is  $12 \pm 5\%$ , the base case is lower than average because the rain deposition factor in base case is 0.35, which is lower than the average value. The highest MC of I-joist wall is  $15 \pm 5\%$ , which is slightly higher than the baseline wall. The MC level of polyisocyanurate wall is similar to I-joist wall, but has no upward trend. The mineral wool wall has the lowest MC level, which is  $10 \pm 4\%$ . All the walls under rain leakage scenario have moisture content lower than 20%.

### Mold growth index

Figure 5 shows the mold growth index over 5 years and probability density function of the 5 years' highest mold growth index for the baseline wall and I-joist wall under air leakage scenario. It can be found that the mold growth index for the baseline wall increases gradually from 0 up to  $1.6 \pm 1.6$ . The 5 years' highest mold growth index has 1.5% probability higher than 3, which exceeds the threshold (visually detectable mold growth) prescribed in ASHRAE 160 (2016). For the I-joist wall the highest mold growth index is about 1.2, which indicates there is no risk of detectable mold growth.

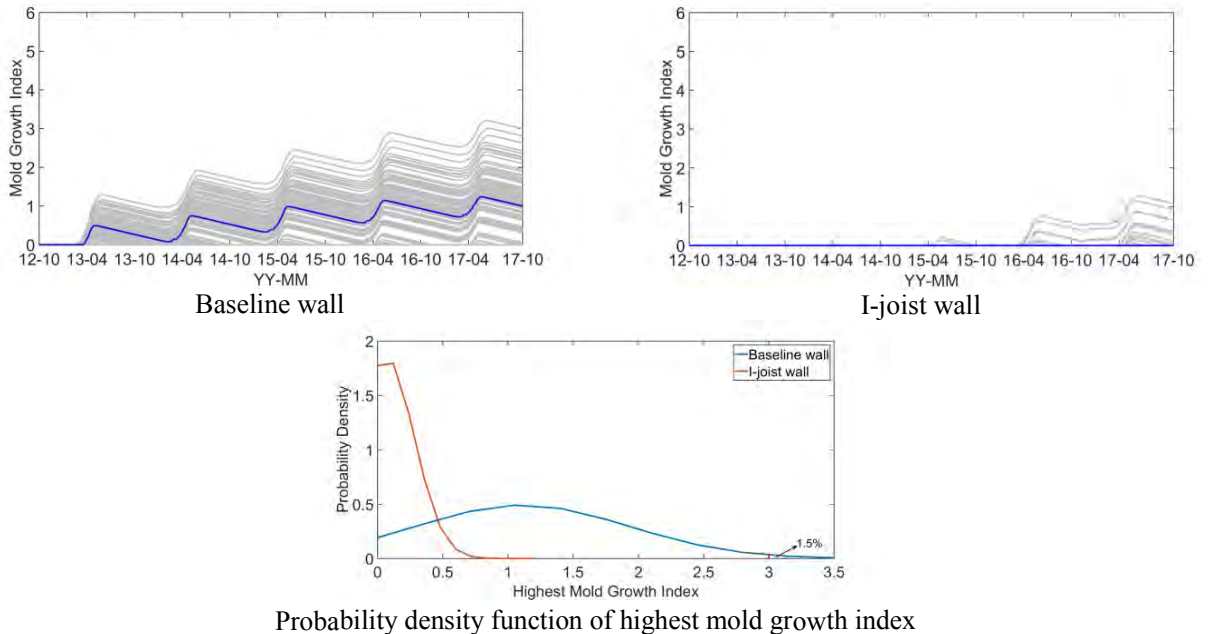

Figure 5 Mold growth index of baseline wall and I-joist wall under air leakage

### CONCLUSION

This paper investigates the hygrothermal performance of highly insulated walls, i.e. I-joist framed deep cavity wall and exterior insulated walls, compared to a conventional 2x6 framed wall with fiberglass insulation (baseline wall) through stochastic approach with consideration of the uncertainties of material properties, air leakage and rain leakage rates. The main findings of this paper are:

- The uncertainties of material properties in I-joist wall and polyisocyanurate exterior insulated wall (low exterior vapour permeance) lead to greater variations of MC of OSB than that in the baseline wall and mineral wool exterior insulated wall (high exterior vapour permeance). Without air leakage or rain leakage, the uncertainty of material properties does not lead to mould growth risk in the walls investigated.
- The air leakage has no influence on the exterior insulated walls using air infiltration simulation method. The MC of OSB in the baseline wall is more sensitive to air leakage than that in the I-joist wall with cellulose fiber. The mold growth risk of the baseline wall is higher than the I-joist wall under air leakage.
- Under climatic condition of South Ontario, the influence of rain leakage is less significant than air leakage for the baseline wall and I-joist wall, while the influence of rain leakage is more significant than air leakage for the exterior insulated walls. The MC of OSB in polyisocyanurate wall has higher uncertainty than that in mineral wool wall under simulated rain leakage, while all the walls studied do not have mold growth risks under simulated rain leakage.

### ABSTRACT

Radon (Rn) stacks, with or without an inline Rn fan, are designed to extract damp soil gas from under basement concrete slabs of homes. Along with Rn gas, moisture vapor also travels up through the Rn stacks. The amount of moisture in the vent pipes can, depending on the circumstances, be significant. In extremely cold weather, this moisture can condense, freeze, form ice and clog the vent pipe at the exit point. In this study, COMSOL Multiphysics was used to examine the amount of insulation required to avoid ice build-up in the Rn vent pipe located in unheated attic space under different outdoor weather conditions. The effects of different parameters on the air temperature in a Rn stack were studied; specifically, (i) air velocities in the vent pipe, (ii) thermal insulations, (iii) different lengths of vent pipe in unheated attic space. The boundary conditions for the model, including the relative humidity, inlet air velocity, and the inlet air temperature in the stack, as well as the temperature in the attic and outdoors were determined based on the data from the Canadian Centre for Housing Technology. Based on the results obtained from numerical simulations, recommendations for insulation to avoid freezing of Rn stack at the exit were proposed. Thereafter, a Rn mitigation system was designed and installed in a home in Ottawa, based on the recommendations. Data was collected from the in-situ experiment during the winter of 2017. This stack was then modeled using the hypothesis used in the predictive simulations, and the model was benchmarked against the data collected from the experiment. The benchmarking results indicated that no freezing was observed using the recommended level of insulation on the Rn vent pipe in an unheated attic and above roof.

### KEYWORDS

Radon Stacks, COMSOL Multiphysics, Numerical Simulations, In-situ Measurements

### INTRODUCTION

Radon (Rn, atomic weight 222) is a naturally occurring radioactive colorless and odorless gas, which can be found in varying amounts in all types of soil and bedrock. Recent research by Health Canada estimates that 16 per cent of lung cancer deaths among Canadians are attributable to indoor Rn exposure (HC, 2010; HC 2014). Since December 2014, provisions in the British Columbia Building Code have required the installation of a full size passive vent pipe (i.e. passive stack) that extends through the building and terminates outside, in high Rn risk areas. A schematic of such a system is depicted in Figure 1.

Seasonal variation of external and indoor environmental conditions (e.g. temperature, RH, air pressure, wind speed and wind direction) may significantly influence the effectiveness of a passive stack. Previous experimental data from the Canadian Centre for Housing Technology demonstrated that the Relative Humidity (RH) of soil gas within the Rn stacks was close to 100%. The amount of moisture being extracted from under a home can be very significant. At lower temperatures air loses its capacity to retain moisture. In cold climates, condensation within an uninsulated vent pipe is inevitable. However, condensation within the pipe can freeze if the temperature inside the stack remains consistently below the freezing point.

Hence, the clogging of Rn stacks due to the formation of ice in the vent pipe can occur in extreme cold climates.

This paper provides a description of numerical simulations using a COMSOL Multiphysics software platform to predict the temperatures and relative humidity of air along the length of a Polyvinyl chloride (PVC) vertical stack used to exhaust Rn gas from beneath a typical Canadian home with an attic, a main floor, and a basement. Different scenarios for insulation thicknesses, insulation material, in-stack air speed, vent lengths in attic and outdoor temperatures were investigated. Based on the numerical results, a suggestion for required insulation was made for an in-situ test to avoid freezing. The results from tests then were compared with the results from the simulations.

## METHODS

A 2D axis-symmetric COMSOL Multiphysics model was employed to examine the temperature profile of soil gas inside a PVC pipe having an outer diameter of 11.43 cm and inner diameter of 10.16 cm (4 inches). Soil gas at 18 °C with the RH of 50%-100% enters the pipe and rises vertically from the basement through the building, into the unheated attic and thereafter is expelled to the exterior atmosphere beyond the roof line. The building other than the attic is generally conditioned and the temperature maintains approximately at 20 °C, which does not appear to affect the temperature in the stack significantly. Therefore, this portion of the stack is not considered in this study. The exposed length of the pipe to outdoor temperature was 30 cm. Different lengths (1 m, 1.5 m, 2 m and 2.7 m) of the part in the attic were studied. Ambient exterior temperatures of -25 °C and -30 °C with the corresponding attic temperatures of -13 °C and -17 °C were considered. Two insulation materials with the thermal conductivities of 0.02 W/(m•K) and 0.04 W/(m•K) were used in the simulations to achieve R7 and R14 insulation. On the outer wall of the pipe located in the attic, natural convection heat transfer coefficient of  $h = 10$  [W/(m<sup>2</sup>•K)] was considered; whereas, the convective heat transfer coefficients on the outer surface of the pipe above the roof were calculated using an average wind speed of 21.5 km/h (6 m/s) and an insulation thickness of 2.54 cm (1 inch), resulting in a forced convection heat transfer coefficient of 30.9 [W/(m<sup>2</sup>•K)] based on the equations from Incropera et al. (2011).

There was also a need to account for the condensation that occurs on the inner surface of the pipe. To simplify the problem, condensation was modelled as a surface heat source at the wall. Both the exit temperature and the condensation amount were unknown but correlated. Hence, an iterative approach was taken to determine both these values. For the first iteration, the heat release from the heat source was assumed to be zero and a simulation was conducted. Based on the outlet temperature, the amount of heat source was calculated as the input for the second iteration. This procedure was continued until the values from two consecutive simulations converged; this usually occurred after three to four iterations.

In order To find the amount of water vapour at each temperature, there was first a need to calculate the saturation vapour pressure of water in air. Monteith and Unsworth (2008) provided Tetens' correlation for temperatures above 0 °C and Murray (1967) provided Tetens' equation for temperatures below 0 °C:

$$P = 0.61078 \exp\left(\frac{17.27T}{T+237.3}\right) \quad T > 0 \text{ } ^\circ\text{C} \quad (1)$$

$$P = 0.61078 \exp\left(\frac{21.875T}{T+265.5}\right) \quad T < 0 \text{ } ^\circ\text{C} \quad (2)$$

**Figure 1. The schematic of system modeled (Left), Temperature sensor in the stack in the attic (Middle), and insulation around the stack in the attic (right).**

Where  $T$  is the temperature in degrees Celsius.  $P$  is the saturation pressure in kilopascals (kPa). The humidity ratio,  $\omega$ , is defined as the ratio of the mass of the water vapor,  $m_v$ , to the mass of dry air,  $m_a$ , and can be calculated knowing the air pressure and saturation:

$$\omega = 0.622 \frac{P_v}{P - P_v} \quad (3)$$

Hence, given the average air temperature at each cross section, the saturation pressure and water vapor pressure could be calculated in relation to the RH and humidity ratio. Calculating the mass flow rate of the inlet air, the water vapor content at the inlet and outlet of the pipe could then be determined. The difference in the water vapor content between the inlet and the outlet of the pipe determined the amount of condensation. Using the latent heat of condensation, the heat source term could be established. Figure 2 shows the Control Volume (CV) that was analyzed.

**Figure 2. Thermodynamics analysis of the control volume**

This analysis can be written as:

$$\dot{Q}_{CV} + \dot{m}_a [(h_{a,1} - h_{a,2}) + \omega_1 h_{g,1} + (\omega_2 - \omega_1) h_w - \omega_2 h_{g,2}] = 0 \quad (4)$$

Where  $\dot{Q}_{CV}$  accounts for heat transfer to the surrounding cold environment;  $\dot{m}_a (h_{a,1} - h_{a,2})$  represents the sensible heat carried by the air, which can be written as  $C_p (T_1 - T_2)$ ;  $\dot{m}_a (\omega_2 - \omega_1) h_w$  accounts for the sensible heat released by the condensed water; and  $\dot{m}_a (\omega_1 h_{g,1} - \omega_2 h_{g,2})$  is the amount of water that condensed. The first two terms in the bracket were calculated in the simulations, whereas the last two terms were calculated after the aforementioned source heat term was established. An excel sheet was created to input the corresponding heat being transferred to the surrounding for each outlet condition.

## RESULTS

**Numerical simulations** — Extensive simulations were conducted to determine the insulation requirement to minimize the risk of stack ice clogging. Two RH levels in the soil gas were

considered, 100% and 50%. It was found that the worst case scenario when freezing is the most likely to occur near the pipe outlet is the case with 50% RH at the inlet. When the RH of the air at the inlet is 50%, condensation is delayed until the air reaches a temperature where the air becomes saturated with moist. The air velocities at the pipe inlet were assumed to be 0.05 m/s, 0.1 m/s and 0.15 m/s. It has been observed that the heat source term decreases as the velocity of the soil gas reduces, and the risk for freezing will thus increase in these instances. Using insulating materials with greater thermal resistances around vent pipe can reduce the overall diameter of the pipe and consequently reduce the overall area exposed to cold temperature, which is preferred.

In order to better determine a threshold for the ice accretion at the end of the pipe, the average temperature at the end cross section was calculated. If the average temperature is above 0 °C, it can be assumed that ice accretion or blockage at the end of the pipe is unlikely to occur. The average air temperatures at the end of the pipe for each case were calculated when outdoor temperature was -25 °C, and the results are shown in Figure 3 (a) and (b), corresponding to  $k = 0.04 \text{ W/(m}\cdot\text{K)}$  and  $k = 0.02 \text{ W/(m}\cdot\text{K)}$  respectively. It can be seen when R7 insulation is used along the entire length of pipe, the average temperature at the end of the pipe can reach below the freezing point when the inlet velocity is 0.05 m/s regardless of the insulation material. As mentioned before, this is the worst case scenario where the vent stack air velocity is minimal (0.05 m/s) and the RH is only 50%; hence, the minimum amount of heat from condensation is added to the control volume. The results also showed that using R14 insulation all along the entire length of pipe is more than sufficient to avoid freezing, however it is also more costly.

Figure 4 depicts the temperature contours along the pipe for the case when R7 was applied to the outer perimeter of the stack in the unheated attic and R14 was used around stack above the roof. We used  $k = 0.02 \text{ W/(m}\cdot\text{K)}$ ,  $V=0.05 \text{ m/s}$ , inlet RH= 50% and the length in attic = 2 m in our simulation and the outdoor temperature was -25 °C. It can be seen that, with the R7/R14 insulation combination, the core of the air flow is still warm at the pipe end and freezing is unlikely to occur. Hence, it is recommended that R7 insulation be used along the pipe section located in the attic and R14 insulation for that section exposed to outdoor conditions.

Validation of simulation using experimental results — The recommendations for Rn vent stacks insulation based on simulation results have been taken by a field study conducted between December 2017 and February 2018 in the National Capital Region of Canada. An outdoor temperature of -26 °C occurred on 28 December, 2017, which was chosen to benchmark the simulation results. The velocity of the vent stack was measured as 0.15 m/s and the RH was 100% at the pipe inlet. The 150 cm of the stack was located in the attic and having R7 insulation. 40 cm of pipe, insulated with R14 insulation, was above the roof line. The air temperature was measured at 86 cm from the pipe inlet and was used to benchmark the simulation. The average temperature derived from the simulation was 13.4 °C, and an average temperature of 13.25 °C was measured from the test. These results confirm that the method used to model the condensation as the surface heat source was rational. The temperature contours for the simulation are shown in Figure 5. It can be seen that the soil gas remains warmer than 0 °C even at the end of the pipe using the suggested insulation. The in-situ observations also confirmed that no freezing developed at the pipe exit.

**Figure 3. Average temperature at the outlet cross section of the pipe for R7 and (a)  $k=0.04$  W/(m.K) insulation, (b)  $k=0.02$  W/(m.K) insulation with an outdoor temperature of  $-25$  °C**

**Figure 4. Temperature contours for the combined R7/R14 insulation using  $K=0.02$  W/(m.K),  $V=0.05$  m/s, inlet RH= 50% and the length in attic= 2 m (a) along the pipe (b) at the end of the pipe**

## DISCUSSIONS

Using the COMSOL Multiphysics package, a study was undertaken to determine the level of insulation required to avoid freezing and ice clogging of Rn stacks in Canadian winters. Different air velocities in the pipe, lengths of vent pipe, insulation level and thickness, and outdoor conditions were investigated. The following outcomes were derived from the simulations:

- Soil gas flow in the stack was found to be vulnerable to freezing; the lower the air velocity is in the pipe, the more likely freezing occurs.
- Using insulation materials with lower thermal conductivity for the same thermal resistance can reduce the surface area exposed to the cold temperature and thereby reduce the freezing risk.
- Minimizing the length of pipe located in the attic and outdoors can reduce the exposure to low temperatures and hence reduce the freezing risk.
- A Rn stack was installed in a Canadian home by applying R7 insulation around the pipe in the attic and R14 insulation around pipe above roof line, as suggested by the simulation results. The combined insulation appeared to avoid freezing of the Rn stack vent effectively, even when the outdoor temperature dropped to  $-26$  °C.

**Figure 5. Temperature contours for the combined R7/R14 insulation using  $K=0.02$  W/(m.K),  $V=0.15$  m/s, inlet RH= 100% and the pipe length in attic= 1.5 m (a) along the pipe (b) at the end of the pipe**

## CONCLUSIONS

This study presents a numerical model to determine the required insulation level around Rn stacks in unheated attic space and above roof, in order to minimize the risk of ice blockage at the exit of the stack. Simulation results provided guidance on insulating a stack in a field study home in cold climate. The soil gas temperature measured from one point in the pipe was compared with the results from simulation. The difference is only 1.2%. This demonstrates the model benchmarking is successful. These results confirm the validity of the assumptions made for the numerical model as well as the recommendations for the insulation level. No freezing in the Rn stack occurred during the coldest days of the test period using the R7/R14 insulation combination. Future field testing from other regions of Canada will demonstrate further whether the combined R7/R14 insulation suggested by simulation work described in this paper is sufficient for Rn stacks to avoid ice blockage at the exit, in cold Canadian winter.

### **ABSTRACT**

This paper presents a workflow to support the decision making for building retrofit and building systems update at urban scale. The workflow includes *i)* a method to extract information from a geographical information system including information on building characteristics, building systems and building typology, *ii)* a method to evaluate the current and future energy demand of buildings using a dynamic building simulation tool, and *iii)* an updated version of the energy hub approach to evaluate best performing options in terms of energy systems update. The developed method is applied to the city of Zurich to evaluate the optimal energy system update for all existing buildings within the city. Modelling results include best performing options in terms of CO<sub>2</sub> emissions, renewable energy share, or energy efficiency while minimizing resulting costs for possible system and retrofitting solutions.

### **KEYWORDS**

Urban energy, energy system optimization, retrofitting of buildings, energy hub.

### **INTRODUCTION**

Buildings and urban energy systems have an important potential to reduce energy consumption and greenhouse gas emissions to meet future energy strategy targets. A combination of measures are usually required to achieve the envisaged targets, which include replacing current fossil fuel based heating systems with more sustainable solutions, to integrate decentralized energy systems, and retrofitting the existing building envelopes. To support the decision making process, optimization tools are required, which allow for a multi-criteria assessment of an optimal combination of measures within urban energy systems. Finding suitable solutions for already existing neighbourhoods depends thereby strongly on the buildings and their installed systems. Questions such as which buildings need to be updated first in order to meet the targets as soon as possible, or which measures are more important compared to others play thereby a critical role.

This paper presents a workflow which builds on simulation and optimization techniques to support the decision making for building retrofit and building systems update at urban scale. Thereby information which is retrieved from Geographic Information Systems (GIS) about the current situation of the buildings (such as layout, U-values, occupancy, etc.) and their systems is integrated in the model. The method can be used to evaluate best performing options in terms of CO<sub>2</sub> emissions, renewable energy share, or energy efficiency while minimizing resulting costs for possible system and retrofitting solutions. In this paper the developed method is applied to 12802 residential buildings of the city of Zurich.

## METHODS

The workflow which was developed, shall support the decision making for identifying optimal building retrofitting measures at urban scale. It includes: *i)* A method to extract geo-spatial information, including information on building characteristics and building energy systems, based on building and census data, *ii)* A method to evaluate current and future energy demands of buildings using an automated process developed in Matlab to deploy EnergyPlus at urban scale, that includes a connection to geo-spatial information and facilitates the computation of energy demand profiles for different scenarios at individual building level, and *iii)* an optimization model to evaluate best performing options in terms of retrofitting and energy system updates, based on multi-criteria decision making. As a result, input information on existing buildings, including their system state, is integrated into the modelling methodology. The tool allows for the evaluation of individual building level solutions, and is additionally able to take renewable energy potentials and boundary conditions of the neighborhood into account.

### Geo-spatial information

To describe the current situation of buildings within a neighbourhood GIS based building information is required such as building layout, building characteristics and environmental information. Relevant input information is collected from different sources, such as census data from Switzerland (BFS, 2013), 3D building information (Swisstopo, 2016), weather information (Meteotest, 2016), etc. This information is further processed in a database structure and connected to the different models presented below.

### Buildings energy demand modelling

#### *Modelling of current energy demand of buildings*

To represent the current situation in terms of energy demand pertaining to heating, cooling, electricity and domestic hot water the bottom up modelling tool CESAR is deployed (Wang et al., 2018). The tool allows for calculation of hourly energy demand profiles for multiple buildings within a neighbourhood. Thereby geo-spatial information pertaining to building floorplans, their height (2.5D shape) and a set of additional input information to derive relevant building characteristics are used as model input. The CESAR tool utilizes the building simulation engine EnergyPlus (U.S. Department of Energy, 2015) to compute for each building heating, cooling and electricity loads separately. Neighbouring buildings are considered as shading objects.

#### *Modelling of building envelope retrofitting potential*

The model can be used to evaluate different envelope retrofitting options. In case of a retrofit of the building envelope, additional insulation is added to the original constructions until required U-Values for retrofitted constructions according to SIA 380/1 are met (SIA, 2009). Additional envelope retrofitting options include replacement of windows, partial retrofitting of individual constructions, such as roofs or facades, and whole building retrofitting solutions which combines all the different measures. The resulting retrofit constructions are structured in a database similar to the non-retrofitted constructions and linked with the model.

#### *Modelling of solar potential*

For calculating the building integrated renewable potential pertaining to the utilization of the solar resource also the tool EnergyPlus is used. The variation of different roof inclinations, and orientations was evaluated. Thereby values between 0 and 60 degrees, with 5 degrees step

for roof inclinations, while the roof orientation could take discrete values from East (90 degrees) to South (270 degrees) with a step of 45 degrees. In total 65 solar simulations were performed to calculate the annual solar profiles for the selected combinations of roof slopes and orientations stored in a solar database. For each building the total roof area was calculated and based on the building orientation and slope of the roof a respective solar profile was assigned to the building.

### ***Simulation results***

Results are computed for individual buildings at an hourly resolution, including actual and future demand for heating, domestic hot water, cooling and electricity, as well as solar potential on roof surfaces. Additionally, annual primary energy consumption and GHG emissions for operation of the buildings, as well as operational energy, embodied energy and economical aspects of retrofit measures are analyzed in detail.

### **Optimization model for optimal retrofitting option**

For selecting the optimal retrofitting strategy for each building an optimization tool based on the energy hub approach is utilized. The model takes a combination of both building envelope retrofitting options and energy supply systems to provide electricity, space heating and DHW into account. The approach is based on a Mixed Integer Linear Programming (MILP) optimization framework (Wu et al., 2017, Mavromatidis et al., 2014). To evaluate multiple objectives the epsilon constraint method is deployed. In this study, the two objective functions for annualized costs and life cycle environmental impacts are considered. The generated energy demand profiles together with the solar potential profiles of individual buildings are taken as input to the model. The demand profiles are further processed to extract typical days, which are then used for the optimizations. A representation of the current system based on the above mentioned database (BFS, 2013) is included in the model. Additionally the following system options are implemented into the optimization framework which pertain to: air source heat-pumps (ASHP), ground source heat-pumps (GSHP), biomass boilers, photovoltaic panels (PV), solar thermal collectors (ST), oil boilers and gas boilers as conversion technologies and hot water thermal storage tanks and batteries as storage technologies. The building envelope retrofitting scenario is implemented as an additional decision variable within the optimization framework.

### **CASE STUDY**

The city of Zurich in Switzerland is taken as a case study. The city has about 400 000 inhabitants, who live in around 35000 residential buildings. Zürich has a heating dominated climate, with an average outside temperature of 9.5°C. From about 20 800 buildings were input information was available, about 12800 buildings were selected for the analysis. Characteristics such as building type, existing building energy carrier, age of building, size of ground floor and building height of the sample set is summarized in Figure 1. As can be seen from this figure, the majority of the buildings are multi-family houses, equipped with a gas or oil heating system and built before 1960.

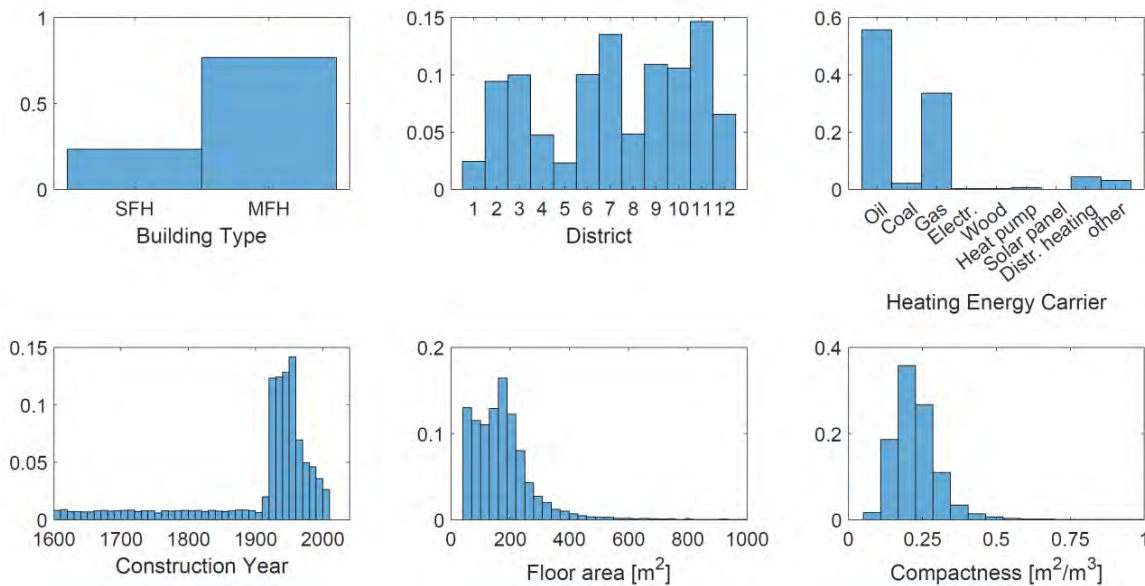

Figure 1. Distribution of building characteristics of all 20863 residential buildings.

## RESULTS AND DISCUSSION

Results were retrieved for the 12802 selected buildings. In a first step the current energy demand of the sample set was calculated with the CESAR tool, as described above. Energy demand of buildings pertain to space heating, domestic hot water and electricity demand. Results are computed for each individual building, Figure 2 shows a histogram of mean annual space heating demand distribution of all buildings. The space heating demand varies between 30 to 280 kWh.m<sup>-2</sup>a<sup>-1</sup>. In a next step, different envelope retrofitting strategies are calculated. Retrofit options considered vary between no retrofit, roof, wall, window retrofit and combinations between them. Additionally, the building integrated maximum solar potential is calculated. Results of the current building characteristics, current energy demand, and potential options for retrofitting as well as the solar potential act as input information for the optimization framework. In a final step, the optimization tool is deployed to evaluate the most cost and CO<sub>2</sub> friendly retrofitting solution. Thereby building envelope retrofitting options together with building system solutions are taken into account. Results are given as pareto optimal solutions for each individual building. Pareto optimal solutions are the set of solutions for which no criterion can be improved without making another criterion worse off. Figure 3 shows Pareto fronts of 3 different buildings in Zurich.

Results of the 3 different buildings show that the shape of the Pareto curve and the selection of retrofitting interventions can vary considerable between buildings. However, results also show that the best performing option in terms of CO<sub>2</sub> is usually a biomass based heating system, which is due to very low CO<sub>2</sub> emissions of biomass. Results also show that the set of Pareto-optimal transformation strategies are depend on the original heating system, while age and size of the building influence the achievable GHG emissions and related costs. The retrofitting of the building envelope option varies considerable between the different buildings. While for some buildings no retrofitting of the envelope was selected, buildings like the one shown in Figure 3a have a wall and window retrofit, and only a few a full retrofitting of the envelope. Figure 4 shows the distribution of optimal solutions for system selection (a) and retrofitting (b) for all Pareto points. As can be seen from these figures the majority of optimal solutions are distributed between no retrofitting, which are clearly the cost

optimal solutions and partly retrofitting of single elements such as roof or wall insulation. A full retrofit of windows, walls roofs and floor construction is only selected for a minority of buildings. This is mainly due to very high costs for retrofitting in Switzerland. At the system side, it can be seen that for the majority of solutions an ASHP is selected, followed by biomass boilers and GSHP.

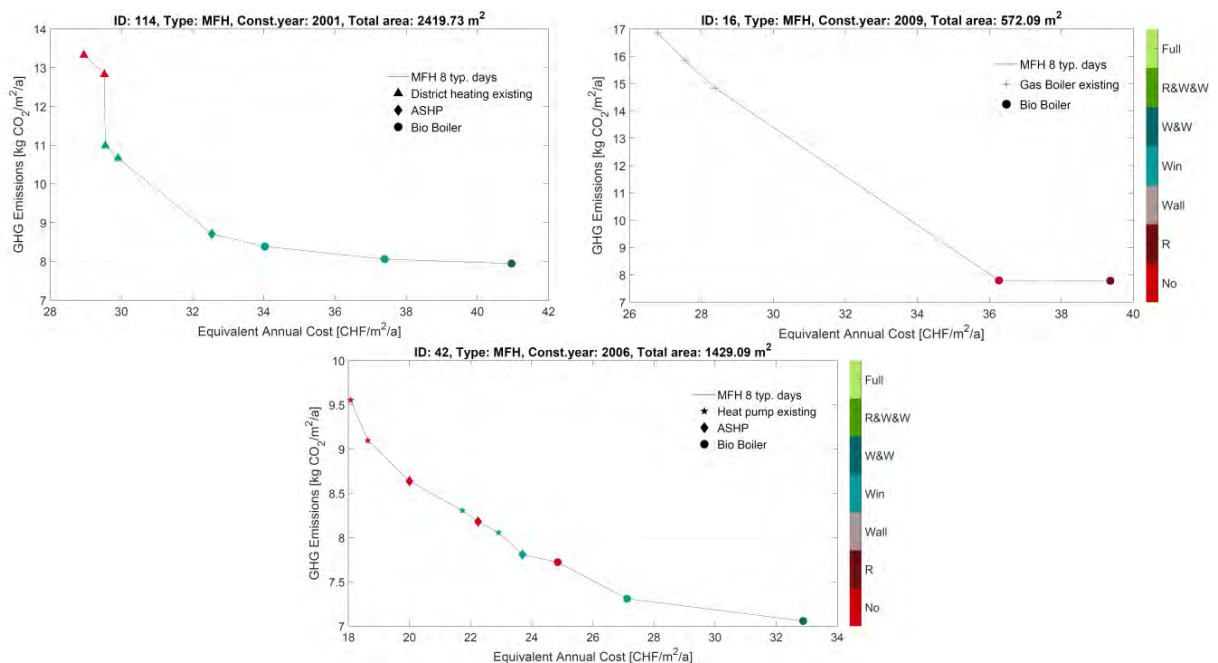

Figure 3. Example of Pareto fronts

Figure 4. Retrofit and system selection shares of the sample set of buildings

## CONCLUSIONS

This paper presents a workflow for evaluating sustainable retrofitting options for buildings at an urban scale. The workflow consists of a combination of a GIS based data collection which is connected to different tools to identify building energy consumption, retrofitting options and finally to evaluate the CO<sub>2</sub> and cost optimal solutions for buildings within a city. The approach can be easily applied to residential buildings in Switzerland. As a case study, 12802 buildings of the city of Zurich are selected. Results of the case study show that solutions vary considerable between the buildings. As a conclusion, it can be summarized that the optimal transformation strategies depend on the original heating system, while age and size of the building influence the achievable GHG emissions and related costs.

### ABSTRACT

In order to curtail energy use by the building sector, consideration of how a "sustainable" building is constructed is paramount, in many respects, to how efficiently it operates over its lifetime. A typical building must be in use for decades before the energy expended in its daily operations surpasses the energy embodied within its initial construction, as a result of the materials used. More vitally: every building has specific vulnerabilities, particularly to hazards (e.g., earthquakes, wind, flooding) whose effects on sustainability are not explicitly considered alongside other aspects of sustainability in the design process – despite the significant environmental impact of damage and repairs after a disaster. Unfortunately, the joint consideration of resilience and sustainability in design is far from trivial, requiring various interdisciplinary perspectives involved in the delivery of building projects. These perspectives each contribute the models and data necessary for integrated evaluation, leading to the notorious challenges of BIM and data interoperability. In response, this paper presents a new end-to-end workflow for life-cycle assessment (LCA) of buildings that captures the dependencies between multi-hazard resilience and sustainability, across multiple dimensions of environmental impact. An illustrative example reveals how consideration of hazards during design and material selection influence embodied energy, ultimately revealing design choices that best achieve joint resiliency and sustainability.

### KEYWORDS

Life Cycle Analysis, Natural Hazards, Resilience, Sustainability, Embodied Energy

### INTRODUCTION

Buildings account for 40% of annual CO<sub>2</sub> emissions in the United States, placing the building industry at the forefront of the growing international mandate to better steward our environment (Dixit et al., 2012). This has prompted the mainstreaming of sustainability assessments into project workflows, with efforts focused on optimizing operating energy. However, a typical building must be in use for decades before its operating energy surpasses the energy embodied in the extraction, processing, manufacture, delivery, repair and disposal of its constitutive materials (Sartori and Hestnes, 2007; Dixit et al., 2012). Additionally, energy expended in material and system repairs due to damage by natural hazards is often not explicitly considered in the design process. However, this evaluation is critical when one recognizes that each building's hazard vulnerabilities are driven by the unique choices of material assemblies that form the building's systems, components, and finishes. This demands an integrated approach to Life Cycle Assessment (LCA) wherein the vulnerabilities that drive hazard resilience can be included in a holistic environmental impact assessment.

Historically, the numerous disciplines involved in building projects have partitioned the analyses central to delivering such integrated LCAs, with each developing unique abstractions of the structure to simplify modeling requirements and fulfill design objectives. This limits

interoperability between modeling environments and discipline-specific data sources, creating barriers in the joint evaluation of resilience and sustainability. However, by leveraging semantic data perspectives from computer science, one is able to efficiently bridge data structures and maintain the vocabularies normative to each domain's tools so they can interoperate. This research adopts such an approach, developing an automated framework for integrated LCAs. This framework is capable of capturing the dependencies between multi-hazard resilience and sustainability, across multiple dimensions of environmental impact, while maintaining the native modeling environments common to building practice. This paper presents a schematic representation of the resulting end-to-end workflow, including methodologies used to conduct its various analyses. An illustrative example building is presented to demonstrate the initial joint evaluation of resilience and sustainability, including the assessment of design alternatives.

Figure 1. Schematic representation of proposed integrated life cycle analysis framework.

## METHODOLOGY

The proposed integrated LCA (depicted in Figure 1) adopts a modularized approach to enable “best of breed” tools to be incorporated as they become available. The sequencing of operations in the LCA framework is now introduced for each of the integrated modules. While the framework conducts multi-hazard evaluations, specific focus is placed upon seismic hazards in the following description and subsequent example for brevity.

1. Primary user interfacing adopts the commercial software Revit®, due to its popularity in practice. The Revit model and building location are circulated into the **Revit Auditor**, which characterizes relevant geometries and creates an inventory of components using ontology-based data patterns (Ferguson et al., 2016a). This provides a queryable semantic “knowledge graph” of building information enabling the extraction of features and data required by subsequent modules.
2. The building location and dynamic properties are retrieved by the **Hazard Module**, which identifies the intensities for each natural hazard at different return periods, (e.g. 500-year event). For seismic hazards, spectral acceleration (e.g., 0.5 g) is used as the intensity measure to construct a hazard curve describing the degree of exposure (return period) at each intensity level (USGS, 2018). In this study, intensity selection effectively partitions the hazard curve into eight intervals.
3. These intensity measures and the corresponding building properties (e.g., floor to floor height and natural period) are utilized in the **Response Module** to calculate the building’s engineering demand parameters (EDPs) over the building’s intended service life (e.g., 50

years). For seismic hazards, EDPs (such as drift ratios and accelerations) are determined through a linear-elastic finite element analysis and FEMA (Federal Emergency Management Agency) P-58's Simplified Analysis Procedure (ATC, 2012).

4. The resulting EDPs are fed to the **Damage Module** to evaluate the vulnerabilities of building components due to hazard exposure. By explicitly representing each building assembly, those most driving resilience or sustainability performance can be identified, providing designers with insight about the broader impact of their design decisions. This is made possible through an assembly-based vulnerability approach (Porter et al., 2001), in which each assembly is comprised of a group of building components that share common vulnerability and cost characteristics. Vulnerabilities are defined using fragility curves, obtained from FEMA's Performance Assessment Calculation Tool (PACT), defined as the probability that an EDP will exceed a threshold defining acceptable structural performance. This provides a detailed damage assessment for each assembly. A parallel physics-based Deterioration Module (see Figure 1) considers service-induced wear, but is beyond the scope of this paper.
5. The **Loss Module** correlates these damages due to hazard exposure to a set of consequences (emphasis herein is on monetary costs, though downtime can also be determined) for various service lives. For this study, the direct seismic losses are evaluated considering the probability of incurring damage and relating this to the corresponding repair cost for each assembly (ATC, 2012; Cardone and Perrone, 2015). For consistency, initial cost of construction is based upon total replacement cost.
6. The embodied energy in the building's initial construction (EE:IC) and its operating energy are evaluated within the **Environmental Impact Module**. Operating energy is calculated through a lumped capacitance model which evaluates the heat flux using material and spatial properties (Ferguson et al., 2016b). It should be noted that plug loads are not included in operating energy calculations, though these can be easily accommodated in the future. Site-specific assessment of the building's operating energy is informed by climatology data from EnergyPlus (DOE, 2018). To determine the EE:IC, material volumes are calculated using the Revit Auditor and multiplied by each material's respective cradle-to-gate embodied energy and density (Hammond and Jones, 2011). Energy embodied in the repair materials (EE:RM) necessitated by hazard exposure is calculated by expressing the monetary cost of each assembly's repair as a percentage of the initial cost and multiplying that by the EE:IC of the assembly for a cradle-to-gate estimate.
7. These results are aggregated by the **Post-Processing Module**, which outputs embodied and operating energy as well as monetary losses by assembly as standard visualizations for different service lives. These assembly-based visualizations provide greater insight into the design choices that are most likely to improve the building's resilience and sustainability over different service lives.

## ILLUSTRATIVE EXAMPLE

The integrated LCA framework is next applied to a building in Los Angeles employing a two-story reinforced concrete (RC) frame with concrete floor and roof slabs. The building consists of a regular floor plan, measuring 7 by 9 meters, with top-of-slab elevations at of 4.15 and 7.65 meters. The structural system of the building is a special moment resisting frame, as required for regions of high seismicity. The envelope consists of infill concrete masonry units (CMU) with a brick veneer. There are two interior partitions at each floor: gypsum wall board on metal stud. The following section presents the evaluation of this Initial Design from the joint perspective of sustainability and resilience using the proposed end-to-end LCA workflow. All results are described by assembly to reveal those which may warrant design revisions. To

further demonstrate how such assembly-based insights can be used, two design alternatives are respectively evaluated: increasing the size of the columns in the special moment frame (termed Frame Upgrade) and selecting an Alternate Envelope using precast RC panels.

Figure 2. Annotated visualization of embodied energy (sequence 1), total energy (sequence 2) and total monetary costs (sequence 3), at inception (1 Year) and as a result of hazard exposure over service lives of 10 and 50 years, for Initial Design and two design alternatives.

## RESULTS

Figure 2 presents a three-panel visualization using images from the post-processing module (annotated in three sequences to facilitate discussion). Each numbered sequence illustrates the increases in the building's embodied energy (sequence 1), total energy (sequence 2) and monetary costs (sequence 3) due to repairs resulting from hazard exposure for service lives of 10 and 50 years. Each bar chart is further discretized to illustrate the relative contributions of different building assemblies (sequences 1 and 3) or energy measures (sequence 2). An examination of the embodied energy (per square meter) (sequence 1) reveals that the building envelope chosen for the Initial Design is the primary contributor to embodied energy. As a result, the choice of the Alternative Envelope significantly reduces the EE:IC (see results shaded in blue in sequence 1, Year 1), as well as the EE:RM over its service life (see results shaded in blue in sequence 1, Year 50). Figure 2's first sequence also illustrates that the Frame Upgrade results in a higher EE:IC (see Year 1 in sequence 1); though over a service life of 50 years, this

choice ultimately results in a lower overall embodied energy due to the reduction of drifts and thereby earthquake-induced repairs over time (see Year 50 in sequence 1). While the Alternate Envelope outperforms other designs from the perspective of embodied energy, this is not the case once operating energy is considered (see sequence 2). The consideration of operating energy reveals that the Frame Upgrade is actually a superior option, due to the Alternate Envelope's larger energy expenditure in operations (see results shaded in blue in sequence 2, Year 1 vs. Year 50). Meanwhile, the monetary costs of each of these options (see sequence 3), considering both construction costs (Year 1), as well as the accumulated cost of hazard-induced repairs over service lives of 10 and 50 years, are driven significantly by the frame and envelope (see results shaded in blue in sequence 3, Year 1 vs. Year 50). As such, while the two design alternatives respectively improve total energy and embodied energy expenditures, the Initial Design requires less up-front investment. Note that the repair costs are not exorbitant, a result of using a highly resilient special moment frame, and these would increase for a more seismically-vulnerable typology. Though difficult to discern in the total costs visualized in sequence 3 due to the high construction cost of the frame, seismic vulnerability was dominated by the envelope, which drove approximately 80% of the annual repair costs in the Initial Design. The selection of an Alternate Envelope reduces annual repair costs by nearly 70%. This illustrative example demonstrates how a more data-informed and comparative conceptual design process could unfold with newfound access to critical resilience and sustainability performance metrics for the building's assemblies.

## DISCUSSIONS

Integrating the tools and data from the professions surrounding the design process into a single workflow is challenging, admittedly necessitating simplifications in the models and even examples used herein to vet this workflow. This paper constitutes an important first step to be followed by more faithful case studies sourced from practice. Nonetheless, this illustrative example demonstrates the importance of material choice in design, as embodied energy can be a key driver of environmental impact, particularly over shorter service lives. Moreover, as advances in energy-efficient building systems and non-grid-based energy sources are outpacing advances in efficient material extraction, manufacturing, transportation, and assembly, material embodied energy will be an increasingly larger portion of the total energy balance for the foreseeable future. As such, embodied energy data, and in particular that associated with the repair of hazard-induced damages, will require continued attention within the community. It is anticipated that embodied energy will routinely surpass operating energy once a more complete accounting is possible. Recent studies further suggest that hazard-induced repairs may consume considerably more energy than that embodied in the repair materials themselves (Simonen et al., 2018). While much work remains to truly quantify these impacts, this at minimum underscores the importance of considering not only embodied energy but also its dependence upon hazard exposure in any sustainability evaluation.

## CONCLUSIONS

This paper reiterates that a parceled approach, where each discipline optimizes a single performance objective/metric in isolation, does not effectively capture the interrelated concerns of resilience and sustainability. It is worth noting that while these independent concerns may be qualified, their reconciliation is hampered by the lack of a universal metric for comparison, given that sustainability and resilience are quantified in far different "currencies," including even the potential loss of human life. Nonetheless, the integrated LCA presented herein enables a data-informed approach to navigating the inevitable trade-offs between monetary cost, resilience and environmental impact. However, it is important to note that while the Revit-compatible workflow herein is, in and of itself, a significant contribution, its utility will remain

dependent on the quality and completeness of the data it relies upon, as well as the ongoing commitment to widely sharing these as linked, open data. The use of semantic data perspectives in the proposed workflow will not only enable the seamless integration of such machine-readable data when it becomes available, but enable a more rigorous geospatial accounting of the life-cycle costs related to the transportation of materials to and from the site. Until that day, the environmental impact of design choices will remain largely speculative. As such, the propagation of uncertainties associated with this source data, as well as those created by the site-specific future hazard/climate exposure and assumptions/simplifications of the wider design process, will be a critical next stage for the authors.

### ABSTRACT

The goal of Building Information Modeling (BIM) is the continuous use of digital construction models from the planning stage onwards. The affected processes are iterative and involve multiple stakeholders who work at varying pace and in varying levels of detail. These stakeholders require highly specific tools based on diverging data models. To satisfy all those requirements one of the best known Open BIM implementations – IFC – offers a data model containing more than one thousand different types – from basic to highly specific. Due to its complexity, potential users must undergo prolonged training. The even bigger challenge for IFC, however, is keeping up with the updates of building regulations or with the ever expanding state of the art in simulation tools. Our approach, SIMULTAN, in contrast to IFC, consist of 26 different basic types. They can be combined to increasingly complex models, which can themselves be used as types for other models. This enables each domain expert to create a custom data structure for any specific task, which is automatically compatible with the data structure of any other domain expert using the same basic types. It shortens the training time and facilitates the loss-, corruption-, and conflict-free exchange of information between domain experts, which is a key aspect of BIM. As a use case, we present the calculation of the U-Value of a multi-layered wall. We compare number, complexity and adequacy of the necessary data modelling steps in IFC4 and in SIMULTAN. The result shows that the flexible data model of SIMULTAN can be better adapted to the task. Another significant advantage of SIMULTAN is its inbuilt separation of responsibilities at the level of the most basic types, which, when combined with secure transaction technologies, can enable safe, effective and easily traceable interaction among stakeholders.

### KEYWORDS

data model, BIM, information exchange, multidisciplinary

### INTRODUCTION

The idea of the *Building Information Modeling (BIM)* is the consistent use of digital building models from planning to realization, from the operational phase to demolition. Already in the 70s, Eastman (1975) published a concept for the construction and the use of virtual building models. In 1992, van Needervan and Tolman (1992) first used the term BIM. One huge advantage of digital building models is the lossless information exchange. However, to ensure this exchange, the whole model must be interoperable, including all information such as climate data, usage information, variants, etc.

The interoperability of BIM models is present to varying degrees depending on the type of BIM. *Little BIM* refers to the use of a specific BIM software by a single planner. In this case, BIM is used without external communication (Jernigan, 2008). *Big BIM* refers to consistent model-based communication between all stakeholders involved in all phases of a building's

life cycle. In addition, a distinction is made between *closed* and *open BIM*, depending on whether vendor-neutral data exchange formats are used or not (Borrmann 2015).

An existing and already widely used standard for BIM is the Industry Foundation Classes (IFC) (buildingSMART, 2018) definition. The IFC models hold geometric data as well as metadata about building objects and are designed to support interoperability. Steel et al. (2012) investigate various issues of model-based interoperability in exchanging building information models between different tools, with particular focus on the use IFC. The authors pointed out that one of the greatest challenges with regard to interoperability is the inconsistency of modelling styles. The modeling language should clearly describe all possibilities so that unexpected alternatives are not possible. The authors Polit-Casillas and Howe (2013) also take up the issue of complex systems and the synchronization of different types of information. In their work, they combine BIM with a systems engineering approach to obtain a model based engineering approach. Thereby, they focus on the interoperability and validation of information in different planning phases, from requirements modelled in a modelling language such as the systems modeling language (SysML) to models drawn in, e.g., Computer Aided Design (CAD) tools.

In this paper, we move towards a big open BIM data model where the information is available at the level of detail at which it is required. This means that general information or information placeholders can be defined at the beginning of planning and later on be refined to become a realistic model that depicts the system behaviour. Our approach has the advantage that the complexity of the data model itself does not increase with the complexity of the represented buildings.

### MOTIVATING EXAMPLE

Let us consider the case of a wall that consists of material layers and has a geometry, which sets an upper limit to its total thickness. The wall, the material layers and their respective materials have properties that are necessary for various calculations (e.g. of the U-Value). Fig. 1 displays an excerpt of the IFC4 data model (buildingSMART, 2013) in Universal Modelling Language (UML) notation (OMG, 2017) that enables the storage of that information. The coloured paths show all types and associations involved in establishing various relationships between objects. In the case of linking a wall with a property set we have just two objects that require the maintenance of 13 types and 3 associations (path 2 in Fig. 1). It must be taken into account that type and object are not synonyms. The distinction between a type *material* and an object *m1* of type *material*, for example, is as follows: The type *material* requires all objects conforming to it to have a text parameter *Name*. Object *m1* conforms to type *material* and therefore has a specific text value (e.g. *Wood*) associated with the parameter *Name*. In other words, the type can be regarded as a template for the creation of (an unlimited number of) objects and the associations between types – as information exchange contracts between the corresponding objects. Fig. 1 contains only types.

Our objective is to decrease complexity by minimizing the number of types and associations required for the production of any object.

### MULTI-LEVEL DATA MODEL

The complete data model of IFC4 contains a total of 1167 type definitions and tens of thousands of associations among them (see Fig. 1). This data model has to be implemented and maintained in each software that manipulates IFC4 object models. Partial implementations carry the risk of loss of information across software boundaries.

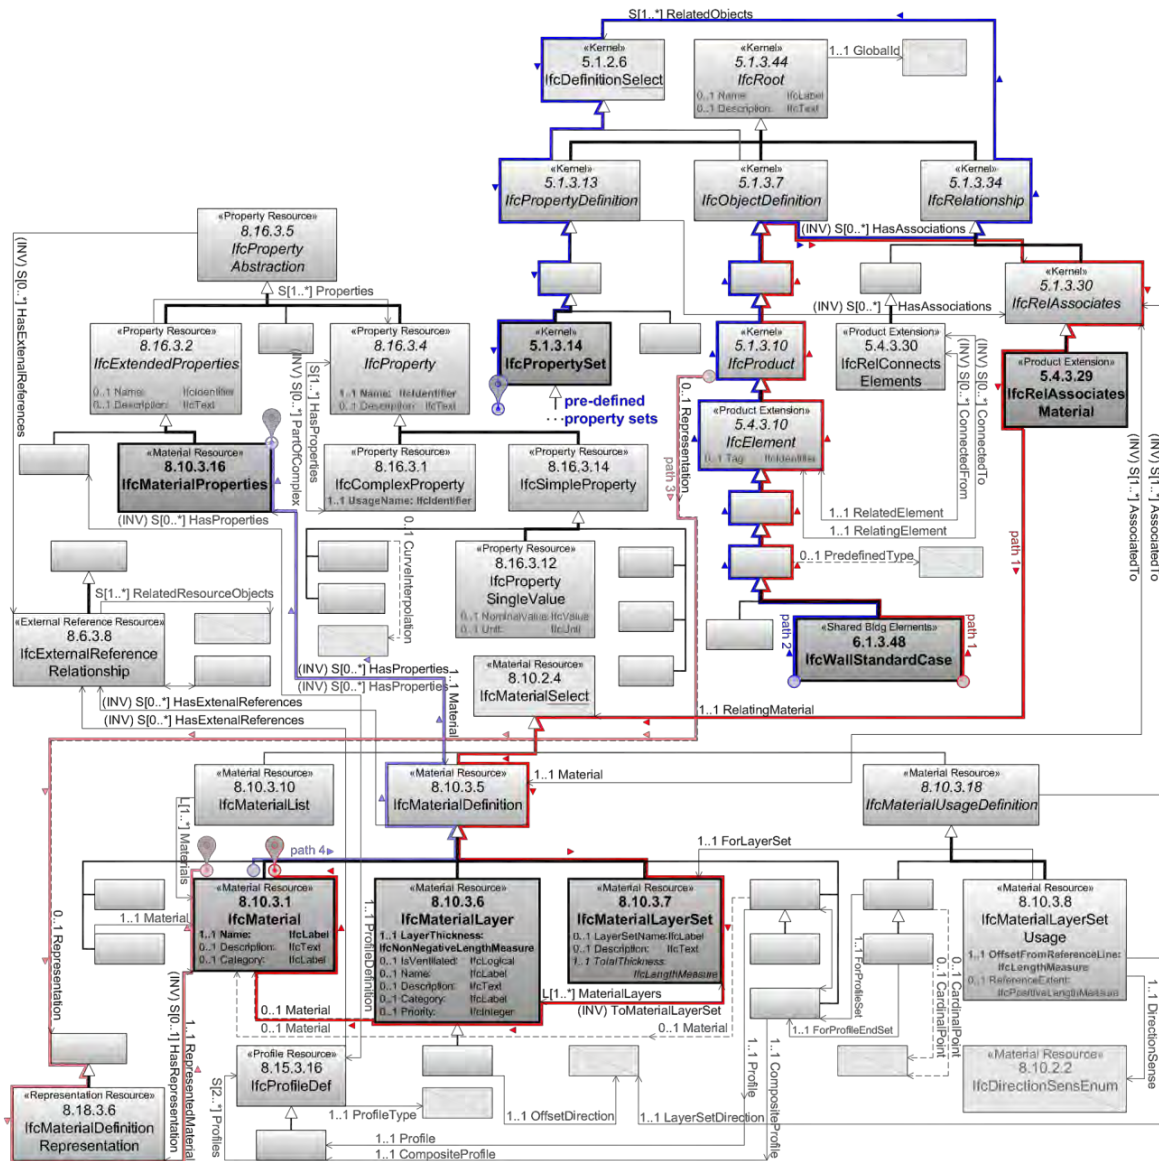

Fig. 1. An abbreviated excerpt of the IFC4 specification. The coloured paths show all types and associations necessary to establish a relationship between two objects: path 1 (in red) - between a wall and a material, path 2 (in blue) - between a wall and its properties, path 3 (in light red) - between a product and a material, and path 4 (in light blue) - between a material and its properties.

IFC4 has a fixed type structure. The information-carrying part – the parameters - are provided as property and quantity sets and are maintained separately (e.g., hosted on a server). It is possible to associate any type with any property or quantity set – a significant loosening of the constraints of the previous IFC version, 2x3. In essence, IFC4 provides a two-part data model that separates data structure from data content. The content has practically unlimited flexibility, since users can create their own property and quantity sets. The structure is rigid and can only be used as a container, but not as a carrier of information.

The SIMULTAN data model takes the next step and uses the type structure as an information carrier in addition to numerical and textual parameters. The type structure of any data model

is its ontology (Liu et al. 2013). A flexible, or editable, ontology allows the continuous incorporation of expert knowledge, as opposed to the development iterations of a data model with a fixed ontology that allows this once every few years (Laakso and Kiviniemi, 2012). Fig. 2 shows the SIMULTAN data model. Its central concept is the *Component* - a type that allows the definition of other types. The definition of *Component* includes a recursive relationship named *Subcomponents* (see Fig. 2), which enables each component to have an arbitrary number of sub-components, each with its own name and set of *Parameters* and *Calculations*. In this way, each component depicts its own ontology (or formal type definition) in its structure. On the one hand, the values of its parameters can be set to a default, in which case the component plays the role of a type or a template (e.g., *Material*). On the other hand, they can be set to values specific for light concrete, in which case it plays the role of an object (e.g., object *Light Concrete* conforming to type *Material*). The refinement of types (inheritance level) and the production of objects (instantiation level) are both possible within the same data model and can be applied an arbitrary number of times. For that reason, SIMULTAN is a multi-level data model.

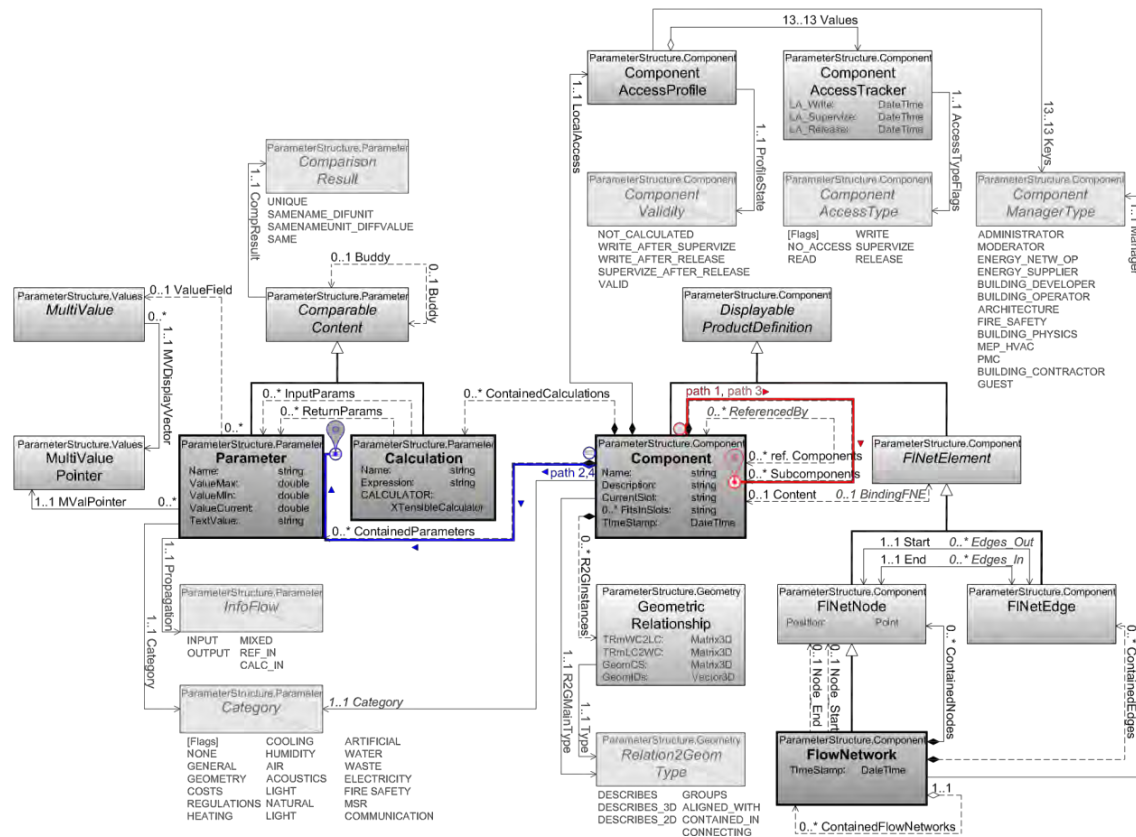

Fig. 2. SIMULTAN data model (the 5 subclasses of *MultiValue* were omitted). The coloured paths show the same relationships as in Fig. 1.

The main advantage of SIMULTAN's simple structure is its ability to depict any data model more complex than itself (e.g., IFC4) through nesting and referencing of components or their incorporation in a flow network (for multivalent dependencies). Thus, it is a universal translator between data models, as it is very easy to implement, maintain and map to and from other structures. It is also flexible enough to incorporate any data structure necessary for any calculation or simulation method. We will demonstrate this in the next section.

## PROOF OF CONCEPT

As demonstration case for our proof of concept, we use the calculation of the U-Value of a multi-layered wall according to EN ISO 6946:2017. As shown in Fig. 1, the association of a wall with a material in IFC4 involves 14 types and 5 associations. For the same purpose in SIMULTAN we need a component *wall* referencing a component *wall construction* (see path 1 in Fig. 1, Fig. 2 and Table 1). Table 1 summarizes the difference in complexity of the IFC4 and SIMULTAN data models and their limitations.

Table 1. Quantitative comparison between the IFC4 and the SIMULTAN data models.

Comparison Criteria	IFC4 Data Model	SIMULTAN Data Model
total no of type definitions	776 entities and 391 types, including 206 enumerations and 59 select types: <b>1167</b> in total	19 classes and 7 enumerations: <b>26</b> in total
total no of pre-defined parameter collections	408 property sets and 91 quantity sets: <b>499</b> in total (not contained in the formal IFC4 specification)	-
total no of user-defined parameter collections	unlimited	unlimited
total no of user-defined calculations	-	unlimited
min. no of types, objects and associations included in <a href="#">path 1</a>	14 types, 2 objects, 5 associations	1 type, 2 objects, 1 association
min. no of types, objects and associations included in <a href="#">path 2</a>	13 types, 2 objects, 3 associations	2 types, 2 objects, 1 association

For the U-Value calculation we now need the following parameters – the external and internal surface resistance  $R_{se}$  and  $R_{si}$ , and, for each homogenous material layer, the thickness  $d$  and the design thermal conductivity  $\lambda$ . In IFC4, this calculation requires the association of a material object with the property set *8.10.5.10 Pset\_MaterialThermal*, containing a *ThermalConductivity* property in addition to *BoilingPoint*, *FreezingPoint* and *SpecificHeatCapacity*. The wall object also needs to be associated with *6.1.4.23 Pset\_WallCommon*, containing a *ThermalTransmittance* property (according to the documentation, corresponding to the U-Value) in addition to 10 others (buildingSMART, 2013). The thickness of each material layer is a direct attribute of the type *IfcMaterialLayer* (see Fig.1). IFC4 has a type *IfcThermalResistanceMeasure* but no pre-defined property or quantity set containing a property corresponding to  $R_{se}$  or  $R_{si}$ , which necessitates the definition of a custom property set. In summary, in order to depict the calculation of the U-Value in IFC4, we need two pre-defined and one user-defined property set, we need to maintain 14 redundant entries in these property sets, and any calculation method using this structure has to read and write both to object values (material layer thickness, total wall thickness) and to parameter sets.

The SIMULTAN data model, on the other hand, allows the user to define exactly the parameters needed for the specified calculation, since additional parameters or calculations can be added later. One possible expression of such data structure can consist of the following: A component *wall construction* contains parameters  $R_{se}$ ,  $R_{si}$  and *U-Value*. Each material layer is a sub-component of it, with parameters  $d$  and the thermal resistance of the layer  $R$ , references a component carrying the material properties, in this case only  $\lambda$ , and calculates  $R$  on its own. The component *wall construction* gathers the information from its

sub-components into its own calculation(s) and determines its own *U-Value*. In this way, SIMULTAN enables not just the efficient storage of information but also manages its flow.

## CONCLUSION AND OUTLOOK

In order to be able to incorporate new methods and technologies data models need flexibility. IFC4 has already made the first step by decoupling data structure from data content. SIMULTAN takes the next step and introduces an adaptable data structure that can define any domain-specific ontology (e.g. building physics) in addition to the traditional numeric and textual parameters and can act as a universal translator. However, with a greater flexibility comes also a greater responsibility for the domain experts defining new data structures. Therefore, SIMULTAN incorporates an access tracking system (see *ComponentAccessProfile* in Fig. 2) as the mandatory equivalent of IFC4's *IfcActorResource*, where each component has an owner solely responsible for its development. Other actors (or stakeholders) can have supervision or publication rights. Thus, our data structure enables the stakeholders to view and modify all necessary information within their workflow. Applications using this data structure adapt to the user's workflow instead of forcing the user to adapt to the application. In a future development step, this system can be coupled with secure transaction technologies, such as BlockChains (Puthal et al. 2018), to provide a solid foundation for reliable and effective interactive work in real time.

## ACKNOWLEDGEMENT

### **ABSTRACT**

Building Information Modelling (BIM), as a new approach to the digital representation of the whole building lifecycle, including design, construction, building operation and maintenance, increases the efficiency and productivity of the architecture, engineering, and construction (AEC) industries. Because of complicated and comprehensive building information, BIM by itself is not able to provide an interactive visual environment for stakeholders and mobile access to the building information model is limited too. This paper aims to integrate BIM and 3D game engines to provide a real-time monitoring, mobile and interactive model. We've developed this building model as a serious game, capable of running on both Windows and IOS platforms. Players go through a virtual building, check enclosure materials, MEP systems, and real-time operating data in the game. A case study has been developed to show the benefits of integrating BIM and 3D game engines for modern building management.

### **KEYWORDS**

BIM, Game Engine, Revit, Database

### **INTRODUCTION**

Building Information Modelling (BIM) is “a new approach to design, construction, and facilities management, in which a digital representation of the building process is used to facilitate the exchange and interoperability of information in digital format” (Eastman, Teicholz, Sacks, & Liston, 2011). A building information model supports all digital building information, such as geometry data, MEP data, and real-time monitoring data.

Building geometry information enables architectural visualization, which is one of the important areas in current Virtual Reality (VR) research into the AEC area. Many BIM tools provide basic architectural visual functions for building design and construction but lack an interactive building environment for users. 3D game engines, however, are considered to provide a real-time, interactive visualization, using first or third person perspectives (Kumar, Hedrick, Wiacek, & Messner, 2011; Yan, Culp, & Graf, 2011). The main area of research into the integration of BIM and 3D game engines involves implementing a real-time and interactive architectural visualization for various goals, such as design review, construction management, fire simulation, construction safety, training and education, etc. Yan and Culp developed a 3D game with BIM to support an innovative Design-Play review in which designers can play their own designed environments and run a simulation of user activities and physical dynamics. Kumar and Hedrick developed a 3D game for reviewing a scenario-based design approach for healthcare facilities. Olofsson and Lee conducted research and found that using BIM/VDC tools saved 20-30% of the labour cost involved in the coordination of MEP systems (Olofsson, Lee, Eastman, & Reed, 2007). A 3D web-based game environment based on a hospital BIM model was developed for the virtual on-site visiting of building HVAC systems. It was then later implemented on an IOS mobile platform later (Shen, Jiang, Grosskopf, & Berryman, 2012). Edwards developed a two-way data transferring channel between BIM and game engines for structural design (Edwards, Li, &

Wang, 2015). A 3D game environment of an existing whole-building HVAC system was developed to enable students to interactively visualize and operate typical HVAC systems on computer monitors (Nandam, 2015). Furthermore, game engines could utilize networking features that enable real-time data exchange for potential data management. A game engine with a query interface connected an architectural semantic web to support calculations and simulations for the design stage (Pauwels, De Meyer, & Van Campenhout, 2011).

## METHODS

The aim of the research is to seek a possible BIM and 3D game engine integration to support the building visualization and the actual building operation process. A framework of a BIM and a 3D game engine integration with an online database was developed, and a small-scale case study was implemented to validate the framework and investigate its potential to assist architectural visualizations and support the building operation processes.

### Framework

A general framework encompassing a BIM, a game engine and a database was developed, demonstrated in Figure 1. Building information from the BIM model was exported into the game engine. Then, a virtual building with the necessary game functions was developed using the 3D game engine to develop an interactive and virtual serious game. Real-time sensor data are collected onsite and uploaded onto the online database for data management. The game engine connects to the online database to show these sensor data and their sensor location on the virtual building in real time.

Figure 1. Framework of the Integrated Platform

### Case study

The case study named ‘Classroom Building’ is a three-story, 73,275-square-foot building located on Virginia Tech’s north campus in Blacksburg, VA. It includes study rooms, group spaces, an auditorium, and laboratories for about 1500 students.

The BIM and game engine integration and its networking features were tested in this case study. Autodesk Revit was used to develop a building information model. Figure 2 shows the actual building and the Revit model. The game engine Unity 3D was used to create the 3D game. Unity 3D provides a visual editor, full and robust scripting and an animation system, and supports multiple platforms, therefore fulfilling the requirements of developing simple game functions and easily running the game on multiple platforms (Unity3D, 2005). The Revit model is exported as an .FBX file and Unity 3D imports these .FBX files to develop assets in the game. The .FBX file is complex because it contains all detailed building components. To reduce the file size, we split the Revit models (Architectural and MEP models) into different parts, e.g. Arch\_1<sup>st</sup> floor, which is the first level of architectural model. 3Ds Max is applied to optimize the original .FBX file and reduce the number of polygons of the model. For example, the number of polygons of the original Arch\_1<sup>st</sup> floor.FBX in 3Ds Max was 902,667. 3Ds Max can reduce about 30% of the number of polygons while keeping

a satisfiable performance. Simple textures were added to the assets in the Unity 3D engine to save the system resources. Room temperature data measured by sensors were uploaded onto a MySQL server and saved manually. Unity 3D provides a scripting API to connect the MySQL server and generate form data. Figure 3 shows the process and method of exchanging building information among the BIM, online database and game engine.

Figure 2. Classroom Building. a) Real project, b) Revit model.

Figure 3. Flowchart: BIM Tools/Systems to Game Engine

The basic functions of the serious game are to visualize the architecture and MEP systems and connect to the online database for better building management. Therefore, the whole virtual Classroom Building, including architecture and HVAC systems, were created in Unity 3D. Figure 4 shows the building envelope and HVAC system model in Unity. Related game functions were developed to help the players understand the building materials and MEP systems. In addition, a link between the online database and the virtual building was developed for checking real-time operational data in the virtual building.

Figure 4. Unity 3D Model. a) Building envelope, b) HVAC system.

Table 1 shows the basic functions of this game. The players walk through and around the whole virtual building, identify the function of HVAC ducts or building envelope materials,

connect to the online database and get the current sensor reading of the room temperature. A mini map helps the player to find their location in the building. For the mobile version, we plan to add location function. When the players come into the actual building, their location will automatically be read and shown in the game to enable accurate loading of the surrounding environment. This function which is currently under development, will help players compare the actual building and the virtual building in a simple way.

Table 1. Game Functions

Function	Game Controls	Comments
Walk through/Mini Map	WASD keys	Navigating inside building
Building envelope	Click the related elements	Show building envelope material
MEP system	Click the related elements/ F1 turn off the Building envelope	Show HVAC system
Identify location(ongoing)	-	Identify user's Location
Sensor data show	Click the Virtual Sensor	Return on-site temperature data
Multiply Platform	-	Windows and IOS

## RESULTS

A virtual building was developed on the Unity 3D platform. Players can walk around and enter the building to check the whole interior space. Figure 5 shows the indoor environment. The player can see the interior space and HVAC ducts from a third person perspective. A mini map was developed to locate the players position in the building. The building envelope and MEP system were imported. When clicking on a building component, such as an interior wall or a duct, the related component information was shown. It is like a virtual tour of the actual building. System components that have a similar function are the same colour, e.g. all equipment used for exhausting air is dark red.

Figure 5. Third person Perspectives. a) Interior space, b) HVAC system.

The player can click on a building element to check the related material or MEP information. Figure 6a shows how, when the player clicks on an interior wall, the game shows the element information as “Basic wall” and its structural information from the Revit model. Temperature data were collected and uploaded onto a local MySQL server. Every room has a special table to save the time and temperature data in the online database. By clicking on the “Temp” button, the game sends the current player’s location as a room number and current time to the database, and then gets the related temperature data from the database. Figure 6b shows the process.

Figure 6. Game Function. a) Material Information, b) Read Temperature.

The whole game was initially run on a Windows platform and was then moved onto an IOS platform in test mode. For the windows platform, the computer configuration is shown in Table 2. The FPS in game is about 30 FPS which is an average speed for RPG.

Table 2. Computer Configuration

Type	Exposed
Operating System	Windows 10
Processor	Intel(R) Core(TM) i7-6700HQ
Video	NVIDIA GeForce GTX 970M with 3GB GDDR5
Memory	32 GB DDR4 2133MHz
Resolution	1920 x1080

The new identify location function will be added for the mobile version. The players can scan the Quick Response (QR) code using the mobile device in the real building and load their actual location (e.g. classroom or lobby) with the surrounding virtual environment in the game automatically. This function should help the players compare the virtual building to the real building, gain a better understanding of the real building and can be used as an educational tool embedded into course work such assignments.

## DISCUSSIONS

Building information models remain a challenge for a 3D game engine. When importing the BIM model into the 3D game engine, all building components will be imported as numerous detailed objects, which is unusual for a common commercial game. Even with only basic functions, the high quality of architectural visualization consumes a huge amount of system resources. However, considering the wide application of portable devices during building construction and management, the virtual building game should support portable devices.

The case study works as a small-scale project without high resolution architectural details and complex gaming functions. More available and efficient methods of optimizing the building product model and importing it into 3D game engines with reasonable architectural details should be considered, as all unnecessary details will have an impact on game performance. The case study has shown that a virtual game can get on-site sensor data. The main challenge in this case was that the real building operation process is complex and numerous sensors work all day and produce a huge data set. It is possible to develop a series of special game functions to work as a basic data management tool, which helps the building managers' routine work, e.g. selecting a series of temperature values within a time range. This means the game developer should have a deep understanding of the game's goal and develop special functions to fulfil the user requirements. In this case study, the sensor data were directly uploaded onto an online database from the data logger, but the BIM can represent the sensor

information. To simplify the whole process, it would be possible to use a BIM server connected to a 3D game engine and the on-site building automation system, and to save and exchange all the BIM related data based on this server, but the research related to making this a reality is currently very limited.

## CONCLUSIONS

This paper provides a framework for integrating BIM and game engines and uses a case study to identify the benefits. The research shows that it is possible to utilize the benefits of both BIM and game engines to create an interactive and virtual building, which can return on-site sensor data from the online database for modern visual and interactive building operation management. A more advanced game could help building managers understand their buildings more intuitively. The data exchange process between BIM tools and game engines work, but the main challenge are the geometric complexities in architectural models and the building scale involved. The prototype game can achieve real-time data, but it is still a very early attempt at using the game to manage a multitude of building operation data.

Future work includes the optimization of network connections for huge amounts of data and the development of proper functions to match the virtual sensors in the building and sensor data from the online database. We envision this virtual building game to help building managers to check on-site indoor air conditioners more visually and conveniently. Furthermore, augmented reality (AR) equipment could probably be applied to this virtual building game as a building management tool. Another typical benefit is that we can use the virtual building in AR and go to the real building to verify if the actual construction matches the design in the virtual building.

## Cross-platform, Public Domain Simulation Tools for Performing Parametric IAQ and Energy Analysis

W. Stuart Dols<sup>1,\*</sup> and Lindsay J. Underhill<sup>2</sup>

<sup>1</sup>National Institute of Standards and Technology, Gaithersburg, MD, U.S.A.

<sup>2</sup>Boston University School of Public Health, Boston, MA, U.S.A.

\*Corresponding email: [stuart.dols@nist.gov](mailto:stuart.dols@nist.gov)

**ABSTRACT:** As building design is being driven towards lower energy use, the relationship between indoor air quality (IAQ) and energy becomes more important due in large part to reduced building envelope leakage, which can lead to higher indoor pollutant levels. Simulation tools that can analyze building design measures that aim to improve IAQ and energy use are necessary for evaluating potential trade-offs involving such measures. This paper will present the use of CONTAM and EnergyPlus, coupled using co-simulation, to perform parametric analysis of IAQ and energy impacts. Both of these tools are available in the public domain and provide cross-platform methods to evaluate both IAQ and energy use. Applications and workflow using these tools and available building models will be presented, including various energy and IAQ related measures that can be addressed with them. In particular, we present a framework for addressing energy measures (envelope tightening, insulation, and mechanical ventilation) and IAQ-related parameters (indoor/outdoor sources, ventilation rate, and filtration) in multi-family housing and effects on occupant exposure via a cohesive simulation environment that minimizes inter-domain coupling issues.

### KEYWORDS

CONTAM, co-simulation, energy, EnergyPlus, indoor air quality, whole building simulation

### INTRODUCTION

Building energy and indoor air quality (IAQ) are intertwined due to the interdependence of heat transfer, airflow, and contaminant transport. Often the same mechanical systems are utilized to maintain the thermal properties of air, e.g. temperature and relative humidity, and to dilute and/or remove pollutants that exist in the indoor environment, e.g., via outdoor air ventilation and filtration. As such, tools are needed to simulate these transport phenomena and associated systems to enable consideration of the interactions of these domains that are important to the health and comfort of building occupants. These tools will support the design and economic considerations of various stakeholders in the building community, including community planners, standards developers, designers and equipment manufacturers.

As highlighted by [Teichman et al. \(2015\)](#), activities related to design and construction of high-performance buildings (HPB) tend to focus heavily on energy-related concerns, and IAQ is often not addressed in a comprehensive and consistent manner. This is also borne out in the common use of building energy simulation, but not IAQ, in HPB design and analysis. However, recent activities by those evaluating HPBs from an IAQ perspective are bringing to bear building simulation methods that address both the energy and IAQ.

Building simulation is often employed to evaluate the impact of various building properties on building performance metrics ([Azimi et al., 2016](#); [M. P. Fabian et al., 2016](#)). For example, improving building envelope airtightness can affect energy use, indoor contaminant concentrations, and occupant exposure. The ability to evaluate the myriad building types;

heating, ventilating, air-conditioning (HVAC) systems; and climate zones, can provide information to those making decisions related to community-level energy use and contaminant exposure ([Levy et al., 2016](#)). To this end, two widely-used, public domain software tools, CONTAM and EnergyPlus, have been coupled to enable more complete evaluations of building performance ([Dols et al., 2016](#)). On their own, each tool is limited in its ability to account for transport processes upon which building IAQ, airflow and energy may be dependent.

EnergyPlus is a whole building energy simulation program with multizone heat balance as its underlying calculation method. EnergyPlus determines zone thermal loads and the energy used by HVAC systems to meet those loads. It calculates zone air temperatures based on current system and plant capacity, including system airflow rates. Generally, infiltration and interzone airflows are user-specified, i.e., not pressure-dependent as in CONTAM, and are not required to be in balance with system airflow rates. Typically, infiltration is modelled based on correlations associated with rectangular, low-rise residential buildings or may be assumed to be constant, but better methods are available ([Lisa C. Ng et al., 2018](#)).

CONTAM predicts airflows, contaminant concentrations, and airborne occupant exposures in multizone representations of whole buildings. In this paper, CONTAM will be used to assess IAQ while estimating infiltration airflows that impact building energy use. The CONTAM mass transport model treats a building as a system of interdependent zones or nodes (e.g., rooms, plenums and duct junctions) that store air and contaminant mass, and airflow paths (e.g., openings, cracks and duct segments) that transport air and contaminants between the nodes. Interzone airflows (including flows between the indoors and outdoors) are determined by calculating the node pressures that satisfy mass balance in each node based on driving forces and boundary conditions that include HVAC system airflows as well as wind and stack pressures exerted on the building envelope. CONTAM does not implement heat transfer calculations, so it requires indoor temperatures as inputs, which are often assumed to be ideally met thermostatic set-points.

The fact that CONTAM, when utilized on its own, requires the user to input zone temperature schedules, makes co-simulation with EnergyPlus an improved analysis approach. This is especially important for those who require analysis of both IAQ and energy related building performance.

## METHODS

The National Institute of Standards and Technology (NIST) has been working with the Boston University School of Public Health to utilize co-simulation between CONTAM and EnergyPlus to evaluate the impact of energy retrofit programs in multi-family apartment buildings on energy savings and occupant exposure. Co-simulation is being used to evaluate multiple types of building energy retrofits, contaminant sources, and building ventilation systems.

### Building Model Overview

The focus of the work to date has been on a four-story, mid-rise apartment building in Boston, Massachusetts. The Mid-Rise Apartment building model is based on the EnergyPlus representation selected from the set of U.S. Department of Energy (DOE) Commercial Reference Building models developed by the National Renewable Energy Laboratory (NREL). NIST developed a corresponding CONTAM representation of this building ([Lisa C Ng et al., 2012](#)) to be compatible with the co-simulation approach outlined in [Dols et al. \(2016\)](#). Both models were modified to include stair and elevator shafts that enable simulation of stack flows that can be particularly important to infiltration, energy use and contaminant transport in multi-story buildings.

The base building model, shown in Figure 1, consists of eight apartments on each floor separated by a central hallway with a stair and elevator shaft located at opposite ends of the hallway. Each apartment is served by a dedicated unitary HVAC system with a direct expansion cooling coil, a natural gas heating coil, and a constant volume supply fan. Each apartment is served by a dedicated exhaust system that is scheduled according to the ventilation system type: infiltration only, balanced outdoor air intake, or continuous exhaust ventilation.

Figure 1. Mid-rise Apartment Building geometry (left) and floor plan in CONTAM (right)

### Simulation Tools Development

The EnergyPlus/CONTAM co-simulation capabilities were previously developed as described in [Dols et al. \(2016\)](#). Coupling was implemented based on the Functional Mock-up Interface (FMI) for Co-Simulation specification according to which EnergyPlus was modified to enable the control of coupled simulations ([Nouidui et al., 2013](#)). However, the CONTAM co-simulation capability was originally implemented to execute only within the Windows operating system. To run a large set of parametric simulations, we required that the co-simulation capability be ported for execution on a high-performance, Linux cluster maintained by Boston University. EnergyPlus and the CONTAM simulation engine (ContamX) were already Linux compatible, so it was necessary to port the component that facilitates the FMI capability between EnergyPlus and CONTAM referred to as the ContamFMU dynamic link library (DLL). Modifications were made to enable the same source code to be used to build the Windows DLL (ContamFMU.dll) and the Linux equivalent referred to as a *shared object* (ContamFMU.so). Modifications were also required to address the methods used to spawn the ContamX process and enable socket communications to perform within the Linux, multi-core processing environment.

### Simulation Setup

The simulation process and associated input files are illustrated in Figure 2. Base building models (template files) were developed for both EnergyPlus (IDF file) and CONTAM (PRJ file). Each of these templates was modified using a text editor to flag relevant values for replacement via a *Factorial Generator Tool* that reads both the flagged input file and a variable parameter file (*PRJ Parameters* and *IDF Parameters*) to create a full set of simulation input files. For the purposes of this demonstration case, Table 1 presents the set of parameters that were varied for a total of 810 simulations. However, these methods can be applied in an almost limitless number of combinations.

The IDF files and PRJ files were generated by the *Factorial Generator Tool* prior to simulation. Scripts were then used to submit jobs to the process manager on the Linux cluster, after packaging files together as required for execution by EnergyPlus using co-simulation. The script then called EnergyPlus and CONTAM post-processing software (ReadVarsESO and simread3, respectively) to glean data from results files for further statistical evaluation.

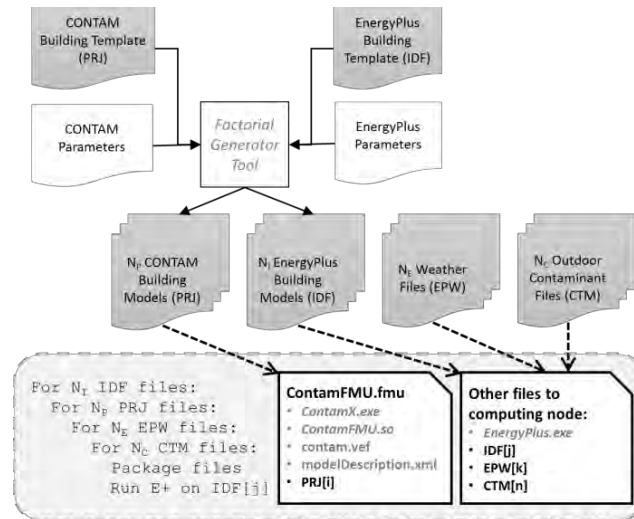

Figure 2. Schematic of parametric simulation process.  $N_P$ ,  $N_I$ ,  $N_E$  and  $N_C$  indicate number of respective file types: CONTAM building model (PRJ), EnergyPlus building model (IDF), weather (EPW), and outdoor contaminants (CTM).

Table 1. Set of Values for Parametric Simulations

Program	Parameter	Values
EnergyPlus (IDF file)	Ventilation Type	Infiltration only, Balanced supply, Exhaust
	Insulation (Walls/Roof)	R12/R13, R16/R30, R21/R35
CONTAM (PRJ file)	Envelope Leakage Rate ( $L/s \cdot m^2$ @75 Pa, exponent 0.65)	10.19, 5.42, 1.25
	Cooking Source	None, Low Cooking, High Cooking, Low Cooking w/ Local Exhaust, High Cooking w/ Local Exhaust
	Smoking Source	Non-Smoking, Smoking
	Filtration - Minimum Efficiency Reporting Value (MERV)	4, 8, 12

## RESULTS

Results presented here are based on simulations performed using Boston, MA weather and outdoor  $PM_{2.5}$  data as described in [P. Fabian et al. \(2012\)](#), i.e., EnergyPlus weather (EPW) and CONTAM contaminant (CTM) files respectively. Detailed analysis of these results will be presented in future publications, but we present a subset of results to demonstrate the capabilities. The first case is a building with indoor particle sources of high-cooking activity and smoking, and outdoor particles, an indoor formaldehyde source, a MERV 4 filter in each air handler, and a relatively leaky building envelope. The second case is the same building with no indoor particle sources, MERV 12 filters, and a relatively tight building envelope. Each case was modelled with three types of ventilation systems: infiltration only, exhaust only, and balanced outdoor air. Figure 3 presents box-whisker data generated by CONTAM and show the average (line inside the boxes), standard deviation, and maximum and minimum air change rates and energy use (Figure 3a) and concentrations averaged across all occupied zones (Figure 3b).

Figure 3a shows whole-building air change rates and total annual energy use. In terms of energy use, all the buildings have the same insulation levels, so they only differ by envelope leakage and ventilation system type. As shown in Figure 3a, the tighter buildings have reduced infiltration rates and lower total energy use for the respective ventilation systems.

Figure 3b shows indoor particle concentrations (grey boxes) and formaldehyde concentrations (yellow boxes). As expected, there are significant differences between indoor particle levels

when source control and filtration are implemented. However, the indoor formaldehyde source leads to elevated concentrations in the tighter buildings especially when no mechanical ventilation is provided. Conversely, from the perspective of improving IAQ, increasing dilution by ventilation may reduce contaminant levels of indoor sources but could lead to increased levels of outdoor pollutants and increased energy use. This is demonstrated in the second case, which shows that exhaust only ventilation, when compared to infiltration only, has lower formaldehyde concentrations but slightly higher particle concentrations due to particles being drawn in through the building envelope, along with a higher total annual energy use. These examples highlight the need for an integrated approach to building design and analysis ([ASHRAE, 2017](#)).

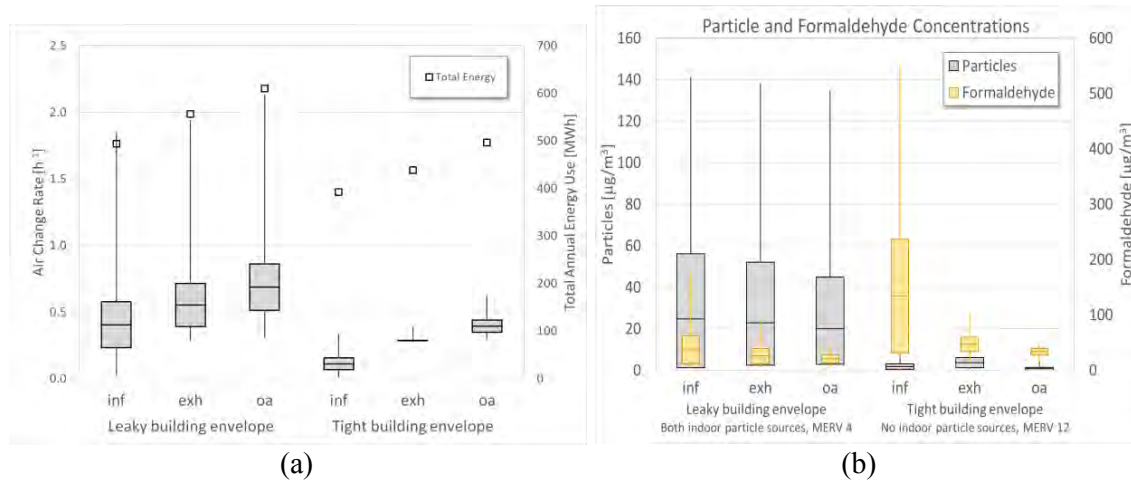

Figure 3. (a) Simulated whole building air change rates and total energy use of a Mid-rise Apartment Building with relatively leaky and tight building envelopes and three different ventilation systems: infiltration only (inf), exhaust only (exh), and balance outdoor air (oa). (b) Simulated particle and formaldehyde concentrations averaged over all occupied zones of a Mid-rise Apartment Building for two cases of envelope air-tightness and source emissions scenarios with same three ventilation systems.

## CONCLUSIONS

Co-simulation between whole-building IAQ, airflow, and energy simulation programs provides a comprehensive tool to evaluate the interactions between IAQ and energy when considering building energy retrofits. This paper highlighted the development and application of cross-platform, parametric simulation tools that provide the foundation to an integrated approach to building design and analysis to address energy and IAQ. The benefits of this integrated approach were demonstrated with an example from a case study carried out by Boston University and NIST. This example showed the interactions between building energy measures and IAQ parameters and their effects on whole-building energy use and occupant exposures, including reduced energy levels from envelope tightening and occupant exposure commensurate with source location and ventilation.

While these tools and parametric analysis methods are useful in their current state, there is also much work to be done to explore and improve them. For example, the coordination of CONTAM and EnergyPlus models is critical to success, and current methods rely on detailed knowledge of both simulation tools. Tools and associated workflows are available to minimize the redundancy and errors associated with coordinating the building representations, but modifications of existing building models can be quite cumbersome. Therefore, one of the goals of this work is to develop a set of coupled building models to be made publicly available. Output

of the simulation tools can be voluminous and difficult to manage. However, they can also provide much greater insight into the interaction among the input parameters and building performance metrics than was presented herein. Work could also be done to provide outputs of desired metrics either directly or by enabling output to be easily manipulated by data processing utilities or scripts.

## ACKNOWLEDGEMENTS

The authors would like to thank Charles A. Jahnke of Boston University (BU) for his invaluable assistance in setting up the simulation platform on the BU shared computing cluster.

### ABSTRACT

A solution was proposed for obtaining white light-emitting-diodes (LEDs) which are suitable for illuminating traditional Chinese paintings painted with inorganic pigments (iop-TCPs) based on the requirements of protective illumination and color quality. The damage laws and degrees of 450nm, 510nm, 583nm, and 650nm monochromatic lights which can construct four-primary white LEDs on the iop-TCPs were obtained through long-term illumination experiment and data analysis by converting color coordinates into CIE DE2000 color difference values. Then we obtained the damage formula of the constructed white LEDs, which can be used to evaluate damage degree. Spectral power distributions (SPDs) of the white LEDs, which can be iterated by brute-force algorithm, were simulated by the Gaussian formula. Constructed SPDs were evaluated by the damage formula and color quality formulas. The color quality eligible white LEDs with higher correlated color temperatures (CCTs) damage less to iop-TCPs. And the lowest damage SPDs satisfying color quality requirements in CCT ranges from 2700K to 4000K were obtained. Achievements can provide the theory and application basis for manufacturing white LEDs suitable for illuminating iop-TCPs; and the method can be further used in preparing white LEDs applicable to other cultural relics.

### KEYWORDS

Inorganic pigments; protective illumination; color quality; white LEDs; spectral optimization.

### INTRODUCTION

Numerous traditional Chinese paintings (TCPs) in museum suffer irreversible damage in various degrees. Among all the influencing factors, illumination cannot be eliminated for the need of visual effect (Dang et al. 2013). And the TCPs were classified as high responsivity to light by a technical report (CIE, 2004) and code (CNSA, 2009). Thus, the protective effect must be considered in museum illumination. Meanwhile, color quality is also an important element because exhibit paintings is a crucial function of the museum. Accordingly, it is urgent to develop museum light sources meeting both the need of the protective illumination and visual effect. The existing traditional Chinese paintings painted with inorganic pigments (iop-TCPs) are old and delicate. Therefore, we aim at solving the museum illumination problems for iop-TCPs which mainly contain natural mineral material made and easy fading, discoloration, color vanishing pigments-ancient graphite, clam shell powder, azurite, cinnabar, and orpiment-based on protective effect and color quality (Wu, 2011).

White LEDs which feature spectrum adjustable (Schubert and Kim, 2005), no infrared and ultraviolet radiation have the potential to form the desired light sources in museum. First, exhibits suffer seriously damage by infrared and ultraviolet radiation. Second, by adjusting the SPDs of the white LEDs, different wishes are made realizable to accomplish optimization

(Lin et al. 2017). At present, SPDs of the white LEDs satisfying the prerequisites of color quality mostly contain primary of red, yellow, green, and blue (Oh et al. 2012, 2014), namely red/yellow/green/blue (RYGB) four-primary white LEDs. Thus, we choose 450nm, 510nm, 583nm, 650nm waveband monochromatic lights as the deputies of the blue, green, yellow, and red monochromatic lights to construct the desired light sources by framing and evaluating the corresponding SPDs. Some researches explored for the influence of visible radiation on paintings, silks and so on (Farke et al. 2016). However, for our purpose to appraise the damage degree of the RYGB type white LEDs, it is indispensable to quantify the various influence of the corresponding monochromatic lights on the iop-TCPs.

It has been a prevalence to simulate SPDs by Gaussian distribution and iterate SPDs for evaluating figures of merit like the color quality, visual performance, circadian effect by algorithms (Wu et al. 2016). Among them, brute-force method which can cycle all the conditions in given ranges and steps provides accurate iterative results (Robinson et al. 2018).

Herein, we conducted a long-term experiment illuminating specimens of the iop-TCPs by the four monochromatic lights, test color parameters of specimens periodically, and calculated CIE DE2000 color differences; then we obtained relative color damage values of the monochromatic lights through data analysis, and based on which we deduced the relative color damage formula of the corresponding four-primary white LEDs to the iop-TCPs. In addition, we optimized the SPDs of the white LEDs by evaluating simulated spectra based on the obtained damage formula and the formulas about color quality parameters-color rendering index Ra and R<sub>9</sub> (CIE,1995; Hayashida et al. 2017), correlated color temperature (CCT), the distance from the Planckian locus (Duv) (Ohno, 2013).

## METHODS

### Models of specimens and experimental light sources

One of four groups of the iop-TCPs specimens (Dang et al. 2017), is shown in Figure 1a. And four monochromatic lights with the peak wavelengths of 450nm, 510nm, 583nm, and 650nm were produced by museum tungsten halogen lamp cooperating with infrared cut-off filters and 20 nm narrow band-pass filters. The irradiance of each light source was kept the same and constant during the long-term experiment, spectra are illustrated in Figure 1b.

Figure 1. (a) One of four specimen illuminated by light sources. (b) Irradiance distribution of four monochromatic lights on the surface of the specimens. (c) Model of the experimental device, L represents the monochromatic light source, S represents specimen. (d) The realistic experimental device. (e) Diagrammatic sketch of the test environment.

### Experimental methodology

The long-term illumination experiment was conducted in the Optical Laboratory. Detail has been depicted by Dang (2017). The experimental scheme is illustrated in Figure 1c-d.

### Test of the parameters

After each cycle of illumination, the specimens were moved under the D65 standard light source; and color parameters of the specimens were measured by the standard color test method of CIE (1999), method shows as Figure 1e. The CIE LAB chromaticity coordinates ( $a^*$ ,  $b^*$ ) and metric brightness value  $L^*$  of four specimens were measured before and each cycle after the illumination, at test points marked in Figure 1b, achieved by Luminance Colorimeter. Color parameters of one pigment in one specimen were determined by the average value of the three test points to minimize the measurement error. Color differences of the five pigments were calculated using the CIE DE2000 formula (Farke et al. 2016).

## RESULTS

### Changing curves of CIE DE2000 color differences

The damage law and the influence degree of different light sources can be seen in figure 2. We conclude from the figure that monochromatic lights with various peak wavelength impact at different degrees on pigments with distinct colors. It also implies that the monochromatic lights differently affect the iop-TCPs.

Figure 2. The changing curve of CIE DE2000 color differences of pigments (a) Azurite, (b) Clam shell powder, (c) Ancient graphite, (d) Cinnabar, and (e) Orpiment.

### Relative damage values of the monochromatic lights

To express the relative damage of different monochromatic lights to the iop-TCPs whose color can be basically represented by the five pigments, the average damage value of the 450nm light to the five pigments is defined as 1.00, to which other values are normalized, detail is given in Table 1. Accordingly, relative damage values ( $D$ ) of the monochromatic lights to the iop-TCPs is  $D(450): D(510): D(583): D(650)=1.00: 1.03: 1.14: 1.06$ .

Table 1. Relative damage values of monochromatic lights on inorganic pigments.

	450nm	510nm	583nm	650nm
Ancient graphite	1.08	1.19	1.38	1.29
Calm shell powder	0.79	1.02	1.10	0.93
Azurite	0.60	0.71	0.76	0.87
Orpiment	1.09	0.97	1.13	1.03
Cinnabar	1.45	1.25	1.34	1.17
Average	1.00	1.03	1.14	1.06

### Damage formula of RYGB four-primary white LEDs

The damage degree to the exposed object is determined by the power of the incident light, the relative spectral responsivity of materials to incident radiation, and the illumination hours (CIE, 2004). The relative damage values we obtain can represent the relative responsivity of the iop-TCPs to the incident radiations; and for one white LED, the four monochromatic light sources constructing it share the same illumination hours; as for the power of the incident light, it is determined by the addition of the spectral power of every wavelength in the waveband. E.g. the power of the 450nm monochromatic light is expressed by Equation 1, and the power of 510nm, 583nm, and 650nm can be calculated in the same way.

$$W'(\lambda) = \int_{\lambda_{450-\Delta\lambda_l}}^{\lambda_{450+\Delta\lambda_r}} S_{450}(\lambda) \cdot d\lambda \quad (1)$$

Where  $\Delta\lambda_{ll}$  and  $\Delta\lambda_{lr}$  represent left and right half spectral width of the spectrum, respectively;  $S_{450}$  is the SPD of the 450 nm monochromatic light.

After confirming the damage factors of the light sources, the relative damage formula for the RYGB four-primary white LED is deduced according to Equation 1, where, the total power of the white LED is divided for eliminating the influence of various energy input:

$$D^*(\lambda) = \frac{1.00W'(450) + 1.03W'(510) + 1.14W'(583) + 1.06W'(650)}{W'(450) + W'(510) + W'(583) + W'(650)} \quad (2)$$

## DISCUSSIONS

### Spectral simulation and construction

All of the figures of merit which we want to optimize for the white LEDs-Ra, R<sub>9</sub>, CCT, Duv, D\*-are determined by the SPDs. And the SPDs of the white LEDs, which are the determinant factor can be theoretically constructed by the addition of monochromatic lights (Ohno, 2005) as the Figure 3e shows, before practical production to avoid waste and unnecessary preparation. And the monochromatic lights can be simulated by the Gaussian distribution, the model of which we select is an accurate modified Gaussian model (Ohno, 2005). Accordingly, the monochromatic spectra are determined by the main parameters of the Gaussian distribution-peak wavelength  $\lambda$ , relative intensities of the peak wavelength  $V$ , and full width at half maximum  $\Delta\lambda$  (FWHM)-depicted in Figure. 3a-d. Peak wavelengths of the constructing lights are confirmed to be 450nm, 510nm, 583nm, and 650nm. While, the other two parameters need iterating to form various spectra for further research and optimization.

Figure 3. The S-model simulated spectral of monochromatic lights with peak wavelength of (a) 450 nm, (b) 510 nm, (c) 583 nm, and (d) 650 nm,  $W$  means the spectral power of the light. (e) spectral diagram of RYGB four-primary WLED, here,  $S$  represents the SPD of the WLED.

For overall scanning of the possible spectra, brute-force method is used. For circulation, relative intensities of the four monochromatic lights are set from zero to one with a step of 0.01 and the FWHM cycled from thirty to fifty with a step of five. After obtaining the spectra, values of figures of merit are calculated for further research.

### Results of optimization

A total of 9150625 pieces of spectra are simulated. Eliminating unsatisfied spectra according to the color quality requirements for light sources illuminating op-TCPs-Ra $\geq$ 90, R<sub>9</sub> $\geq$ 90, |Duv| $\leq$ 0.005, 2700K $\leq$ CCT $\leq$ 4000K (CNSA, 2009; ANSI, 2015)-6742 pieces remain.

Then we analyze the relative damage values  $D^*(\lambda)_1$ - $D^*(\lambda)_{6742}$  of the satisfied SPDs, which were normalized to the range 0-100 for better comparison. The relationship among  $D^*(\lambda)$

values, the amount of the satisfied SPDs, and the relative average damage values in different ranges of CCTs (the ranges of CCTs are divided by the interval of 100, e.g., 2650 K-2750 K represents the range of 2700 K) is displayed in Figure 4.

Figure 4. A diagram of  $D^*(\lambda)$  values, the amount of satisfied SPDs, and the relative average damage in different ranges of CCT, the points of SPD with the same CCT range are enclosed by the red rectangle. The lowest damage points in the CCT ranges are marked with triangle.

We can see from the Figure 4 that: First, with the increase of the CCTs, relative average damage values in 2700K-4000K ranges appear an overall decrease trend (the black line), mainly damage less to the iop-TCPs; second, the amount of SPDs satisfying requirements of color quality increases with the rise of CCTs (shown in the upper axis of Figure 4). e.g., the amount of qualified SPDs in the range of 2700 K is 325, while 647 for the 4000 K; third, when producing white LEDs, from the consideration of cultural relics protection, SPDs in high CCT ranges should be selected preferentially for lower damage, that means SPDs in the range of 4000 K are preferable. For further selection in the selected range, choosing SPDs with the damaged order of low to high in the selected range of CCTs, e.g., for 647 SPDs in the range of 4000 K, the SPD of point N in Figure 4 is firstly developed, but, if the SPD of the point N cannot be manufactured due to technical restrictions, other points in the range of 4000 K will be developed from low to high of the damage degree; fourth, if low CCT light sources are indispensable for reasons like the need of exhibition effect or some others which need further researching, the development should choose SPDs from the low damage to high damage in the target range.

## CONCLUSIONS

Different monochromatic lights influence variously on different color pigments. Among all the painting types, the iop-TCPs suffer the damage of 450nm, 510nm, 583nm, and 650nm monochromatic lights by the damage proportion of 1.00: 1.03: 1.14: 1.06, by which a damage formula for the corresponding white LEDs is developed. The specific influence law is illustrated in Figure 2. Then the corresponding RYGB four-primary white LEDs can be evaluated protection effect by our damage formula.

By further analyzing the parameters of the constructed RYGB white LEDs, we conclude that the damage of the RYGB white LEDs to iop-TCPs decrease with the CCT ranges increase. When satisfying the requirements of color quality, the “CCTs,” “spectra amount in different ranges of CCTs,” and “relative damage of each spectrum to iop-TCPs” of the four-primary white LEDs have clear relationships, demonstrated in Figure 4. And in the realistic production of new type white LEDs, method for choosing SPDs is introduced.

The method flow of the illumination experiment, the data analysis, and the optimization of the spectra can be extended to develop and evaluate spectra of white LEDs using for other high-

responsivity cultural relics like lacquerwares, frescos, folding screens, dyed silks and so on. In addition, the white LED spectra we obtain by the method flow, which are applicable for different kinds of cultural relics, can be manufactured by the lighting systems due to the tunable characteristics of white LEDs, for which fundamentally solved the problem of protective illumination for cultural relics in museums.

### **ABSTRACT**

Existing research on the performance of shallow geothermal systems are prone to investigate the ground as a large thermal mass at a constant temperature despite possible temperature increase at depths - otherwise commonly known as the geothermal gradient. Most of the existing analytical models that predict the heat exchange between a borehole heat exchanger with the soil does not allow for the geothermal gradients to be accounted for. The few models that actually does account for the geothermal gradients, on the other hand, does so by enforcing a pre-existing temperature gradient only. We are presenting a bottom up approach in this paper to solve the temperature distribution by accounting for both the convective heat transfer from the working fluid and the conductive heat transfer through both the pipe and the soil. Assuming the heat transfer is entirely axisymmetric, we approach the problem by solving the Navier-stokes equation and energy equation with a finite difference solver that calculates the temporal change of temperature with given diameter, depth of borehole and geothermal gradient. The heat transfer through the pipe and into the ground can therefore be further calculated. We were able to determine a CBHE configuration that allows maximized thermal output by assuming a synthetic heating/cooling load for year-round production of heat.

### **KEYWORDS**

geothermal gradient; CBHE; geothermal energy; ground-source heat pump

### **INTRODUCTION**

Existing research on the harvesting geothermal energy categorizes the harvesting process with respect to the depth of the ground roughly into shallow geothermal systems and deep use systems. The prior are often associated with harvesting the energy solely for thermal purposes, in particularly exploiting the benefits from geothermal energy as a source of large thermal mass where energy can be deposited and/or extracted while the source maintains relatively consistent temperatures (Lund, 1999). The deep use systems, on the other hand, are usually associated with geothermal basins and highly pressurized steams that can be used for power generation. For the shallow geothermal system, the temperature of the working fluid extracted from the boreholes commonly rises up to 25 degree Celsius, while for the deeper geothermal systems, this temperature could go up to 225 degree Celsius (Lu, 2018). Obtaining the working fluid at a temperature in-between is a much less practiced approach.

This would have been made possible by exploiting the geothermal gradient that was known to be at 25 to 50 K/km for different types of geological conditions. According to data released from NGDS where the temperature at the bottom of 17,462 boreholes were made public, the temperatures at the bottom of deeper boreholes could go up to 75 degree Celsius since some

of the boreholes went as deep as 2.4 km. Admittedly, these boreholes were neither designed to be delivery heat to households, nor were they to ever be connected to municipal district heating networks. Yet the temperatures alone could cast questions as to whether spending much more money to drill deeper boreholes could in fact repay such investments with higher quality of energy coming out from the boreholes. To fully appreciate the scope of this questions, we are presenting a numerical study that we are currently investigating in this paper as we try to determine the most optimized design for a coaxial borehole heat exchanger (CBHE) since it provides the maximized amount of surface area for heat exchange comparing to other alternatives.

## METHODS

We have created a three-step solver to investigate the flow regime within a CBHE with a set of known design parameters so that the temperature inside the borehole, at the casing and outside of the borehole can all be calculated. At every single time step, the temperature distribution and velocity field within the borehole heat exchanger will first be solved. The temperature at the wall and pipe interface are then used to calculate the temperature within the pipe and casing. The resulting temperature at the outside of the casing will then be used to compute the temperature distribution at the end of this time step.

Assuming water to be the main working fluid, the flow that is being modelled should be considered incompressible. Solving the hydraulic performance of a CBHE while considering the convective heat exchange between the water and the borehole casing, we are essentially solving the flow conditions with respect to the following three equations:

$$\nabla \cdot \mathbf{u} = 0 \quad (1)$$

$$\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} = -\frac{1}{\rho} \nabla p + \nu \nabla^2 \mathbf{u} + g\alpha \Delta T \quad (2)$$

$$\frac{\partial T}{\partial t} + \mathbf{u} \cdot \nabla T = \kappa \nabla^2 T \quad (3)$$

Equation 1 denotes the continuity of an inviscid fluid, Equation 2 is the Navier-Stokes equation which can be solved to understand the fluid condition for an inviscid fluid, while Equation 3 is the Boussinesq approximation that can be used to solve for temperature distribution. For the in-pipe fluid flow, we solve the N-S equation for an incompressible flow condition. The incompressibility acts as a constraint for the pressure. Within the borehole, for every single time step, the velocity profile will be imported, following which the pressure field can be updated with the new velocities. The further influence of the boundary conditions can then be used to further constraint the new pressure condition within the heat exchanger, creating new pressure conditions, leading to an updated velocity profile, thus updating the temperature profiles in Equation 3.

Since we are working with an axisymmetric coordinate system, it is possible to assume Equation 2 can be further simplified into a 2D form, with an exception of its final term .

$$\rho \left( \frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} \right) = -\frac{\partial P}{\partial x} + \mu \left[ \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} \right] \quad (4)$$

$$\rho \left( \frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} \right) = -\frac{\partial P}{\partial z} + \rho g \alpha \Delta T + \mu \left[ \frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2} \right] \quad (5)$$

To solve for the pressure term, we took divergence of Equation 4 and 5, adding them up, and simplified with the continuity constraint Equation 1, it is possible to arrive at a Pressure Poisson Equation of

$$\frac{1}{\rho} \left( \frac{\partial^2 P}{\partial x^2} + \frac{\partial^2 P}{\partial y^2} \right) + \frac{g \alpha \Delta T}{\beta} = \left( \frac{\partial u}{\partial x} \right)^2 + \frac{\partial v}{\partial x} \frac{\partial u}{\partial y} + \left( \frac{\partial u}{\partial x} \right)^2 \quad (4)$$

After updating the temperature for the fluid is determined, the temperature of the fluid that is most adjacent to the casing and inner pipe can then be introduced Equation 5, where the conduction within the casing. The  $\rho$  stands for the pipe density,  $C$  stands for their specific heat capacity ( $J/kg \cdot K$ ), while  $k$  stands for the pipe's thermal conductivity.

$$\rho C \frac{\partial T(x,t)}{\partial t} = \nabla \cdot [k \nabla T(x,t)] \quad (5)$$

As we are solving energy equation for a incompressible fluid in an internal space before moving on to the heat conduction happening in the soil, it is also necessary to non-dimensionalize both the momentum equation and the energy equations. The non-dimensionalize terms that will be used are the following:

$$u = \frac{u^*}{U_\infty}, \quad v = \frac{v^*}{U_\infty}, \quad \theta = \frac{T - T_\infty}{T_w - T_\infty}, \quad (6)$$

$$x = \frac{x^*}{L}, \quad y = \frac{y^*}{L}, \quad t = \frac{t^*}{L/U_\infty}$$

such that Equation 5 can be re-written in the form of non-dimensionalized form as

$$\frac{\partial \theta}{\partial t} + u \frac{\partial \theta}{\partial x} + v \frac{\partial \theta}{\partial y} = \frac{1}{Pe} \left[ \frac{\partial^2 \theta}{\partial x^2} + \frac{\partial^2 \theta}{\partial y^2} \right] + \frac{Ec}{Re} \Phi \quad (7)$$

Since the flow velocity is very small ( $M \rightarrow 0$ ),  $Ec$  also disappear so that the last term on the right hand side disappears, the temperature can therefore be fully written as a function that can be obtained from the  $u$  and  $v$  velocity components with the help of the Peclet number which we can obtain with Equation 8.

$$Pe = Pr \cdot Re = \frac{Lu}{\alpha} = \frac{Lu\rho c_p}{k} \quad (8)$$

where  $L$  represents the characteristic length,  $u$  is the local velocity,  $\rho$  is the density,  $c_p$  is the specific heat capacity, and  $k$  is the thermal conductivity of water. We will be using the depth of the borehole as the characteristic length hence  $L = H$ . The resulting temperature distribution, specifically the temperature at the outside of the casing resulting from the calculations were then introduced into Equation 4 again, with different set of parameters, where  $\rho$  stands for the soil density,  $C$  stands for soil specific heat capacity ( $J/kg \cdot K$ ), while  $k$  stands for the soil thermal conductivity. As all the computation were resulted from discretized analytical modeling, we were able to construct this solver in a light-weight, easy-to-interpret Python module that takes in only diameter of borehole, depth of borehole as inputs to produce the geothermal energy. The parameters this study was subjected to are as the following in Table 1:

Table 1. Parameters used in the numerical simulation

Material	Density, ( $kg/m^3$ )	Specific heat capacity ( $kJ/kg \cdot K$ )	Thermal conductivity ( $W/m \cdot K$ )
Soil	$1.8 \times 10^3$	0.8	1.59
Pipe	$0.95 \times 10^3$	1.9	0.5
Casing	$7.9 \times 10^3$	0.47	14.9
Water	$1.0 \times 10^3$	4.1844	0.609

To further decrease the computational costs, both the control equations and inputs were further non-dimensionalized in both the vertical and axial directions, more specifically with

respect to  $2H$ , where  $H$  stands for the depth of the proposed borehole depth designs. This nondimensionalization method is consistent with a few existing studies. The parameters from Table 1 were then used to run a series of iterations of simulations to simulate the temperature out at different flow velocities. The pseudocode for the algorithm used can be found in Table 2 as is shown below.

Table 2. Algorithm used to calculate the temperature field inside and around CBHE

Temperature outside of the outer tube and inside the soil solved from heat conduction equations;

$t = t + dt$

Output Velocity fields  $U, V$  and Temperature fields  $T$

**End**

---

Assigning the time of simulation ( $T$ ) to be 1 h and the size of time step at 0.005s for the simulation, the temperature distribution inside and outside of the borehole can be simulated. We will be assuming a constant temperature of 10°C within the scope of this paper, but could switch to a varying  $Q(t)$  since the temperature development was strictly temporal hence can handle varying heating/cooling demand. This is a placeholder for variable heat input that can better simulate the load coming from actual buildings in the future. It is also important to point out that we will be assuming a geothermal gradient of 30 K/km, and no underground water flow that interacts with the CBHE within the context of this study. We will be modeling the analytical problem with the central difference approximation scheme as it provides a much better smoothness and could serve our purpose better. Due to the page limit imposed on this paper, the actual discretization expressions will be omitted.

## RESULTS

The proposed solver was very time consuming to develop, and was very time-consuming to develop. We were able to determine the flow pattern using the 2D solver we developed. For every time step, the velocity and temperature can be computed by solving the Navier-Stokes equation with the Boussinesq Approximation. At every step in time, the pressure term is first solved from the velocity and temperature profile of the last time step. Velocity and temperature profile are then calculated and developed over time, as is being shown in Figure 1.

The in-borehole temperature distribution development within the borehole can be qualitatively captured over time. Since we used  $dt = 5.4e-6s$  for the simulation, a fully developed flow pattern at the 1st hour requires a total of 61 minutes to compute. This was computationally very expensive comparing to similar solvers in TRNSYS and COMSOL.

Figure 1. Temporal change of the temperature distribution within the in-bore model from the solver as time steps forward  $t = 0.1\text{s}$  (left),  $0.5\text{s}$  (middle),  $0.7\text{s}$  (right).

## DISCUSSIONS

To save computation time and avoid excessive read/write to the hard drive, we did not store the temporal change of the temperature field. What was stored, was rather only data at the end of calculation, i.e. by the end of the 1st hour of hypothetical borehole operation. Understanding the temporal change of temperature was not of significant interest for this paper, but we would like to acknowledge its importance with follow-up studies, since the temporal response of the borehole is of major research interests to many preliminary borehole assessment simulations where thermodynamic properties can be compared against simulation results. We believe the first step to further this investigation is to compare their performances both in terms of computation time and the resulting temperature and velocity profiles. A clear benefit of our method would be the simplification of creating meshes as it'd be fully automated for any given diameter and depth of borehole, while any change in the geometry of a CBHE requires a new mesh generated to be calculated. Also highly simplified is the geotechnical conditions around the borehole. As we assumed homogeneous soil condition for this study, the actual soil conditions are often observed to vary significantly and needs to be described with an entire set of thermodynamic properties instead of the one set that was used in this study. As this study is, again, purely numerical, it might be possible to further customize the soil conditions through assigning different soil properties that exist by layers but is off the focus of this research and are hence not pursued within the scope of this paper.

Additionally, there is a missing link that this solver does not provide information for, but could prove helpful to further analyze: stress/strain on the borehole wall, in particular the stress and strain on the outer tube/casing interface. Better characterization of the temperature increases' influence on the harvestation of geothermal energy may very likely increase the awareness of how to better quantify the heat exchange with the ground in other modeling practices, i.e. helix geothermal heat exchanger, single and double U-tube geothermal heat exchanger as well as multiple inlet/outlet energy pile systems. There are currently no existing research that quantitatively compare the differences in between their performances, which we are also very interested in quantifying in the near future.

Last but not the least, it is important to stress that existing commercial softwares does not achieve the similar level of resolution during design-stage analysis. In short, refined solution

of the temperature profile within a CBHE is relevant to harvest the most amount of thermal energy to ground level, but cannot be achieved without fine grids in numerical simulations - which is impossible when the depth of a CBHE is yet to be determined through parametric analysis. The proposed method, on the other hand, will allow such analysis at the expense of computational time but has its own merits in the ease of use as steady-state results after prolonged periods of operation can be calculated and compared against another - as well as using variable insulation levels for the inner pipe of the annulus. We believe this is research that is crucial to further the current understanding of borehole heat exchangers and could be brought further by putting additional attention to rewrite the algorithm in compiled language to reduce the computational time in the near future.

## CONCLUSIONS

We have devised the very basics of fluid mechanics in conjunction with the heat exchange by solving the hydraulic condition within the CBHE. Working with the basic assumption that the flow inside a CBHE can be assumed to be axisymmetric, we based our model on the fundamentally solving the Navier-Stokes equation with the boundary constraints of a CBHE with known inlet and outlet information, we demonstrated that it is possible to use a simple 2D model to predict the temperature distribution within and outside of the borehole. Admittedly, the result we reached can also be completed with commercially available softwares, we believe our method is much more simplified to run parametric studies and/or for further optimization.

### ABSTRACT

Lattice Boltzmann method (LBM), as a new computational fluid simulation method, has aroused widespread attention in recent decades within engineering practice. LBM with large eddy simulation (LBM-LES) model is commonly used in predicting high Reynolds flow, and is considered to have a prediction accuracy similar to traditional finite volume method (FVM-LES). Nonetheless, a systematic discussion on the accuracy of LBM-LES, and its consistency with FVM-LES, in indoor turbulent flow situations, is still insufficient. In this study, simulations of an indoor isothermal forced convection benchmark case (from IEA Annex 20) are implemented by using both LBM-LES and FVM-LES, with the aim of comparing the accuracies of LBM-LES and FVM-LES, in indoor turbulent flow situations. A comparison of their relative computation speeds, and parallel computation performances, is also implemented. The results show that LBM-LES can achieve the same level of accuracy as FVM-LES, in indoor turbulent flow situations; however, more refined meshes are required. Compared with FVM-LES, half size grids are required for LBM-LES to approach similar levels of accuracy, meaning that the meshes of LBM-LES are approximately eight times as large as FVM-LES. The computation speeds of both LBM-LES and FVM-LES scale well, with the increase in the number of computation cores in one node. Their computation speeds (with the same accuracy) approach a similar level; however, the parallel computation speed of the LBM-LES speed can be larger than FVM, owing to its superior parallel speedup performance.

### KEYWORDS

Lattice Boltzmann method, Finite volume method, Large-eddy simulation, Indoor turbulent flow

### INTRODUCTION

The lattice Boltzmann method (LBM) has recently been applied in indoor turbulent flows (Sajjadi et al. 2016), in place of the conventional finite volume method (FVM). Based on the lattice Boltzmann equation, the LBM simulates the fluid motion process by assuming a collection of particles colliding, and a stream behavior for their distribution functions (Chen and Doolen 1998). When solving turbulent flow problems with a high Reynolds number, the LBM can be used with a large eddy simulation (LBM-LES) model, as in the FVM (FVM-LES). As it is necessary to solve the Poisson equation in the FVM, there is an obvious disadvantage in that the calculation load and time cost are tremendous. However, the LBM shows more promise in high-speed LES simulations for complex and large-scale urban flows, owing to its simpler algorithm, and it is also more appropriate for parallel calculations.

Although the LBM has been applied in the flow simulation of indoor turbulence, a systematic comparison of its accuracy, consistency, and computation speed with the FVM is still insufficient. Therefore, in this research, simulations of an indoor turbulent flow benchmark case from IEA Annex 20 (Lemaire et al. 1993) are implemented by using both the LBM-LES and

FVM-LES, to verify the accuracy of the LBM-LES and to compare this accuracy with that of FVM-LES. The computation speeds and parallel computation performances are also determined.

## OUTLINE OF LBM

### Lattice Boltzmann equation

Instead of the Navier-Stokes equation, the LBM in this research simulates the fluid using the lattice Boltzmann equation, with the BGK approximation (Bhatnagar, Gross, and Krook 1954). The non-external-force lattice Boltzmann-BGK equation is expressed as Equation (1), where  $\Delta t$  is the discrete time,  $\mathbf{e}_a$  is the discrete speed in the  $a$ -direction,  $f_a(\mathbf{r}, t)$  is particle  $a$  s distribution function,  $f_a^{eq}(\mathbf{r}, t)$  is the equilibrium function, and  $\tau$  is the relaxation time.

$$f_a(\mathbf{r} + \mathbf{e}_a \Delta t, t + \Delta t) - f_a(\mathbf{r}, t) = \frac{1}{\tau} [f_a^{eq}(\mathbf{r}, t) - f_a(\mathbf{r}, t)] \quad (1)$$

### Discrete velocity scheme

The DdQq (d = spatial dimension, q = discrete particle speed) discrete velocity scheme (Qian, D Humières, and Lallemand 1992) is widely accepted for the LBM. In this research, the D3Q19 scheme was employed, as shown in Figure 1. Cubic lattices are used in this scheme, with 18 adjacent points for every lattice point. The particles only exist on the points, and move to an adjacent point, or just rest, during each time step. Therefore, the D3Q19 scheme has three types of particles, with motion speeds indicated in Table 1, where  $e$  is the particle speed,  $e = \Delta x / \Delta t$ , and  $\Delta x$  is the lattice length.

Figure 1. Lattice system of the D3Q19 scheme

Table 1. Discrete velocity of each particle

Particle No.	Discrete velocity	Motion paths
0	0	rest
1–6	$e$	along the normal axis
7–18	$\sqrt{2} e$	along the diagonal

### LES model in LBM

In this study, the LES (using the standard Smagorinsky SGS model) is implemented. According to the LES theory, the total viscosity  $\nu_{total}$  is composed of the molecular viscosity  $\nu$  and the eddy viscosity  $\nu_t$ . The  $\nu_{total}$  and  $\nu_t$  are given by Equation (2).

$$\nu_{total} = \nu + \nu_t, \quad \nu_t = (C_s \Delta)^2 |\bar{s}| \quad (2)$$

where  $C_s$  is the Smagorinsky constant,  $\Delta$  is the filter, and  $\bar{s}$  is the strain rate tensor. This is as same as the LES theory of the FVM.

Furthermore, the total viscosity can be calculated using Equation (3) by the LBM s theory.

$$\nu_{total} = e_s^2 (\tau_{total} - 0.5) \Delta t \quad (3)$$

where  $e_s$  is the speed of sound of the particles, and  $\tau_{total}$  is the total relaxation time. Therefore, the total relaxation time  $\tau_{total}$  is obtained from  $\nu_{total}$ , and it substitutes the original relaxation time  $\tau$  in Equation (1), to implement the LBM-LES simulation.

## OUTLINE OF SIMULATION TARGET AND SIMULATION CONDITIONS

The LBM-LES and FVM-LES (abbreviated to LBM and FVM below) approach was conducted for the indoor isothermal forced flow. The room model and simulation boundary conditions are shown in Figure 2 and Table 2, respectively. The room characteristics are  $L/H = 3$ ,  $h/H = 0.056$ ,  $t/H = 0.16$ , and  $Re = 5000$ , where  $L, H, h, t$  and  $Re$  represent the room length, room height, slot inlet height, outlet height, and the Reynolds number (refer to the inlet height and velocity), respectively. Since the inlet turbulence intensity of the experimental data is only 4% according to the IEA report, it can be considered to have a very small impact on the velocity, and thus, the inlet turbulence intensity was ignored in this simulation. A set of various uniform grid resolutions were employed, as illustrated in Table 3.

Figure 2. Sketch of the simulation target (from IEA Annex 20)

Table 2. Boundary conditions (B.C.)

Item	FVM-LES	LBM-LES
Sub-grid scale model	Standard Smagorinsky model ( $C_s = 0.12$ )	
Damping function	Van Driest-style	
Simulation domain	9.0 m (L) $\times$ 3.0 m (W) $\times$ 3.0 m (H)	
Time discretization	Euler-implicit	-
Space discretization	2 <sup>nd</sup> -order central difference	-
Simulation Period	Preparatory: 18 min, average: 6 min (air change rate: 0.172 min <sup>-1</sup> )	
Inlet B.C.	Uniform velocity boundary, $U_{in} = 0.455$ m/s, (no fluctuations)	
Outlet B.C.	Gradient-zero	
Other B.C.	Wall function (Spalding's law)	No-slip (Bounce-back)

Table 3. Case study

Case Name	Simulation Method	Grid size	Mesh quantity
LBM_004	LBM-LES	0.04 m (1/75 H)	1.6 M
LBM_002		0.02 m (1/150 H)	10.1 M
LBM_001		0.01 m (1/300 H)	81 M
FVM_004	FVM-LES	0.04 m (1/75 H)	1.6 M
FVM_002		0.02 m (1/150 H)	10.1 M

## RESULTS AND DISCUSSIONS

### Time-averaged scalar velocity

Figure 3. Normalized time-averaged scalar velocity of each cases

Figure 3 shows the normalized time-averaged scalar velocity of the central vertical section for the different cases. A large air circulation flow, which was equivalent to the room size, occurred

from the inlet, with a region-stagnated air flow in the center of the room. The LBM represented the flow features as well as the FVM. Nonetheless, a tendency of moving lower away from the ceiling, for the airflow from the inlet, could be observed clearly in LBM\_004. This is most probably because the LBM employed the standard bounce-back boundary condition, which excludes a wall function (such as the Spalding rule) for calculating the eddy viscous drag at the wall layer. Also, the damping function (such as the Van Driest style) is absent from the LBM, causing an overestimation of the eddy viscosity adjacent to the ceiling compared with the FVM, and it weakened as the LBM's grids became finer. This phenomenon did not occur in the FVM, regardless of grid resolutions, since the wall function and the damping function was employed.

### Comparison of the accuracy of LBM and FVM

The experimental data (Nielsen, Rong, and Olmedo 2010) was used to validate the accuracy. As shown in Figure 4, both LBM and FVM were generally able to represent the distribution tendency of  $\langle U \rangle$  (the mainstream direction component of the time-averaged mean velocity), except for LBM\_004, which demonstrated the most unacceptable accuracy. The LBM's accuracy improved as the grid resolutions improved in each region. For  $x = H$ , the velocities of all the LBM cases were under-predicted in the jet, most probably due to the absence of the damping function, while the FVM agreed well. Further, both LBM and FVM slightly underestimated the velocity on the height of the inlet at  $x = 2H$ , and the same was true along  $y = 1/2h$ . Along  $y = H - 1/2h$ , LBM cases agreed well with the experiment, as did the FVM.

Figure 4 shows the comparison of the RMS profiles of the horizontal velocity component ( $\text{RMS} = \sqrt{\langle u'^2 \rangle}$ ). Near the ceiling, at  $x = H$ , FVM overestimated the RMS, while the accuracy of the LBM was higher (especially LBM\_001). Along  $y = 1/2h$ , the FVM also over-predicted the RMS, and the LBM achieved a higher accuracy. On the other hand, both the LBM and FVM underestimated the RMS at the lower area, at  $x = 2H$  and along  $y = H - 1/2h$ . This underestimation of the RMS also appeared in the FVM-LES implemented by Davidson (Davidson and Nielsen 1996). In addition, because both the LBM and FVM demonstrated an underestimation at these areas, it may not be not an inherent problem of the LBM, but rather due to a difference between the simulations and experimental conditions.

Figure 4. Distribution of  $\langle U \rangle$  (top row) and RMS (bottom row)

The accuracy of simulations is quantitatively evaluated by considering all the experimental and predicted data of the corresponding spots, using the mean error (ME) defined by Equation (4), where  $V_{EXP(i)}$  and  $V_{LBM \text{ or } FVM(i)}$  are the experimental or predicted data of corresponding spots.

$$ME = \frac{1}{M} \sum_{i=1}^M |V_{LBM \text{ or } FVM(i)} - V_{EXP(i)}| \quad (4)$$

Figure 5 shows the ME of the measurement points at all the points (All Data), the points adjacent to the ceiling ( $y = 1/2h$ ), the ground ( $y = H - 1/2h$ ), and points far away from walls ( $x = H, 2H$ ). Generally, among all the LBM cases, the accuracy of  $\langle U \rangle$  was markedly improved when the grid resolution was changed from 0.04 m to 0.02 m, but only slightly improved when it was changed from 0.02 m to 0.01 m. The accuracy of the FVM cases was between that of LBM\_002 and LBM\_001. With respect to RMS, the accuracy of the LBM was almost the same at any grid resolution and was slightly better than the FVM. Whether for all points, or sub-regional points, the previous tendency was clearly observed. With regard to the sub-regional points MEs (for  $\langle U \rangle$ ), the maximum and minimum MEs appeared adjacent to the ceiling ( $y = 1/2h$ ) and to the ground ( $y = H - 1/2h$ ), respectively, regardless of simulation methods and grid resolutions. The difference in RMS among different sub-regions was small.

Figure 5. Mean Error (ME) of different grid resolutions

In conclusion, the same grid resolution of the LBM and FVM led to different accuracy levels in this study. More refined grids were required for the LBM to achieve the same accuracy than the FVM. The accuracy of LBM\_002 and LBM\_001 approximated that of FVM\_004 and FVM\_002, respectively, showing that the LBM required half the grid width of the FVM.

#### COMPUTATION SPEED AND PARALLEL COMPUTATION PERFORMANCE

The computation speeds, and parallel computation performances attained using the two methods, were compared using one node including two Intel (R) Xeon (R) E5-2667v4 @ 3.20 GHz (8 cores) CPUs, and the simulations were performed with different core utilization situations (1, 2, 4, 8, and 16). The elapsed computation time was normalized by the physical time for the flow motion (24 min), as shown in Figure 6. The computation times of both the LBM and FVM linearly decreased (approximately) with the increase in the cores, indicating that their speeds scaled well. The computation times of LBM\_002 and LBM\_001 were of almost the same order as those of FVM\_004 and FVM\_002, respectively, signifying that for the same accuracy, LBM and FVM used the same amount of computation time.

Figure 7 shows the LBM's computation speed ratio of the FVM of LBM and FVM with different core usage situations, and parallel efficiency for both the FVM and LBM. The computation speed of the LBM using one core was only 0.4 times that of the FVM, but it increased with increase in the number of cores, and finally became about 1.2 when the number

of cores approached 16. Although the parallel efficiency of both the LBM and FVM had initial values of 2-3, the parallel efficiency of the LBM increased to 24, whereas that of the increased only to 9. This signified that the parallel efficiency of the LBM responded much better to an increase in the number of cores.

Figure 6. Normalized computation time

Figure 7. Parallel computation efficiency

## CONCLUSIONS

In the indoor turbulent flow situation, the LBM can accurately represent the physical flow structure, and this accuracy improves as the grid resolution becomes higher. The grid width needed for the LBM is approximately half that of the FVM, to achieve the same level of accuracy, partly due to the absence of the wall function in the LBM. Regarding the computation speeds, the speeds of both the LBM and FVM scaled well with an increase in cores quantity in one node. The speeds of LBM and FVM were on approximately the same level for the same degree of accuracy, even though the LBM's mesh was 8 times that of the FVM's. The speed of the LBM corresponding to 1-core is much slower than the FVM, while the speeds corresponding to 16-core became faster due to the better parallel simulation performance of the LBM. Furthermore, the LBM parallel speedup scales well with the increase in the cores, whereas FVM suffers from an upper limitation. Therefore, the speed of the LBM may be further increased by employing more cores (for e.g., in supercomputers); this will be considered in future research.

### ABSTRACT

The U.S. Department of Energy supports the development of commercial building energy codes and standards by participating in industry reviews, update processes, and providing technical analyses to support both published model codes and potential changes. In support of ANSI/ASHRAE/IES Standard 90.1 and the International Energy Conservation Code, 16 commercial prototype building models were developed that cover 80% of the commercial building floor area in the United States for new construction, including both commercial buildings and mid- to high-rise residential buildings, across all U.S. climate zones. However, the current set of commercial prototype building models does not include a supermarket building type, which is one of major building types defined in the Energy Information Administration's Commercial Building Energy Consumption Survey. As part of an ongoing effort to expand the current Commercial Building Prototype Model suite, this paper presents the procedure used to develop the prototype supermarket building model based on multiple studies as well as a previously developed reference building model. The final set of prototype models includes 68 models for different vintages of ASHRAE Standard 90.1 (i.e., 2004, 2007, 2010, and 2013) and for 17 ASHRAE climate zones.

Commercial Building Prototype Model, EnergyPlus, OpenStudio, Supermarket

### INTRODUCTION

The U.S. Department of Energy (DOE) supports the development of commercial building energy codes and standards by participating in industry reviews and update processes, and provides technical analyses to support both published model codes and potential changes. DOE publishes its findings to ensure transparency and to make its analysis available for public use. In conjunction with this effort, DOE's flagship building energy modeling (BEM) tools consist of the open-source EnergyPlus simulation engine and the OpenStudio software development kit. These tools allow a user to modify a building and estimate energy use. New releases of these tools are typically downloaded by over 40,000 users.

As part of DOE's support for ANSI/ASHRAE/IES Standard 90.1 (ASHRAE, 2016a) and the International Energy Conservation Code (IECC) (ICC, 2015), researchers at Pacific Northwest National Laboratory (PNNL) apply a suite of prototype buildings covering approximately 80% of the U.S. commercial building floor area (Goel et al., 2014; Deru et al., 2011). These buildings include new and existing construction, mid- to high-rise residential buildings and span all U.S. climate zones. These prototype buildings—derived from DOE's Commercial Reference Building Models<sup>1</sup>—cover all Reference Building types except for supermarkets, and an additional prototype representing high-rise apartment buildings. Since Standard 90.1 and IECC are updated every three years, PNNL modifies the commercial

<sup>1</sup> Available in <https://www.energy.gov/eere/buildings/commercial-reference-buildings>

prototype building models with extensive input from ASHRAE 90.1 Standing Standards Project Committee (SSPC) members and other building industry experts.

The prototype models include 16 commercial building types in 17 climate locations (across all 8 U.S. climate zones) for recent editions of Standard 90.1 and IECC. The combinations result in an overall set of 2,176 total building models (in EnergyPlus Version 8.0). The supermarket model was excluded from the original prototype suite for the following reasons: 1) the building type covers a relatively small percentage of total commercial floor area (EIA, 2003), 2) the refrigeration equipment/system was not regulated by earlier versions of ASHRAE Standard 90.1, and 3) there was insufficient data regarding common design practice. Newer versions of ASHRAE Standard 90.1 include regulations for refrigeration systems, and more data is now available for supermarket building characteristics (especially for refrigeration systems). This study leveraged multiple sources to develop the OpenStudio supermarket prototype building model. This paper presents the research conducted to define the building and system characteristics for prototype supermarkets, and the final prototype building energy models for supermarkets.

## METHODS

The new supermarket prototype building model was developed based on extensive review of existing literature and resources as well as the original, post-1980 supermarket reference model. The basic building size, shape, and window distribution of the new prototype follows the original reference model, consisting of a one-story building, 4,181 m<sup>2</sup> floor area, floor-to-floor height of 6.10 meters, and window area of 130 m<sup>2</sup>. This building form was originally defined based on the 2003 *Commercial Buildings Energy Consumption Survey* (CBECS) and DOE Benchmark documents (EIA, 2003; DOE, 2008). Subsequently, the space types and their internal layout were updated based on the *Grocery Store 50% Energy Savings Technical Support Document* (Leach et al., 2009). The updated space types in this report were also used in the development of the baseline model found in ASHRAE's *Advanced Energy Design Guide (AEDG) for Grocery Stores* (ASHRAE, 2015). Figure 1 shows allocated floor area for each space type in the newly-developed prototype building model. The original reference model consists of 6 space types, whereas the updated prototype building consists of 13 space types. With the additional space types, the model more accurately reflects actual supermarket buildings. In addition, the corresponding space attributes (including occupancy density, lighting power density, plug load and ventilation rate) are defined for each space type to represent properties based on surveys of supermarket buildings. These space attributes are in alignment with the requirements from each vintage of ASHRAE Standard 90.1 and ASHRAE Standard 62.1 (ASHRAE, 2016b). The operating hours for the prototype supermarket are 6:00

Figure 1. Supermarket space layout and floor area per space type

am through 10:00 pm, Monday through Sunday, with occupancy and lighting schedules defined in accordance with ASHRE 90.1-1989. The dominant wall type is mass (e.g., brick, stone, or concrete) (EIA, 2003) and the roof type is all insulated above deck (ASHRAE, 2016a).

The heating, ventilation, and air conditioning (HVAC) system for the new model consists of a unitary rooftop unit with direct expansion (DX) coils and natural gas heating, as defined by CBECS (EIA, 2003). The supply fans are constant volume. The efficiency of the cooling and heating units, including economizers, are defined per ASHRAE 90.1 requirements.

Major updates were made to the refrigeration system in the new prototype building model. Since there were no regulations for the refrigeration system in ASHRAE Standard 90.1-2004, the requirements for the refrigeration system were assumed to be the average of nationwide standard design practice in the corresponding year. In updating the refrigeration system, first, based on the AEDG project committee's feedback, the original refrigeration system in the reference model was modified with longer display cases and increased walk-in cooler/freezer space. The original reference model has 6 refrigerated display cases, 5 refrigerated walk-ins, and 4 compressor racks, while the updated model has 26 refrigerated display cases of 7 different types, 10 refrigerated walk-ins, and 4 refrigeration systems. The low-temperature (LT) display case models include specifications for coffin ice cream, coffin frozen food, reach-in ice cream and reach-in frozen food cases, while the medium-temperature (MT) display case models include coffin, vertical open, service and reach-in cases. For "old" systems (ASHRAE 90.1-2004, 2007 and 2010) and "new" systems (ASHRAE 90.1-2013), typical values for the rated capacity, fan power, lighting power, anti-sweat heater power, defrost type and power, and evaporator temperature of these display case types (for both "old" and "new" vintage cases) were defined, based on statistical analysis of refrigeration system manufacturers' data. A summary of the display case types and their specifications are given in Table 1. Furthermore, walk-in cooler/freezer cooling capacity was defined in terms of walk-in floor area, based on a least-squares fit of walk-in manufacturers' performance data. In the prototype supermarket models, the total length of the display cases is 225.2 m, and the total insulated floor area for the walk-ins is 321 m<sup>2</sup>.

Table 1. Summary of selected display case performance parameters.

Case Type	Rated Cooling Capacity (W/m)		Defrost Type		Evaporator Temperature (°C)	
	Old	New	Old	New	Old	New
<b>LT Cases</b>						
Coffin Ice Cream	695	521	Electric	Electric	-28.9	-32.2
Coffin Frozen Food	589	436	Electric	Electric	-25.6	-26.7
Reach-in Ice Cream	618	462	Electric	Electric	-28.3	-27.4
Reach-in Frozen Food	584	425	Electric	Electric	-23.9	-23.3
<b>MT Cases</b>						
Coffin	1250	303	Off cycle	Electric	-6.1	-6.4
Vertical Open	1438	1143	Off cycle	Off cycle	-6.1	-3.1
Service	404	599	Off cycle	Off cycle	-7.8	-6.4
Reach-In	--	309	--	Off cycle	--	-0.8

Generic compressor performance maps are provided for modeling “old” compressor racks (using reciprocating compressors) and “new” compressor racks (using scroll compressors). Compressor racks utilize air-cooled condensers, and condenser fan power has been fit to compressor heat rejection capacity based on condenser manufacturers’ data. To simplify the model development, only limited number of inputs value were entered, and other required input parameters were automatically calculated based on further study from refrigeration system manufacturers’ data and statistical analysis.

Once all the building characteristics for the prototype supermarket building were defined, the prototype building model was generated in an automated fashion. An OpenStudio Measure was used to automatically generate the supermarket prototype building for 16 climate locations and 4 building standards (Roth et al., 2016). This measure, OpenStudio-Standards, provides mechanisms to add new building types, such as the supermarket, and its building characteristics. Additionally, the measure automatically assigns and models all 90.1 building standard requirements. By using an OpenStudio Measure, the OpenStudio-Standards can be used to generate OpenStudio Prototype Buildings using all OpenStudio workflows.

## RESULTS

Based on the procedure described above, the final set of 68 prototype supermarket models were created covering different vintages of ASHRAE Standard 90.1 (i.e., 2004, 2007, 2010, and 2013) and for 17 ASHRAE climate zones. We compared the models for ASHRAE Standard 90.1-2004 to the original, post-1980 vintage reference building. Figure 2 presents the annual site energy by end use for the prototype building models and the post-1980 reference building models. The comparison shows that the overall refrigeration system energy use increased for the new prototype models in all climate zones since there were major updates to the refrigeration system, and the size (e.g., linear length of case) of the refrigeration system increased. The reduction in cooling energy use in warmer climates and heating energy use in colder climates is primarily due to improved building envelope systems and reduced infiltration rates. Other end uses such as interior/exterior lighting and interior equipment are nearly identical. The difference in total site energy use between the new prototype model and the original referent model ranged from -13% to 11%.

Total simulated energy use was also compared with real-world surveys of energy use data from EIA’s CBECS (EIA, 2003). According to CBECS, the national average energy use per unit floor area for the building type “food sales” is 630.2 kWh/m<sup>2</sup>. The simulated energy use intensity (EUI) across climate zones for the new supermarket model are between 610 and 902 kWh/m<sup>2</sup>. These simulation results appear reasonable given that CBECS includes all (i.e., old and new) existing supermarket buildings. The largest energy use within the supermarket is attributed to “Refrigeration”, and CBECS shows the EUI for refrigeration energy use is about 299 kWh/m<sup>2</sup>, close to the simulated refrigeration use, which ranges from 233 to 298 kWh/m<sup>2</sup>.

Figure 3 shows the total site energy use of the prototype supermarket model for different climate zones and different ASHRAE 90.1 vintages. As shown, the total energy use decreases for newer vintages, but there is a larger decrease for the 2013 vintage. This is primarily due to the reduced refrigeration energy use since the refrigeration system in 2004, 2007, and 2010 was defined as an “old system”, while the system for 2013 model was defined as a “new system”. The total energy use for the 2013 model is about 29 to 36% lower than the 2004 model.

Figure 2. Annual site energy for the 2004 prototype supermarket models (left) vs. the post-1980 reference supermarket models (right)

Figure 3. Annual site energy for the supermarket models corresponding to ASHRAE 90.1-2004, 2007, 2010, and 2013.

## DISCUSSIONS AND CONCLUSIONS

As an effort to expand the current Commercial Building Prototype Model suite, this paper presents the procedure and results of developing a prototype supermarket building model. The final set of prototype models includes 68 models for different vintages of ASHRAE Standard 90.1 (i.e., 2004, 2007, 2010, and 2013) and for 17 ASHRAE climate zones, and the modelled energy uses are consistent with existing data from multiple sources.

### ABSTRACT

The urban street canyon has been widely recognized as a basic surface unit in urban micrometeorological studies. Urban canopy models (UCMs), which quantify the exchange of energy and momentum between the urban surface and the overlying atmosphere, often adopt this type of street canyon representation as the fundamental surface element. Since UCMs can be coupled to regional-scale weather and climate models such as the Weather Forecast and Research Model (WRF), parametrizations of the surface momentum and scalar fluxes in UCM are of paramount importance. However, many current single-layer UCMs rely on empirical relations that were obtained over 80 years ago and often invoke the exponential wind profile derived from the existing literature for vegetation canopy. In this study, we conducted wall-modeled large-eddy simulations (LES) to study the forced (very weak buoyancy) convective heat transfer over idealized two-dimensional street canyons. It shows that the transfer efficiency computed following commonly applied resistance formulations can be one order of magnitude lower than LES results. The main reasons for the deviation include inaccurate wind speed parameterization and the use of a log-law based formulation for turbulent heat exchange between canyon air and the flow above.

### KEYWORDS

Large-eddy simulation, convective heat transfer, urban canopy model

### INTRODUCTION

Buildings do not exist as isolated objects. Their energy consumptions are subject to their external environment and especially the climatic factors such as wind speed, temperature and moisture (Li and Sailor, 1995). To represent this impact of urban climate on building performance, various building energy models have been implemented into urban canopy models (UCMs) (Kikegawa et al. 2003; Salamanca et al. 2010; Bueno et al. 2011). A UCM is one type of urban land-surface model that accounts for the surface heat balance using the street canyon as the prototypical element for the surface. Different UCMs of different degrees of complexity exist in the literature, e.g. (Masson, 2000; Ryu et al. 2011; Wang et al. 2013). Buildings exchange energy with the surrounding environment via conductive, radiative, and convective heat transfer processes. While the two former processes are captured relatively well by current UCMs, convective transfer poses significant challenges.

Nevertheless, accurate modelling of convective heat transfer is essential for building energy simulation (Mirsadeghi et al. 2013). For example, as summarized by Palyvos (2008), the wall convective heat transfer coefficient (CHTC), often denoted by  $h$ , could lead to errors in energy demand calculation of 20-40% if set improperly. The convective heat transfer due to turbulent air motions around the building envelopes has been parameterized in UCMs using empirical relations derived in the 1920s, such as the so-called Jürges formula (Rowley et al.

1930). One way to obtain better estimates of  $h$  is to use computational fluid dynamics (CFD) modelling to calculate the rate of convective heat transfer, with the CFD model coupled to the building energy model (Zhai et al. 2002; Zhai and Chen, 2004; Defraeye et al. 2010). However, this is not feasible for more than a few buildings and thus not applicable directly in a UCM. However, CFD results could be used to develop reduced parametrizations of convective heat transfer in UCMs, which have not been analyzed in detail. Therefore, this study conducts large-eddy simulations (LES) to assess the current formulation of convective heat transfer, as well as to propose possible reasons for its success or failure.

## METHODS

LES is one type of computational fluid dynamics models, in which the large-scale fluid motions are explicitly resolved and appropriate subgrid-scale models are implemented for turbulence closure. We use a research code, which shares many commonalities with the open-source code LESGO (<https://github.com/lesgo-jhu/lesgo>). Details of the current LES code, validations of the turbulent quantities and convective heat transfer coefficients for two-dimensional roughness elements can be found in previous studies (Bou-Zeid et al. 2005; Chester et al. 2007; Li et al. 2016a,b). A surface of two-dimensional street canyons of various height-to-width aspect ratios  $H/W$  are considered in this study. The boundary conditions are horizontally periodic and free-slip for velocity at the top of the domain (Figure 1a). The net radiation on all surfaces (i.e., roof, wall, and road) is kept at  $800 \text{ W/m}^2$ , and the wall-model is coupled to a conduction model with a constant indoor temperature at  $25^\circ\text{C}$ , similar to the setup in Li and Wang (2017). 16 points are used to represent the obstacle height  $H$  at 12.5 m. The total number of points in each direction is shown in Fig. 1a and grid resolution is the same in all three directions.

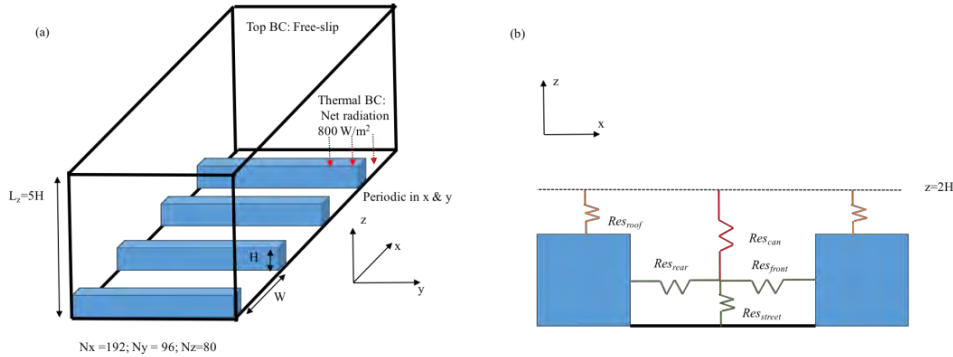

Figure 1. Sketch showing domain setup of LES in (a) for  $H/W=1/2$  and (b) schematic diagram of resistance, the dotted line denotes the ‘reference height’ at  $z=2H$ , which is not shown to scale.

## RESULTS

The exchange of energy between building facets with canyon air and canyon air with the flow above is often conceptualized as a resistance network (Fig. 1b), such as in previous UCMs and those coupled with EnergyPlus (Bueno et al. 2011). Resistance is related to  $h$  by  $R = (h/\rho C_p)^{-1}$ , where  $\rho C_p$  is the volumetric heat capacity. Since  $h$  is the heat flux divided by the wall-fluid temperature difference, the normalized canyon resistance is computed as

$$R_{can} = \frac{\langle T_{can} - T(z=2H) \rangle}{\langle Q_H \rangle / \rho C_p}, \quad (1)$$

where  $\langle \rangle$  denotes averaging over the canyon width for all canyons in the computational domain;  $T_{can}$  is the air temperature averaged over the entire canyon;  $T(z=2H)$  denotes air

temperature at  $z=2H$ ;  $Q_H$  is the sensible heat flux from the resolved and subgrid-scale contributions. Values of the canyon resistance span almost two orders of magnitude for the five different cases of canyon aspect ratios considered in this study (Fig. 2).

Figure 2. The canyon resistance  $R_{can}$  normalized by  $u_*$ , the friction velocity, for different values of  $W/H$  indicated by the legend.

Figure 3 shows the height averaged canyons resistance,  $\langle Res_{can} \rangle_z$  plotted as a function of the difference between  $U_a$ , the horizontally averaged mean streamwise velocity at  $z=2H$ , and  $U_{can}$ , which is defined as the average magnitude of the vector sum of the horizontal and vertical components of velocity averaged over all non-solid grids for  $z \leq H$  (Fig. 3a). All velocities in subsequent analyses are normalized by  $u_*$ . The square symbols denote modelled values based on the log-law and constant momentum and heat roughness lengths (e.g. Masson 2000).  $\langle Res_{can} \rangle_z$  is also plotted as a function of the streamwise velocity averaged over the canyon space,  $\langle U \rangle_z$ , in Fig. 3b.

Figure 3. The averaged canyons resistance plotted as a function of  $U_{can}^2$  in (a) and  $\langle U \rangle$  in (b). Square: model in (Masson 2000), where  $Res_{can} \sim \log(z/z_{0m})\log(z/z_{0h}) / (U_a - U_{can})$ ; circles are LES results.

The wall resistance  $R_{facet}$  is computed as the average over the facet of

$$R_{facet} = \frac{T_{facet} - T_{canyon}}{\langle Q_{Hwall} \rangle / \rho C_p} \quad (\text{rear, street and front facets}), \quad R_{roof} = \frac{T_{roof} - T(z=2H)}{\langle Q_{Hwall} \rangle / \rho C_p}, \quad (2)$$

where  $T_{air}$  is the air temperature at the closest grid to the wall surface;  $T_{canyon}$  is the air temperature averaged over the canyon space (for all rear, front and street facets) or  $T_{air}$  at  $z=2H$ ;  $\langle Q_{Hwall} \rangle$  is the facet-averaged sensible heat flux computed from the wall model in LES. Figure 4 shows the spatial variability of  $u_*(h/\rho C_p)^{-1}$  for different facets of the two-dimensional obstacles, where  $h$  is the CHTC computed from the LES wall-model averaged over  $y$ . Cases with  $H/W=2$  and 1 have similar roof resistances (Fig 4a), but a wider street canyon, especially  $W/H=5$ , has approximately 25% higher resistances than those in  $H/W=2, 1$  and  $1/2$ . It is also interesting to note that the rear surface resistance is higher for smaller aspect ratio (i.e.  $H/W < 1/2$ ), which could lead to overall smaller average wall resistance as demonstrated in Figure 5. The wall resistance averaged over different facets as a function

$U_{can}^2$  and comparisons to some of the convective heat transfer formulations defined as  $\rho C_p(11.8+4.2U_{can}^2)^{-1}$  (Rowley et al. 1930) in UCMs are plotted in Fig. 5.

Figure 4. The wall resistance normalized by  $u^*$  for different facets of the street canyon for  $W/H$  indicated by the legend. a) roof, b) rear surface, c) front surface, d) ground.

Figure 5.  $Res_{facet}$  averaged over different facets as a function of  $U_{can}^2$ . The mean of  $Res_{facet}$  is the average over rear, ground and front surfaces. From low to high  $U_{can}^2$  corresponds to  $H/W = 2, 1/5, 1/11, 1$  and  $1/2$  respectively.

## DISCUSSION

The spatial variation of canyon resistance demonstrates some commonalities for canyons of different aspect ratios. The most pronounced peak in  $Res_{can}$  is observed for  $H/W = 1/2$  at around  $z/H = 0.6 - 0.8$  in Fig 2. Although other cases also show similar peaks, the pronounced peak is associated with street canyons that are categorized as ‘wake interference’ flow regime (Oke 1987), where the recirculation regions behind the two-dimensional obstacles impinge on the obstacle downstream. For regions  $z/H < 0.5$ ,  $R_{can}$  decreases with aspect ratio as shown in Fig. 2. Street canyons with  $H/W < 1/2$  have a smaller resistance, leading to higher turbulent heat fluxes given a constant temperature difference between the canyon air temperature and surface temperature. However, the canyon averaged  $R_{can}$  as shown in Fig. 3 is predominantly affected by the maximum values of  $R_{can}$ . The recirculation region, where the mean streamwise velocity becomes negative, is evident for  $H/W > 1/2$ . The case of  $H/W = 1/2$  features the most negative canyon averaged streamwise velocity and the highest  $\langle R_{can} \rangle_z$ , which is the  $R_{can}$  averaged over the entire street canyon.  $\langle R_{can} \rangle_z$  decreases monotonically with the canyon averaged wind speed. Notice that the simulations only consider the canyon axis perpendicular to the streamwise direction, which facilitates the formation of strong recirculation bubble. The ubiquitously adopted exponential wind profile for the canopy layer in UCMs (Masson 2006; Ryu et al. 2011; Wang et al. 2013) are usually considered as an average over all wind directions. Future studies of variable wind directions can be included in LES and investigate

how the canyon wind speed can be used as the key dependent variable for parameterization of the canyon resistance.

The canyon wall resistance is important to quantify the turbulent heat transfer between individual facet and the canyon air for the rear, front and ground faces in particular. The Jürges formula (Rowley et al. 1930) applied with the canyon wind speed computed from LES (Jürges 2) has almost one order of magnitude difference compared to the LES results, although the decreasing trend with higher  $U_{can}$  is consistent. Results using the parameterized canyon wind speed according to Masson (2000) (not shown here) show over prediction of the canyon wind speed. This demonstrates that the importance of improving the accuracy of the canyon wind speed when the Jürges formulation is invoked, such as using a CFD model to parameterize  $U_{can}$  for different wind directions as propose by Ryu et al. (2011). The empirical Jürges formula in the form of  $(a+bU_{can}^2)^{-1}$ , where  $a$  and  $b$  are both tuneable parameters, could still be a valid formulation.

On the other hand, the roof resistance in Fig. 4 shows both inconsistent trend and large bias in magnitude compared to the formulation based on the log-law wind profile over a rough surface. Alternative parameterization of the roof resistance assuming the flow is a free shear layer (Harman et al. 2004) gives rise to  $R_{roof}=(U_{ref}-U_{roof})/u_*^2$ . We also tested plotting  $R_{roof}$  as a function of  $\Delta U=U(z=2H)-U_{roof}$ , where  $U_{roof}$  is taken as the velocity at  $z=1.06H$  averaged over points directly above the roof surfaces (not shown here). A monotonic change in  $R_{roof}$  with  $\Delta U$  suggests that the free shear layer could be a more appropriate conceptual model to parameterize the roof resistance, instead of using the parameterization based on log-law, which assumes that the boundary layer is in equilibrium with the roof surface. More investigations of how the free shear layer impacts the roof resistance will be carried out.

## CONCLUSIONS

We applied the LES model to study the convective heat transfer coefficient for idealized two-dimensional street canyons of different aspect ratios. The canyon and surface resistance were computed and compared with the Jürges formula (for rear, front and ground surfaces) and log-law based formulation (for canyon and roof surface). It was found that the current formulation, on average, predicts resistances one order of magnitude smaller than results from LES. Although the Jürges formula appears capable of capturing the trend of surface resistance as a function of the canyon wind speed, it is essential to obtain more accurate estimates of the canyon wind speed. Canyon wind speed computed from the exponential relation has been shown by Castro (2017) to be inappropriate for roughness canopy and alternative wind speed parameterizations need to be formulated for better representation of forced convective heat transfer. Our preliminary results also show that the canyon and roof resistances could be improved by considering a free shear surface and using the difference in mean velocity as the dependent variable. Future work includes simulations of multiple wind directions, expanding the range of canyon aspect ratio and testing the resistance parameterizations in UCMs.

## ACKNOWLEDGEMENT

This work is supported by the US National Science Foundation's Sustainability Research Network Cooperative Agreement 1444758. The simulations were performed on the supercomputing clusters of the National Centre for Atmospheric Research through projects P36861020 and UPRI0007.

### ABSTRACT

Energy modeling packages such as EnergyPlus and TRNSYS come with capable airflow network solvers for natural ventilation evaluation in multi-zone building energy models. These approaches rely on pressure coefficient arrays of different wind directions based on simple box-shaped buildings without contextual obstructions. For specific sites, however, further attention is needed to avoid geometric oversimplification. In this study, we present an automated and easy-to-use simulation workflow for exterior airflow simulation based on OpenFOAM to generate pressure coefficient arrays for arbitrary building shapes and contextual situations. The workflow is compared to other methods commonly used to obtain pressure coefficients for natural ventilation simulation.

### KEYWORDS

Natural Ventilation, Airflow Networks, Pressure Coefficients, Computational Fluid Dynamics.

### INTRODUCTION

Due to urbanization and population growth, the United Nations expects a construction demand that is equivalent to 750 times the size of Rome (Heilig, 2012). This may be a unique opportunity to improve the built environment and quality of life through an integrated design process that utilizes Building Energy Modeling (BEM) to create high-comfort habitats with low carbon footprints. The majority of the construction volume is expected to take place in warmer, subtropical and tropical climates. Here, studies have shown that natural ventilation (NV) can be an effective method for space cooling and can lead to significant energy savings compared to mechanical ventilation (Cardinale, Micucci, & Ruggiero, 2003; Oropeza-Perez & Ostergaard, 2014). BEM packages like *Energy Plus* and *TRNSYS* come with capable airflow network (AFN) solvers for NV evaluation in multi-zone BEMs. These solutions rely on pressure coefficient ( $c_p$ ) arrays of different wind directions and exterior simulation nodes. For simple, box-shaped buildings without contextual obstructions, lookup tables and fast methods for surface-averaged pressure coefficient generation exist, such as the work of Swami and Chandra (Swami & Chandra, 1988) now implemented in *EnergyPlus*, or the wind-pressure distribution model *CpCalc+* developed for *COMIS* (Grosso, 1992). Since then, many attempts have been made to deal with air flow sheltering effects for simplified urban geometries and there is an evolving literature about pressure coefficients for sheltered buildings that are summarized by (Costola, Blocken, & Hensen, 2009). However, for specific sites such as dense urban environments, further attention is needed to avoid geometric oversimplification (Cheung & Liu, 2011). In such cases, computational fluid dynamics (CFD) analyses are required. CFD is a numerical method to calculate the desired flow variables on a number of grid points within a simulation domain by solving discretized Navier-Stokes equations (NSE).

However, the expertise, the modeling effort, and simulation overhead required to perform such analyses often hinder a wider dissemination of AFN-based NV studies. To facilitate modeling of NV in early design processes at urban and complex architectural scale, the authors introduce

*Eddy*, an easy-to-use tool, that utilizes OpenFOAM to conduct isothermal exterior airflow simulations to generate pressure coefficient ( $c_p$ ) arrays for the AFNs. The framework is fully automated and generates  $c_p$  arrays for arbitrary building shapes and contextual situations using a novel cylindrical domain approach to avoid expensive re-meshing of the domain for different wind directions. Further, a case study for an urban building is presented to compare CFD-based  $c_p$  values against the wind pressure distribution model of *CpCalc+* and *EnergyPlus*' internal  $c_p$  calculation method called "Average-Surface Calculation" (Swami & Chandra, 1988). The  $c_p$  results of each method are subsequently passed on to an *EnergyPlus* BEM with an AFN to evaluate the differences in NV potential using the different NV simulation modes provided by *EnergyPlus*.

## METHODS

**Overview:** Usually, five steps are required to compute  $c_p$  arrays for AFN simulations: (1) modeling the building geometry and context with CAD software; (2) defining the simulation domain and meshing of the building geometry and topography; (3) conducting isothermal airflow simulations for a set of wind directions using appropriately assigned boundary conditions; (4) post-processing the CFD data and extracting pressure values on openings for multiple directions and (5) setup of energy model and AFN while providing  $c_p$  arrays for all openings in the model. In most cases, these steps are conducted manually and tend to be tedious and error-prone, especially when they have to be repeated multiple times. For step 2 and 3, several best practice guidelines propose adequate domain dimensions, convergence criteria, and relaxation factors. For basic urban CFD simulations, it is considered best practice to construct a box-shaped virtual wind tunnel with predefined dimensions with respect to the building geometry that shall be simulated. A widely used best practice proposed by (Tominaga et al., 2008) suggests the size of the simulation domain to be  $z = 6H_{max}$ ,  $l = 20H_{max}$  and  $w$  given by a blocking ratio of  $\leq 3\%$ , where  $z$ ,  $l$ , and  $w$  are the dimensions of the domain and  $H_{max}$  is the height of the tallest building in the building agglomeration. The blocking ratio is defined as the ratio of building area perpendicular to the inlet to the total area of the inlet. A visual representation of those suggestions is illustrated in Figure 1 (A). For cases where symmetry cannot be exploited and where the weather does not have strongly pronounced predominant wind directions, the steps 2-4 would have to be repeated at least eight times to cover approaching wind in  $45^\circ$  increments. However, interpolating the remaining in-between directions often results in significant errors (Cheung & Liu, 2011). This can only be overcome by further increasing the wind direction increments, resulting in greater meshing, simulation, and post-processing time.

**Cylindrical simulation domain:** To circumvent re-meshing of the simulation domain for every wind direction and to reduce manual and computational overhead, a cylindrical mesh is used to facilitate the simulation of arbitrary wind directions, see Figure 1 (B). The modeling approach has been validated against three cases with measured data showing insignificant differences compared to the best practice box-domain approach (Kastner & Dogan, 2018). Furthermore, the proposed method automates the setup of boundary conditions so that a significant amount of time will be saved to change the boundary conditions in case of an annual wind analysis. More specifically, every lateral cylinder patch represents an adjustable and therefore sufficiently small circular sector and can be assigned to either inlet (blue) or outlet (red) conditions depending on the wind direction of interest, see Figure 1 (B).

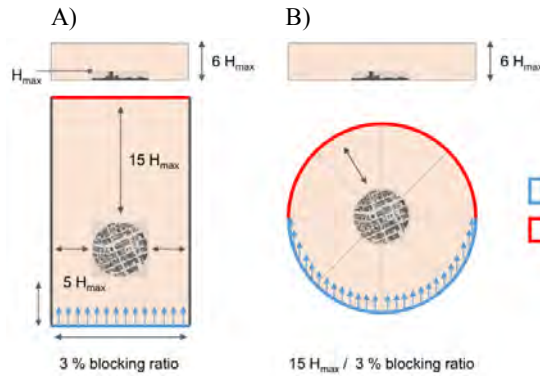

Figure 1: Top view of the (A) of a typical simulation domain for an arbitrary urban area; (B) top view of proposed cylindrical simulation domain accounting for the same best practice requirements.

Figure 2: CAD model of the test case. Case one is simulated without contextual obstructions. Case two is simulated as depicted. Red highlights the zone that was modeled in EnergyPlus.

Figure 3: Flow-chart for proposed  $c_p$  generation methodology

**Implementation:** The procedure above has been fully automated and implemented in C# as a plugin for Rhino v5 (Robert McNeel & Associates, 2016b) and Grasshopper (Robert McNeel & Associates, 2016a) for seamless design workflow integration. The developed tool, called *Eddy*, consists of the following main components: (1) the Domain-Builder sets up the cylindrical simulation domain by analyzing the input geometry and applying best practice rules. The Domain-Builder organizes geometric and non-geometric input data and manages the setup of all cases required to model different wind directions (2). The Meshing-Component creates one circular domain mesh that can be used for all wind directions. (3) The CFD-simulation component executes the simulations and encapsulates the result processing routines and probes data for a given slice, envelope or point (figure 4).  $c_p$  values are then automatically calculated for all façade openings. A coupling to the Archsim interface for *Energy Plus* (Dogan, 2018) is provided. All simulation framework components and the flow of inputs and outputs are illustrated in Figure 3. Numerical simulations are based on the open source CFD library *OpenFOAM*, using its steady-state RANS models and solvers in combination with a  $k-w-SST$  turbulence model. Pressure and velocity were coupled with the SIMPLE algorithm using three non-orthogonal correctors. Buoyancy effects were neglected due to the domain-decoupled approach and the given air velocities that are well above 1.8 m/s (Ramponi & Blocken, 2012; Tecle, Bitsuamlak, & Jiru, 2013). The framework uses a combination of a logarithmic, exponential or uniform profile as introduced by (Bueno, Roth, Norford, & Li, 2014). Further, we assumed that convergence was obtained when reaching residuals of  $1e-4$  for  $p$  and  $1e-5$  for the remaining parameters. The relaxation factors were chosen to be 0.7 for  $p$  and 0.3 for  $U$ ,  $k$ , and  $\omega$ . Relative wind pressure coefficients ( $c_{p,r}$ ) are defined as the difference of the wind pressure coefficient with respect to the inlet condition as given in equation (1) (ASHRAE,

2013). The subscript (*i*) labels the inlet condition. The pressures  $c_p$  and  $c_{p,i}$  are obtained from CFD simulation results. The reference velocity ( $u_{ref,nv}$ ) is mainly used to normalize the nodal pressure, and can therefore be set as the largest freestream velocity at the top of the modeling domain. Further, ( $\rho$ ) is the density of air given in kg·m<sup>-3</sup>. Those pressure differences can be utilized to calculate flow rates and air changes per hour, thus in turn estimating the NV potential.

$$c_p^* = c_p - c_{p,i} = \frac{p - p_{atm}}{\frac{1}{2}\rho u_{ref,nv}^2} - \frac{p_i - p_{atm}}{\frac{1}{2}\rho u_{ref,nv}^2} = \frac{p - p_i}{\frac{1}{2}\rho u_{ref,nv}^2} \quad (1)$$

**Case study:** Figure 2 shows the case study (Architectural Institute of Japan, 2003) used for the coupling of CFD-based  $c_p$  values with an *EnergyPlus* energy model using an AFN. The scale ratio used for the simulations in this paper is 100:1. The  $c_p$  values generated with the proposed CFD workflow are compared to *CpCalc+* and the Swami & Chandra model implemented in *EnergyPlus*. The latter only calculates surface-averaged  $c_p$  values for orifices with respect to the incident wind angle. The obstructed case shown in Figure 2 is compared to an unobstructed case for which all eight surrounding buildings have been removed. Further, a single zone on the third floor with two opposing orifices (red) is modeled in *EnergyPlus* to compute indoor temperatures, air change rates, cooling loads, and the ASHRAE 55 Adaptive Comfort model. For this zone, a hybrid NV system is assumed that switches to full mechanical cooling if the outdoor air temperature increases beyond 28°C. For each variant, the zone is modeled based on either a residential, classroom or office setting using SIA space templates (SIA, 2006) as well as based on heavy mass or lightweight structure with an average envelope U-Value of 0.4 [W/m<sup>2</sup>K]. Using weather data from Darwin, Cairo, Hyderabad, Mumbai, New Delhi, Nairobi, Mexico City, Karachi, Manila, Bangkok, Tunis, Izmir, Taipei, Caracas, Cape Town, Melbourne, and Singapore — each variant was further tested yielding a total 102 simulation variants.

## RESULTS

Figure 4 compares the  $c_p$  values retrieved from the CFD simulation and *CpCalc+*. Without the surrounding buildings, both methods are in good agreement. With surrounding obstructions, *CpCalc+* exceeds its confidence interval and is neither able to estimate  $c_p$  distributions nor pressure differences between facades. A comparison of the  $c_p$  values of all three methods for eight wind directions is given in Figure 5. The results show that both *CpCalc+* and Swami & Chandra consistently overestimate the  $c_p$  arrays. This overestimation leads to significantly deviating air change rates calculated by the AFN in *EnergyPlus* as shown in Figure 6 (left and middle). However, this influence is less significant with respect to the comfort hours where the majority of predictions fall within a  $\pm 5\%$  interval (Figure 6 (right)). Nonetheless, significant outliers exist when the cooling potential of NV reaches its limit and is thus more dependent on high flow rates.

## DISCUSSION AND CONCLUSION

The study has shown that it is possible to automate and streamline CFD-based  $c_p$  generation and the coupling with AFN workflows. The juxtaposition of  $c_p$  values calculated with different methods reveals that NV modeling is still subject to great uncertainty. Especially in denser environments where contextual building geometries change wind patterns, the current user-friendly tools significantly overestimate wind-induced air flow rates and NV potential. It should be noted that a fairly simple building geometry was used for the case study. It is therefore likely that the performance of the methods by *CpCalc+* and Swami & Chandra will be worse for geometries for which symmetries cannot be exploited. Thus, they are not recommended for (1) geometries that differ from cuboids, (2) projects that are sited in hilly topography (3) buildings with significant contextual obstructions such as urban areas. For such cases, the tool introduced provides a viable alternative that may be used for NV analysis in case of complex building

geometries and dense urban sites. It is worth noting that both the setup of the presented study as well as the coupling with the annual AFN simulation took less than 10 minutes. Further, the CFD simulations converged in less than one hour on consumer hardware. As such, it is the authors' hope that the presented tool facilitates the use of CFD-based NV analysis for sustainable and passive design strategies.

## Unsteady-state exergy analysis on two types of building envelopes under time-varying boundary condition

### ABSTRACT

In the built environment, the thermal exergy behavior is very sensitive to the change of environmental temperature, because the temperature difference between the reservoir and a system of interest is small. Moreover, the transient characteristics become very important for the building envelope, which is primarily affected by the environmental temperature changes and has a relatively large heat capacity. Most of the exergy analyses have been performed under steady-state assumption. However, it may miss some important details of the transient process. Thus, when the transient transfer process becomes important, the unsteady-state exergy analysis should be conducted. In this study, we propose complete energy, entropy, and exergy equations in their partial differential forms. By solving them numerically, we examined the transient exergy process inside the building envelope composed of concrete and insulation layers under time-varying boundary condition. Using this new methodology, we can improve the temporal and spatial resolution of the exergy analysis and thus provide more complete information about exergetic behavior.

### KEYWORDS

Unsteady-state heat conduction; Thermodynamics; Numerical exergy analysis; Warm and cool exergy; Building envelope

### INTRODUCTION

Applying exergy analysis method to a system of interest, we can quantify the part of the energy supplied that is not converted into work and the one that is converted (Shukuya, 2013). Here, we want to focus more on the temporal change of system state and discuss it in more detail. This transient exergetic process has not been well understood yet, because the majority of the exergy analyses have been conducted under steady-state assumption.

Consider building envelope as the system of interest, which is primarily affected by the dynamic change of the environmental temperature. In general, the building envelope has low thermal conductivity and large thermal capacity. Thus, when there is a temperature difference between the boundaries, the temperature distribution inside the envelope is not uniform. With respect to the environmental temperature, a very complex exergy process occurs that is dependent on the outer and inner surface temperatures, temperature distribution inside the envelope, and indoor air temperature. In other words, if we consider the building envelope as several discretized subsystems, the direction of heat flow changes dynamically with time due to the relationship between the temperatures of the adjacent subsystems. Consequently, the state and flow of warm or cool exergy and consumption change dynamically as well. For such a system, applying steady-state assumption could overlook some important details of the transient processes. Thus, when the transient exergy transfer process becomes important, an unsteady-state exergy analysis should be conducted.

Recently, we have proposed a complete form of unsteady-state exergy analysis which can be applied to any heat conduction problem (Choi, Ooka, & Shukuya, 2018). The governing equations for the energy, entropy, and exergy were presented in the differential form. Moreover, the numerical solution approach was described in detail and the numerical integrity of proposed methodology was verified by comparing the numerical result with the steady-state analytical solution. In this study, based on the developed method for unsteady-state exergy analysis, we studied transient exergy process in building envelopes.

## GOVERNING EQUATIONS FOR UNSTEADY-STATE EXERGY ANALYSIS

### Partial differential forms for energy, entropy and exergy equations

The governing equations for one-dimensional energy, entropy, and exergy transfers are given by Eqs. (1), (2), and (3), respectively. The details can be found in (Choi et al., 2018).

$$\frac{\partial Q}{\partial t} = -\frac{\partial q}{\partial x} \quad (1)$$

$$\frac{\partial S_{st}}{\partial t} = -\frac{\partial}{\partial x}\left(\frac{q}{T}\right) + q \frac{\partial}{\partial x}\left(\frac{1}{T}\right) \quad (2)$$

$$\frac{\partial X_{st}}{\partial t} = -\frac{\partial}{\partial x}\left(q - T_0 \frac{q}{T}\right) - q \frac{\partial}{\partial x}\left(\frac{1}{T}\right) T_0 \quad (3)$$

Here, the infinitesimal change of thermal energy stored in a unit volume and the rate of heat flux are defined as  $\partial Q = C \partial T$  and  $q = -k(\partial T / \partial x)$ , respectively. Additionally,  $\partial S_{st} (= \partial Q / T)$  is the stored entropy,  $X_{st} (= Q - T_0 S_{st})$  is the stored exergy,  $C$  is the volumetric thermal capacity,  $T$  is temperature,  $t$  is time,  $x$  is the space coordinate,  $k$  is the thermal conductivity and  $T_0$  is the environmental temperature. It should be noted that the temperature used in the entropy and exergy equations is the absolute temperature and has the units of Kelvin.

### Discretized form of energy, entropy, and exergy equations

Using finite difference method, the governing equations can be solved. We used a central difference scheme and the hybrid Crank-Nicolson scheme for the temporal and spatial discretization, respectively. The discretized forms of the energy, entropy, and exergy equations are given by Eqs. (4), (5), and (6), respectively. The entropy and exergy equations are written in the form of [inflow] - [entropy generation or exergy consumption] = [stored] + [outflow] to explicitly represent the balance within the system.

$$\frac{T_i^{n+1} - T_i^n}{\Delta t} = \frac{1}{2C_i \Delta x_i} \{-q_{i+}^n + q_{i-}^n - q_{i+}^{n+1} + q_{i-}^{n+1}\} \quad (4)$$

$$\sigma_{fi,i} + \sigma_{gi} = \sigma_{st,i} + \sigma_{fo,i} \quad (5)$$

$$\chi_{fi,i} - \chi_{ci} = \chi_{st,i} + \chi_{fo,i} \quad (6)$$

It should be noted that each term in Eqs. (2) and (3) has the units of  $W/(m^3 \cdot K)$  and  $W/m^3$ , respectively, but Eqs. (5) and (6) have the units of  $W/(m^2 \cdot K)$  and  $W/m^2$ , respectively. Each term in Eqs. (5) and (6) has the following forms: entropy inflow,  $\sigma_{fi,i} = (q_{i-}/T_{i-})|^{n+0.5}$ , entropy generation,  $\sigma_{gi} = (\Delta x_i/k_i)(q_i^2/T_i^2)|^{n+0.5}$ , entropy stored,  $\sigma_{st,i} = \Delta x_i C_i (T_i^{n+1} - T_i^n)/\Delta t (T_i)^{n+0.5}$ ,

entropy outflow,  $\sigma_{fo,i} = (q_{i+}/T_{i+})|^{n+0.5}$ , exergy inflow,  $\chi_{fi,i} = \{q_{i-}(1 - T_0/T_{i-})\}|^{n+0.5}$ , exergy consumption,  $\chi_{c,i} = (\Delta x_i/k_i)(q_i^2 T_0/T_i^2)|^{n+0.5}$ , exergy stored,  $\chi_{st,i} = \Delta x_i C_i (1 - T_0/(T_i))^{n+0.5} ((T_i^{n+1} - T_i^n)/\Delta t)$ , and exergy outflow,  $\chi_{fo,i} = \{q_{i+}(1 - T_0/T_{i+})\}|^{n+0.5}$ . Additionally, the subscript  $i$  is the  $i$ -th node,  $i_+$  and  $i_-$  are the quantities defined between the nodes  $i$  and  $i + 1$ , and  $i - 1$  and  $i$ , respectively, superscript  $n$  is the time step and  $n + 0.5$  is the time step required for the Crank-Nicolson scheme. The detailed definition of each quantity and numerical scheme used can be found in (Choi et al., 2018).

### PROBLEM SETTING

Concrete and insulation layers which have a thickness of 10 cm and 6 cm, respectively, were considered. Its thermal properties are listed in Table 1. To examine the difference in exergetic behavior depending on the location of insulation, two different envelope configurations were used. From the outside, the wall composition in the order of insulation–concrete or concrete–insulation is referred to as IC or CI, respectively (Figure 1).

The envelope was discretized at the uniform intervals of 1 cm as shown in Figure 1. The calculation conditions are summarized in Table 2. The total calculation period was 180 h, but the first 120 h were considered as the warm-up period. Thus, we only present the results of the last 60 h. Time-varying Dirichlet boundary condition (BC) using 24-h period sine curve was assigned for the outer surface BC,  $T_{os}$  and regarded as the environmental temperature,  $T_0$ . For the inner surface BC,  $T_{is}$ , the constant temperature of 20 °C was assigned.

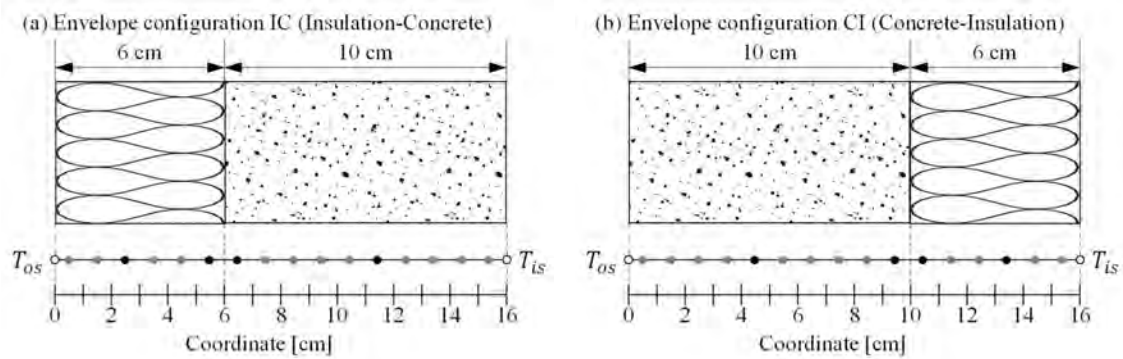

Figure 1. Schematic of two envelope configurations and nodes ( $T_{os}$ : outer surface boundary temperature,  $T_{is}$ : inner surface boundary temperature).

Table 1. Thermal properties of concrete and insulation.

Material	Thermal conductivity	Specific thermal capacity	Density
Concrete	1.5 W/(m·K)	2000 J/(kg·K)	1000 kg/m <sup>3</sup>
Insulation	0.04 W/(m·K)	1500 J/(kg·K)	30 kg/m <sup>3</sup>

Table 2. Calculation conditions ( $T_{ini}$ : initial temperature of calculation domain).

Time step	Calculation period	$T_{ini}$ [°C]	$T_{os} = T_0$ [°C]	$T_{is}$ [°C]
20 s	180 h (120 h warm up)	20	$T_{os} = 20 + 10 \sin\left(\frac{2\pi t}{24 \cdot 3600}\right)$	20

## RESULTS

### Energy results

The temperature variations obtained by solving the energy equation are shown in Figure 2 (a) and (b). In IC, the effect of time-varying outer BC reduces significantly through the insulation layer. As a result, the temperature near the interface between two material layers (near  $x = 6$  cm) does not change a lot from the inner BC of 20 °C, and consequently the change of the external BC does not have a significant influence on the concrete layer. On contrary, CI has the concrete layer with low thermal resistance of the outer side, and thus the effect of time-varying  $T_{os}$  is transmitted through the concrete layer to the outer surface of the insulation layer without significant attenuation. Therefore, the interface temperature (near  $x = 10$  cm) in CI is affected more by the change of  $T_{os}$  compared to that in IC.

In the plots of heat flux (Figure 2 (c) and (d)), we can observe a large difference between two cases. It should be noted that the direction of  $q$  from the outer to inner surface is defined as the positive value. The maximum magnitude of  $q$  in IC occurs at the outermost surface (approximately  $\pm 6.5$  W/m<sup>2</sup>) and there is no significant difference between the insulation and concrete layers (Figure 2 (c)). In contrast, in CI, the difference in  $q$  between the layers is significant. In concrete layer, the maximum  $q$  of  $\sim \pm 130$  W/m<sup>2</sup> is generated at the outermost surface, but the one in the insulation layer is  $\sim \pm 6$  W/m<sup>2</sup> only, that is almost of the same magnitude as the maximum  $q$  in IC (Figure 2 (d)).

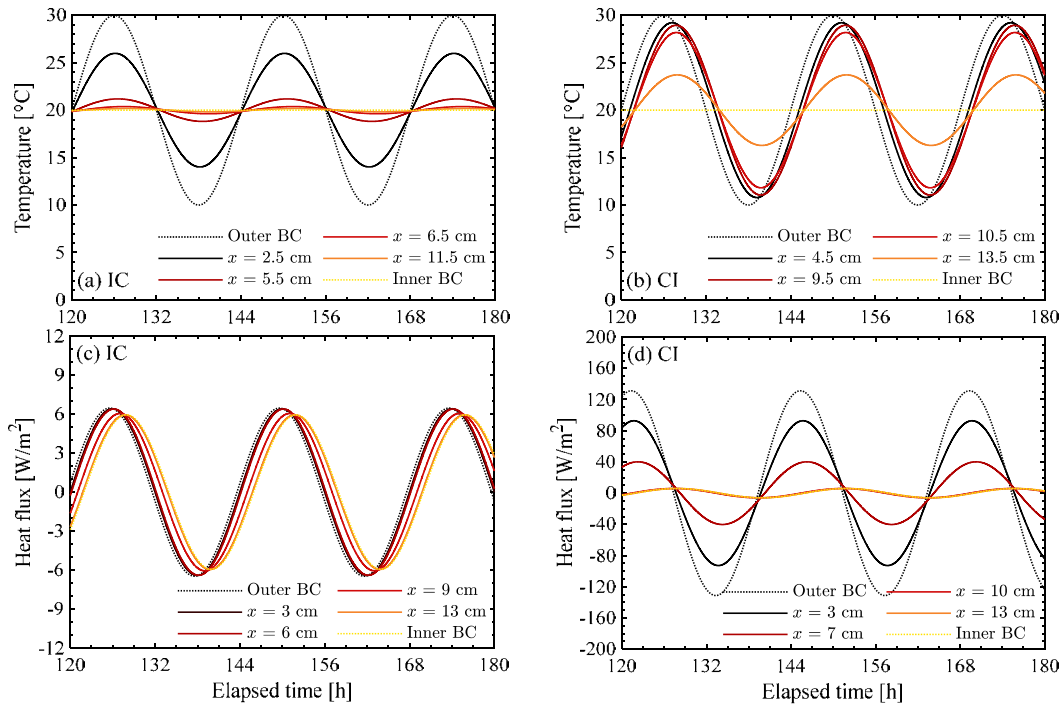

Figure 2. Node temperatures and heat flux at the interfaces: (a) temperature in IC; (b) temperature in CI; (c) heat flux in IC; and (d) heat flux in CI

### Exergy results

Based on the results for the temperature and heat flux, entropy and exergy calculations are performed. Because the entropy is considered in the exergy equation, only the results of the exergy are presented. Figure 3 shows the exergy consumption rate,  $\chi_c$ , stored rate,  $\chi_{st}$ , and flow,  $\chi_f$ , for some nodes and at the interfaces in the computational domain. The dashed and solid lines represent the values in insulation and concrete layers, respectively.

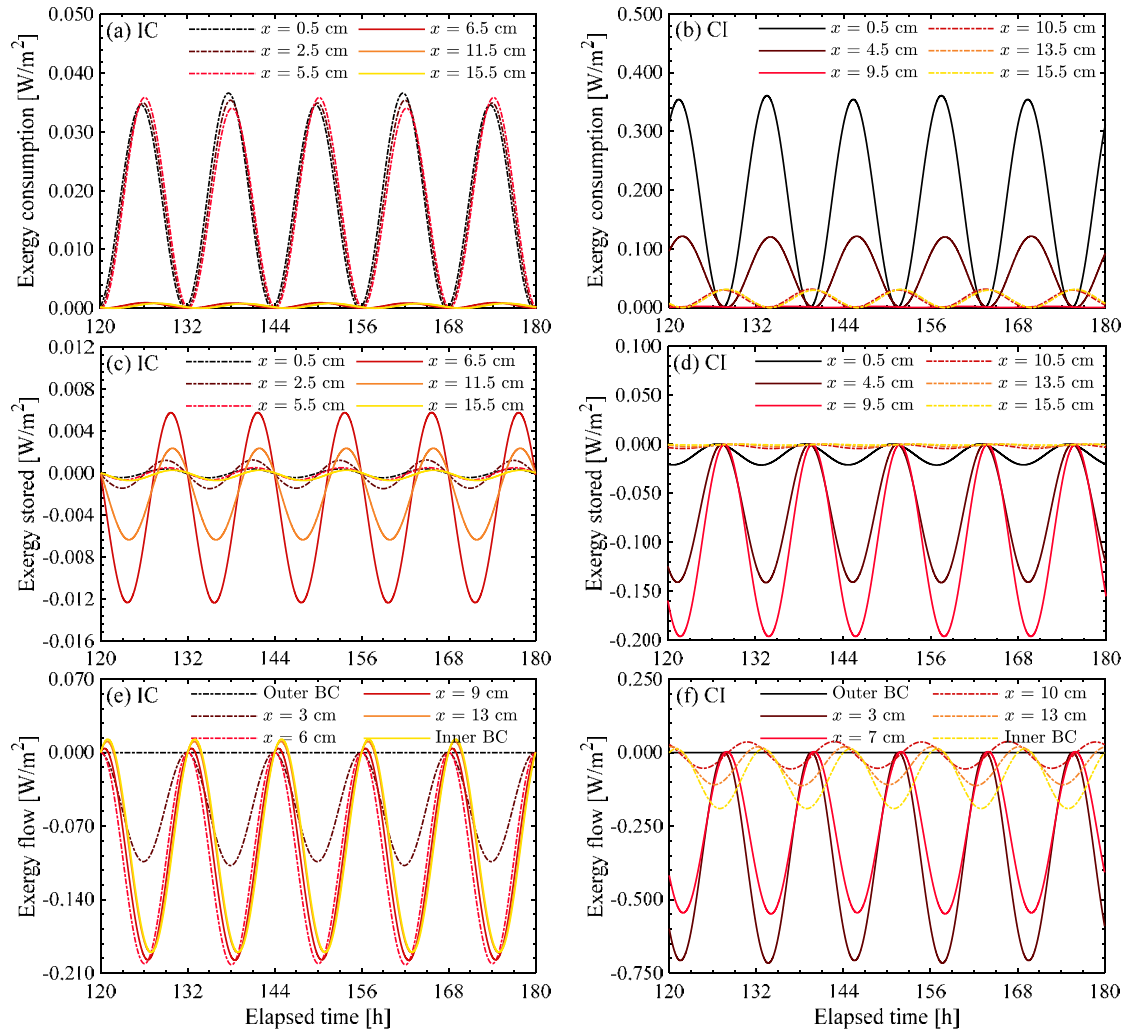

Figure 3. Exergy consumption rate, exergy stored rate, and exergy flow: (a) exergy consumption in IC; (b) exergy consumption in CI; (c) exergy stored in IC; (d) exergy stored in CI; (e) exergy flow in IC; and (f) exergy flow in CI.

Figure 3 (a) and (b) show that the maximum  $\chi_c$  in CI is 10 times larger than that in IC (Note the difference in scales of vertical axes). This is because the heat flux,  $q$ , presented in Figure 2 is the dominant factor influencing  $\chi_c$ . If the magnitude of  $q$  is similar, the larger the resistance, the greater the exergy consumption. It can be confirmed when we compare the magnitudes of  $\chi_c$  in the insulation and concrete layers of IC.

The exergy stored rate,  $\chi_{st}$ , is determined by Carnot coefficient  $(1 - T_0/T_i)$  at the node, the time derivative of the node temperature  $\partial T_i/\partial t$ , and the volumetric heat capacity,  $C_i$ . Whether it becomes cool or warm is dependent on the sign of the node Carnot coefficient, and the increase or decrease of exergy stored rate is determined by the sign of  $\chi_{st}$ . Because  $C_i$  of concrete is  $\sim 44$  times larger than that of insulations (Table 2), we can observe large  $\chi_{st}$  in the concrete layer for both cases (Figure 3 (c) and (d)). In addition, in terms of the time derivative of temperature,  $\partial T_i/\partial t$  of the concrete layer in CI is larger than that in IC, because the effect of time-varying  $T_{os}$  is significantly reduced by the insulation layer placed at the outer side. Therefore, we can observe a large difference in  $\chi_{st}$  for the concrete layer for IC and CI cases. Moreover, the behavior of  $\chi_{st}$  changes depending on the location of the insulation. CI has

negative  $\chi_{st}$  value for most times, which means that it moves only in a decreasing direction, whereas IC has a certain range of positive  $\chi_{st}$  values.

The exergy flow,  $\chi_f$ , is determined by the product of Carnot coefficient and heat flux. Because of the nature of the problem, that assumes the outer surface boundary as the environmental temperature,  $T_0$ , the exergy inflow at the outer surface is zero, because the Carnot coefficient is always zero at the outer surface (Figure 3 (e) and (f)). As shown in Figure 2 (c), IC has very small spatial variations in the magnitude of  $q$ . Thus, there is no significant spatial variations in  $\chi_f$  (Figure 3 (e)). However, in CI, a large attenuation of  $q$  from the outer to inner surface is observed (Figure 2 (d)) and it leads to the large spatial variations of  $\chi_f$  (Figure 3 (f)). As mentioned previously, the heat flux from the outer to inner surface was defined to be positive. Thus, if the exergy flow has a negative value with the associated heat flux to be positive, then it is a cool exergy flow and its direction is opposite to the heat flux (i.e., the flow is from the cell interface to the outer surface).

We further analyzed the effects of insulation location on  $\chi_c$  for the entire envelope. The total  $\chi_c$  for two configurations and  $\chi_c$  in each material layer are shown in Figure 4 (a) and (b), respectively. In the insulation layer,  $\chi_c$  in IC is slightly larger than that of CI. In contrast, in the concrete layer, there is a significant difference in  $\chi_c$  between two cases. The maximum  $\chi_c$  in concrete layer are  $\sim 0.008 \text{ W/m}^2$  and  $\sim 1.33 \text{ W/m}^2$  for IC and CI, respectively. This significant difference is because  $\chi_c$  increases quadratically with the heat flux  $q_i^2$ . Therefore, the difference in  $q$  is further amplified in the results of  $\chi_c$ . As a result, the total  $\chi_c$  for the period of 120–180 h (i.e.,  $\chi_c \Delta t$ ) for IC and CI is 11.8 and 76.4 kJ/m<sup>2</sup>, respectively.

Figure 4. (a) total exergy consumption rate for two cases and (b) exergy consumption rate in insulation and concrete layers.

## CONCLUSIONS

In this study, we have conducted an unsteady-state exergy analysis for two different building envelopes under time-varying boundary condition. This methodology provides insight into the transient exergetic behavior that is missing in the steady-state analysis. Moreover, it can provide higher temporal and spatial resolutions for the system of interest. In future, the studies will be conducted with more realistic problem setting considering radiative and convective exergy transfers.

### **ABSTRACT**

Optimization in building performance simulation (BPS) has become increasingly important due to the growing need for high-performance building design and operation. Numerous research efforts have been dedicated to decreasing optimization runtime by introducing improved optimization algorithms and advanced sampling techniques. This paper presents a novel model order reduction (MOR) algorithm tailored for speeding up building energy simulation. The algorithm identifies archetype zones simplifying the needless repetition of thermal zones. For an entire optimization process, this MOR method can be repeated recursively to reproduce reduced models. The proposed method can be used to speed up large-scale simulations including optimization, uncertainty analysis and model predictive controls. Preliminary results with parametric simulations show a runtime reduction of about 76% reduction for 15 simulations while still maintaining the predicted total annual energy consumption within a 10% margin. Further research will be conducted to compare the optimization results when applying the proposed MOR algorithm and determine if the reduced model produces the same optimal design. The proposed method may significantly improve the optimization runtime with a minor effect on optimization accuracy, thus increasing the overall usability of BPS optimizations.

building performance simulation, EnergyPlus, optimization, model reduction

### **INTRODUCTION**

With the growth of interest in a sustainable built environment, the need for building performance simulation (BPS) has been accelerating (Infiniti Research Limited, 2015). Optimization in BPS has been used to find the optimal building energy performance within a considerable number of design variations. The recent development of generative community and building design have also led to the broader use of optimization in BPS. Furthermore, BPS optimization has also been applied in model predictive control to come up with optimal control strategies. While optimization is a powerful tool, the requirement for computational power and lengthy simulation time have been noted in many previous research, which hinders the practical usage of such technologies.

Reducing computation complexity and speeding up BPS optimization have been investigated by numerous researchers in the past. The following paragraphs will discuss three main approaches to this problem.

The first approach is to improve existing optimization algorithms. Many researchers have looked into improving the efficiency of commonly used optimization algorithms used for BPS (Christensen, Anderson, Horowitz, Courtney, & Spencer, 2006; Hamdy & Sirén, 2016; Nguyen, Reiter, & Rigo, 2014). A faster optimization process decreases the number of simulations

needed to obtain the optimal outcome, but it does not reduce the runtime of individual simulations.

Some researchers have also proposed the use of surrogate models. Surrogate models, or meta-models, are statistical models or machine learning models used to imitate BPS outputs based on different parameter changes. Examples of this approach include the use of support vector regression (Eisenhower, O'Neill, Narayanan, Fonoberov, & Mezić, 2012) for BPS optimization. The resulting surrogate models can produce outputs significantly faster than individual simulation runs. The shortcomings of this approach include the requirement of a large simulated dataset, as well as accuracy run-off when the inputs go outside of the trained parameter space. This approach is more reliable when the parameter space remains constrained, which makes it more suitable for model predictive control applications.

Finally, it is possible to reduce BPS model complexity. This approach aims to directly reduce the complexity of the BPS model to cut down simulation time. A mixture of physics-based abstraction and machine learning methods can be used for this purpose. The reduced model can be generated by simplifying the original model, or by building up a template model to approximate the original model. Van Treeck and Rank (2007) demonstrated reduction of building geometry by using graph theory. Georgescu and Mezić (2015) used a Koopman operator to merge similar adjacent zones into a single joint zone. The main disadvantage of this approach is that the reduced model can no longer be transformed back into the original model after the reduction process (Schilders, 2008).

This paper focuses on the building energy simulation (BES) aspect of the BPS. It is an extension of a previously published BPS MOR method called Model-Cluster-Reduce (Shi & O'Brien, 2017). The goal is to achieve faster BES optimization by integrating the MOR method with conventional iterative BES optimization. Unlike surrogate models, this MOR method only requires one simulation to obtain the reduced model. The reduced model is still a standard BPS model capable of accepting parameter changes beyond its trained parameter space. The reduced model can be opened up for troubleshooting. Throughout this paper, the original BES model is called original model, and the simplified BES model is called reduced model.

## METHODOLOGY

In this paper faster optimization is achieved through the reducing the original model from one simulation run, then use it to partially or entirely replace further optimization steps. An overview of this process is shown in Table 1.

For a serial optimization process, multiple optimization steps can be carried out with the reduced model. Then the newly optimized parameters can be validated by a direct comparison between the reduced model and the original model. If the accuracy of the reduced model is confirmed, the optimization path based on the reduced model is accepted, and the optimization process will carry on. For an optimization process using a population, such as evolution algorithm, the reduced model can be used to replace a subpopulation of the models to speed up optimization. After a certain number of optimization steps, the newly updated reduced models need to be validated by the updated original models with the same parameter inputs, similar to the previous serial optimization process.

*Table 1. Pseudo code for the proposed optimization procedure*

1. Simulate original model
2. Create reduced model through selective zone elimination
3. Simulate reduced model
4. **If** results from the reduced model agrees well with the original model:
5.     Optimize reduced model until parameters deviates too much or a certain number of iterations is reached
6.     Update original model
7. **Else:**
8.     Follow normal optimization procedures

The central philosophy behind this model reduction process is to selectively eliminate redundant thermal zones inside a BPS model and replace them with their archetypes. There are three main steps called model-cluster-reduce for this model reduction process:

The model step captures the characteristics of the original thermal zones by parameterizing a physics-based or statistically-driven model. This step produces a reduced number of parameters from the original model. Parameters estimated from inverse modelling and area normalized heating/cooling profile can be used to represent the zone characteristics. The normalized heating/cooling time series is selected to represent each zone in this paper, and the reduced parameter  $p$  is calculated as below:

$$p = \frac{\text{zone hourly heating/cooling load}}{\text{zone floor area}}$$

The cluster step uses the parameters obtained from the previous step to group thermal zones automatically using clustering techniques. Then the resulting centres of each clustered group become archetype zones needed for model reduction. Affinity Propagation (AP) is used in this research to form zone clusters and identify archetype zones. AP splits thermal zones into two categories: archetypes and zones belonging to their archetypes. This clustering process is achieved by iterating messages (availability and responsibility) between thermal zones until the similarity distance between the zones and their archetypes are minimized. For details about AP, the original paper by Frey & Dueck (2007). In this application, the similarity distance  $s$  is calculated by the Euclidean distance between the thermal zones:

$$s(\beta, \alpha) = -\|p_\beta - p_\alpha\|^2$$

As its name suggests,  $s$  represents how similar zone  $\beta$  is to its archetype zone  $\alpha$ . The availability and responsibility are the same from the original AP paper by Frey & Dueck (2007).

The archetype zones are then used to produce the reduced model with a scale factor. All other zones except the archetype zones are removed from the model. The scale factors are calculated from attributes such as floor area and volume. If the boundary condition of the archetype zones' surfaces is not exterior or another archetype zone, it will be converted to adiabatic. In this application the scale factor is calculated from floor area:

$$\lambda_\alpha = \frac{\sum A_{\beta\alpha}}{A_\alpha}$$

Where  $\lambda$  is the scale factor,  $A$  is the zone floor area. More details about the model reduction process can be referred to the original paper by the authors (Shi & O'Brien, 2017).

## RESULTS

A calibrated mixed-used building model is created in EnergyPlus (Crawley et al., 2001) and used as a proof of concept demonstration for this paper. The modelled building is located at London, Ontario, Canada. The model contains a total number of 51 zones with a mixture of retail and office space. The reduced model created from the reference design consists of 6 zones in total, resulting in an 86% reduction in computation time for each simulation run on an Intel® i5-7600 processor. For the whole optimization process using the proposed procedure, the total computation time is cut down by about 76%, from 44 minutes to 11.5 minutes.

Figure 1 shows a comparison of the predicted annual consumption from the original model and the reduced model. The difference in total energy consumption is approximately 10%, though with a significant difference in interior lighting. This discrepancy can be explained by the model reduction process being only focused on the heating/cooling response of the thermal zones while overlooking the internal load components. The implications of this will be further commented in the discussion section.

Figure 1. Comparison of the reference models

The reduced model and the original model were further tested in a series of parametric simulations to imitate an optimization process. Insulation levels, infiltration rate and south-facing window type were varied randomly to create 16 samples for each model. The results of these simulation runs are summarized in Figure 2 in the form of energy usage intensity (EUI) in kWh/m<sup>2</sup>. EUI of the baseline model is approximately 220 kWh/m<sup>2</sup>. As seen in the figure, as the parameter variations become larger and the EUI reduction from the reference model increases, the deviations of the energy savings predicted between the original model and the reduced model becomes larger. To alleviate this deviation inside the reduced model, after the initial ten simulations, the original model was updated with the new parameters, and a new

reduced model regenerated. The refreshed reduced model was able to provide closer simulation results to the reduced model, thus making the overall optimization process more reliable.

Figure 2. Comparison of the predicted EUI reduction between the original model and the reduced model over 15 simulations

## DISCUSSIONS

Overall the proposed model reduction method shows potential to reduce the optimization time of large-scale BES. It also requires much less training data when compared to surrogate models. However, discrepancies in lighting loads were still identified, possibly due to the model reduction process only focused on heating/cooling characteristics. Fortunately, in this case study these loads are less significant than the other components, making the reduced model still reasonably accurate when used for parameter optimization. Other inverse modelling techniques can be tested to determine if this issue could be resolved.

As for the parametric simulation part, the first ten simulation runs performed quite well but the reduced model starts to diverge as its parameters deviate more from the values it was trained from. This mandates an iterative reduced model validation and retraining process inside an actual optimization process. This validation process can be designed to perform intermittently on a determinant number of optimization steps or based on the divergence of parameters from reference values. Even though new reduced models need to be regenerated intermittently, this model reduction process could still significantly reduce the overall simulation time.

Currently, the proposed model reduction process is not yet fully integrated with the existing BES optimization tools; part of the future work would be integrating it as part of a BES optimization package to provide a complete toolkit to the users. More simulation studies are also needed to further validate the proposed model reduction method.

## CONCLUSIONS

This paper introduces a novel model order reduction method based on selective zone elimination to achieve faster building energy simulations. This method could significantly reduce the run time of large-scale simulation by providing approximations of best optimization path. Compared to surrogate models based on machine learning methods, this model reduction process still provides a first-principle BES model and requiring fewer simulations to generate

training data. The case study used in this paper shows a 76% reduction in total optimization time while still providing reasonable accuracy. The authors are planning to integrate this process with existing BES optimization packages and make it available as an open-source project.

## ACKNOWLEDGEMENT

The authors would like to acknowledge the support they received from Autodesk Research and Natural Science and Engineering Research Council of Canada for implementing this work. The authors would also like to thank the valuable insights and advice provided by Dr. Ian Beausoleil-Morrison on this topic.

### ABSTRACT

A change-point (piecewise linear regression) model fitted to the pre-retrofit data as the counterfactual for the savings calculation, is considered to be the best approach to evaluating the energy savings of building retrofits (ASHRAE Guideline 14). However, when applied to a large portfolio savings analysis with substantial multi-year data, the change-point model does not fit the data well in some cases. The study thus aims to improve the accuracy of the change-point model by: 1) using more advanced non-linear models, 2) incorporating additional input features, and 3) increasing the time resolution of input variables. We found that random forest regression (RF) models with an array of climate (humidity, wind, solar radiation, etc.), time (day of the week, season, holiday), and energy consumption of the immediate past 1-4 hours (energy lag terms) outperformed the change-point model, shallow neural networks, and support vector machine regression (SVR). Our result implies that high resolution smart meter data should be used in place of monthly utility bills to more accurately evaluate retrofit savings. We further explored the relative contribution of the input variables to the random forest regression model using Shapley Value, a game theoretic variable importance metric. We found that the most important input feature is the energy consumption of the immediate past (or energy lag terms). We also found that solar radiation and weekend day indicators are more important than outdoor temperature. The improved model could provide better insights to portfolio managers in planning future energy retrofits. Policy makers could also use such models to evaluate the average energy saving potential for energy policy changes, such as the requirement of minimum insulation level, and lighting equipment efficiency.

### KEYWORDS

Energy Performance Prediction, Random Forest Regression, Inverse Modelling, Comparison

### INTRODUCTION

In the U.S., buildings account for 40% of the nation's energy consumption (EIA 2018). Reducing the energy consumption of the building sector is critical to mitigating the global climate change. Energy efficiency upgrades could save 5% to 50% of energy consumption in buildings (DOE 2018). However, in order to accurately evaluate the impact of these upgrades, differences in weather, operating schedules and modes, occupant behavior, and other unobserved factors between pre and post retrofit needs to be accounted for. This will require a counterfactual energy model that accurately describes the potential energy consumption had the upgrade not have happened, or the counterfactual.

In ASHRAE guideline 14, the counterfactual is estimated with a change-point regression model (ASHRAE 2014). The saving is calculated as the difference between the model estimated consumption and the measured post-retrofit consumption. We, and many studies aimed to compare and improve the prediction accuracy of such counterfactual energy models (Zhang et al. 2015; Brown et al. 2012). Unlike most existing studies with only a handful of case studies,

this study evaluates models on a larger sample size of 65 buildings. We tested hypothesis about whether the following three strategies improve on model accuracy: 1) advanced models using only the temperature input, 2) adding more input features, and 3) increasing the time resolution from monthly to hourly.

## METHODOLOGY

The input energy data consists of 2014 to 2016 15-min interval electricity consumption data of 65 commercial buildings (24 office, 14 courthouses, 11 courthouse/office, 11 unknown) in the General Service Administration (GSA) portfolio. The climate data is retrieved from the national solar radiation database (NRSDB) Physical Solar Model (PSM).

### Model evaluation procedure and metric

For each building, the input features are aligned by their timestamps. The aligned data set is then randomly split into a training set and a test set using year-month index, the first 70% of the year-months is the training data, and the rest is the validation data. The error is evaluated in Coefficient of Root-Mean-Square Error (CV-RMSE). CV-RMSE is root-mean-square error divided by mean electricity consumption (Equation 1,  $\bar{y}$  is the sample mean of the energy data,  $n$  is the number of data points,  $y_i$  is the  $i$ th observed electricity consumption,  $\hat{y}_i$  is the corresponding predicted electricity consumption,  $(n - p)$  is the degree of freedom). However, the degree of freedom may not be well defined for models other than linear regression, for example, the effective degree of freedom for Neural Network models is changing through the training process (Anzai 2012). We believe the degree of freedom could be left out as we evaluated the model on a held-out test set. Thus, we used the adjusted CV-RMSE (Equation 2) in the evaluation.

$$CV - RMSE = \sqrt{\sum_i \frac{(y_i - \hat{y}_i)^2}{n - p}} / \bar{y} \quad (1)$$

$$CV - RMSE_{adj} = \sqrt{\sum_i \frac{(y_i - \hat{y}_i)^2}{n}} / \bar{y} \quad (2)$$

## Models

We compared the prediction accuracy of the following five models: 3-parameter change-point model (baseline algorithm), neural network with one hidden layer, neural network with two hidden layers, kernelized support vector machine regression (SVR), and random forest regression. The Change-point model is implemented using Python scipy optimize package, and the other models are implemented using Python scikit-learn package (Pedregosa et al. 2011).

Change-point model splits the range of temperature into 2 to 3 different segments and fits a separate linear regression model in each segment, with continuity requirement at the boundaries of segments. The method is adopted by ASHRAE Guideline 14 (ASHRAE 2014) and IPMVP (Efficiency Valuation Organisation 2012). In this study the change-point model is implemented with a grid search over the temperature range from 40F to 80F according to (Kissock et al. 2003).

Neural network is a popular predictive method applied in a variety of fields. A neural network consists of inter-connected neurons and non-linear activation functions. Most commonly, neurons form a layered directed acyclic graph (DAG) structure with one input layer, some hidden layers, and one output layer. Directed links are formed between layers, and assigned

weights using the backpropagation algorithm. Two shallow network structures are tested in this study: one with one hidden layer, and one with two hidden layers. We used the tanh activation, following the choice of (MacKay 1996; Dodier and Henze 2004). A grid-search method is applied to find the optimal number of hidden units per layer.

The support vector machine algorithm is developed by Vapnik and Chervonenkis in 1963, as a “nonlinear generalization of the Generalized Portrait algorithm” (Sewell n.d.). It can be applied to both classification and regression tasks. Support vector machine regression (SVR) tries to find a function as flat as possible that is at most  $\epsilon$  from training data (Smola and Schölkopf 2004).  $C$  and  $\epsilon$  are two hyper-parameters to be optimized. A grid search of the optimal  $C$  is performed in the range of 1 to 1000 with step size 100.  $\epsilon$  is left as default.

Random Forest Regression is an ensemble method which constructs many regression trees at the training time, and forms predictions by taking a weighted average of the output of individual trees. In the study, the tuning parameter, maximum tree depth, is set as default 30.

## RESULTS

### Hypothesis 1: advanced models have better accuracy using only temperature input.

We tested whether applying more advanced nonlinear models could directly reduce the prediction error by using just temperature as the input. Our result suggests that advanced models (NN, SVM, RF) perform similarly to simple change-point model using only temperature input.

Figure 1. Violin plot, showing distribution of CV-RMSE (the prediction error) across buildings, for each method. All methods appear to have similar error distributions.

### Hypothesis 2: Additional input features improves model performance.

By adding the following input variables (Table 1), in addition to temperature, we saw substantial reduction in CV-RMSE (prediction error) using random forest regression (Figure 2).

Table 1. Additional input variables.

Climate	Humidity	Dew Point
		Relative Humidity
	Solar Radiation	Diffuse Horizontal Irradiance (DHI)
		Direct Normal Irradiance (DNI)
		Global Horizontal Radiation (GHI)
		Solar Zenith Angle (Z)
	Pressure	
	Precipitable Water	
	Wind	Wind Direction
Time	Season	Wind Speed

	Day of the Week
	If a Day Is Federal Holiday
Energy	Energy lag term (Energy Consumption in Previous 4 Steps)

Figure 2. Violin plot, showing distribution of CV-RMSE (prediction error) across buildings, for each method: light grey uses only temperature input, dark grey is using all features in Table 1.

To compare the relative importance of these variables for prediction accuracy in random forest regression, we applied a game-theory metric, the Shapley Value imputation (Lipovetsky and Conklin 2001). The Shapley Value for the  $i$ th variable is shown in Equation 3.  $n$  is the number of input features.  $v$  is a function from feature subsets to real numbers.  $v(S)$  represents the “expected sum of payoffs” (“Shapley Value” 2018) using the feature set  $S$ . In our case,  $v(S)$  is CV-RMSE.  $R$  is a permutation,  $P_i^R$  is the list of features before the  $i$ th one. Computing the exact Shapley Value is #p complete (Fatima et al. 2008), i.e. intractable, so we computed an estimated Shapley Value using a random sample of permutations. The estimated Shapley Value is shown in Figure 4. The variables with lower Shapley Value are more important. The energy lag terms are the most important. A series of solar radiation related factors (GHI, DHI, etc.) ranked second, and the indicators for weekends ranked third.

$$\phi_i(v) = \frac{1}{n!} \sum_R v(P_i^R \cup \{i\}) - v(P_i^R) \quad (3)$$

Figure 4. Shapley Value estimates for all input features

### Hypothesis 3: Higher resolution input improves model performance

For each modelling method, we compared the following two approaches: 1) use monthly average of the input features in hypothesis 2 to predict monthly electricity consumption; 2) use hourly input to predict hourly electricity and aggregate the result to monthly. With higher resolution hourly input, Random Forest Regression achieved significantly better performance than using monthly average inputs (Figure 3).

Figure 3. Violin plot, showing distribution of CV-RMSE across buildings, for each method: dark grey is using monthly average input to predict monthly electricity, light grey is using hourly input to predict hourly output then aggregate to monthly.

## DISCUSSIONS

### Findings

All models perform similarly when only using temperature as the input variable. Random forest regression model with an array of climate and time variables outperformed our implementation of shallow neural networks, SVR, and change-point models in terms of lowest CV-RMSE. For the random forest regression model, the most effective predictors for the hourly energy consumption are the energy lag terms, followed by solar radiation, then indicator variables for weekends.

### Limitations and next stage work

We observed outliers in the 15-min electricity data that are: negative records, a large positive immediately followed a large negative record, and extremely large values followed by a data gap. A simple outlier removal rule is applied for the analysis: 1) remove negative entries 2) remove data points greater than 1.5 times the 97th percentile of the positive records. Further research into the reasons for the outliers, and more advanced outlier detection routine might help improve the model accuracy. In the Shapley Value computation, we used a sample of 100 random permutations to construct an initial estimate. The number of permutations here is chosen arbitrarily. Analyzing the convergence rate of the Shapley Value estimate, i.e. how many samples are needed to achieve certain approximation accuracy, would be a next step of the study. All the counterfactual models in this paper and many other papers under the ASHRAE Guideline 14 framework are based on the assumption of no un-measured confounding factors. In this sense, adding more covariates to the models, other than just temperature, could make the model prediction more accurate, and make it more viable to draw causal conclusions.

## CONCLUSIONS

The paper compared the prediction accuracy of five data-driven energy counterfactual models under three conditions: 1) using only temperature input 2) using an array of climate and energy inputs, and 3) using higher resolution hourly inputs to predict monthly energy. We found that random forest regression model ensures the best performance when supplied with additional inputs with higher temporal resolution. The most important input features for Random Forest Regression are energy lag terms and solar radiation.

The predictive power of the energy counterfactual model determines the accuracy of the ECM savings evaluation. The result could assist ESCO companies to better predict the potential savings for implementing certain retrofit. In addition, our improvement of such energy

counterfactual models could also be useful in system fault detection, and development of new control strategies (Zhang et al. 2015).

## ACKNOWLEDGEMENT

This research is made possible through a collaboration with the General Service Administration to evaluate their portfolio-wide energy retrofit impact (contract PR201508040012). The author also wishes to thank Professor Matt Gormley for recommending the machine learning methods.

### **ABSTRACT**

Mathematical models are essential in Model-Predictive Control (MPC) for building automation and control (BAC) application, which must be precise and computationally efficient for real-time optimization and control. However, building models are of high complexity because of the nonlinearities of heat and mass transfer processes in buildings and their air-conditioning and mechanical ventilation (ACMV) systems. This paper proposes a method to develop an integrated linear model for indoor air temperature, humidity and Predicted Mean Vote (PMV) index suitable for fast real-time multiple objectives optimization. A linear dynamic model is developed using SIMSCAPE language based on the BCA SkyLab test bed facility in Singapore as a case study. Experimental data is used to calibrate the model using trust-region-reflective least squares optimization method. The results show that the mean absolute percentage errors (MAPE) of predicted room temperature and humidity ratio are 1.25% and 4.98%, compared to measurement, respectively.

### **KEYWORDS**

Model predictive control; modeling; model calibration; linearization.

### **INTRODUCTION**

Developing an appropriate building mathematical model has been a major challenge of MPC implementation for building automation and control (BAC) application (Cigler et al., 2013). Henze (2013) pointed out that about 70% of project costs were consumed by model development and calibration for MPC in buildings. Cigler et al. (2013) also found more than 55% of project time spent on modeling work for implementing MPC in different two buildings. The mathematical model of the building must be sufficiently accurate in predicting building dynamics and computationally efficient for real-time control and optimization in MPC. A viable solution is to develop linear models of buildings that are of medium to high fidelity and is computationally more efficient (Cigler et al., 2013). Currently, two modeling methods, thermal resistance-capacitance (RC) model (Sturzenegger et al., 2012) and system identification (Cole et al., 2014) have been adopted to develop linear building models for control purpose. However, most of the previous studies focus on the prediction of indoor temperature whereas the indoor humidity and human thermal comfort are seldom covered (Kramer et al., 2012). To improve indoor thermal comfort and building energy performance with MPC further, it is necessary to include humidity and thermal comfort index in the prediction model of MPC.

This work aims to develop a general methodology for constructing a linear model for indoor thermal comfort and energy optimization with MPC. A building model is developed based on the BCA SkyLab test bed facility in Singapore, as a case study, to predict indoor temperature,

humidity, and thermal comfort. The thermal and humidity dynamic models are created using the RC network. A linear approximation method is proposed to linearize the nonlinearities in the ACMV cooling coil model and PMV calculation model. A model calibration procedure is also adopted to refine the proposed linear model.

## METHODS

### Room space model

For air-conditioned room spaces, the heat and moisture balance could be modeled by equations (1) and (2),

$$m_{air,z} \frac{d\psi_z}{dt} = \dot{m}_{occ} + \dot{m}_{ACMV}, \quad (1)$$

$$m_{air,z} C_{air} \frac{dT_z}{dt} = Q_{inte} + Q_{env} + Q_{ACMV}, \quad (2)$$

where  $Q$  is heat flow rate (W),  $\dot{m}$  is mass flow rate (kg/s),  $m$  is mass (kg),  $T$  is temperature (K) and  $\psi$  is humidity ratio (kg/kg). The subscript *inte* refers to internal, *z* refers to thermal zone, and *env* refers to envelope.

### RC models of walls, ceiling and floor

Figure 1 shows the lumped parameter and RC representations of a building wall model. The wall is virtually split into two aggregates and only heat conduction in the normal direction is considered. The RC model is a 5R2C model, which includes two thermal capacitances of the two aggregates, three thermal conduction resistances of aggregates and two surface thermal resistances between surface and air (outer and inner surfaces).

Figure 1 a) lumped parameter and b) RC representations of a building wall model

In Figure 1, the symbols  $R$ ,  $C$ , and  $q$  refer to thermal resistance (K-m/W), thermal capacity (J/K) and heat flux ( $W/m^2$ ), respectively. Subscripts *sur*, *o*, *1*, *the*, *sol*, *z*, *tra*, and *int* refer to surface, outside, aggregate number, thermal, solar radiation, thermal zone, transmission, and interior respectively. The same model treatment is applied to the roof and the floor.

### Linearized cooling coil model

When the ACMV system is in operation, the supply air relative humidity (RH) is assumed 100% and the heat/mass transfer between the mixed air and the cooling coil can be described by,

$$Q_{cc} = \dot{m}_{ma}(C_{air} + C_{vap}\psi_{ma})(T_{ma} - T_{sa}) + \dot{m}_{ma}L_{vap}(\psi_{ma} - \psi_{sa}), \quad (3)$$

$$\psi_{sa} = 0.62198p_{vap,sat}/(p_z - p_{vap,sat}), \quad (4)$$

$$p_{vap,sat} = e^{(77.345 + 0.0057T_z - 7235/T_z)/T_z^{8.2}}, \quad (5)$$

where the subscripts *ma*, *vap*, *sat* and *cc* refer to the mixed air in FCU, water vapor, saturation and cooling coil, respectively.  $L$  refers to the specific latent heat (J/kg) of water condensation.

For temperature between 283.15K – 293.15K (covering the typical range of supply air temperatures), nonlinear equations (4) and (5) can be approximated by the linear equation,

$$\psi_{sa} = 7.014 \times 10^{-4}T_{sa} - 0.1913. \quad (6)$$

With this assumption, the indoor moisture and sensible heat load removed by ACMV system can be calculated by,

$$\dot{m}_{ACMV} = 2.58 \times 10^{-4} \dot{m}_{fa} T_{fa} + 2.58 \times 10^{-4} \dot{m}_{ra} T_{ra} - 2.57 \times 10^7 Q_{cc} + 0.633 \dot{m}_{fa} \psi_{fa} - (\dot{m}_{fa} + 0.368 \dot{m}_{ra}) \psi_{ra} - 0.0703 \dot{m}_{fa} - 0.0703 \dot{m}_{ra}, \quad (7)$$

$$Q_{ACMV} = 369.4 \dot{m}_{fa} T_{fa} - (1005 \dot{m}_{fa} + 635.6 \dot{m}_{ra}) T_{ra} - 0.368 Q_{cc} + 9.062 \times 10^5 (\dot{m}_{fa} \psi_{fa} + \dot{m}_{ra} \psi_{ra}) + 1.734 \times 10^5 \dot{m}_{fa} + 1.734 \times 10^5 \dot{m}_{ra}, \quad (8)$$

where the subscripts *fa* and *ra* refer to fresh air and return air. When the supply air flow rate and fresh air flow rate are constant, the equations become linear. The equations are valid under the conditions of  $RH_{sa} = 100\%$ ,  $283.15\text{K} < T_{sa} < 293.15\text{K}$  according to the assumptions in the modeling procedure.

### Linearized PMV calculation model

Predicted Mean Vote index (Fanger, 1970) is calculated according to the equation,

$$PMV = (0.303e^{-0.036M} + 0.028) Q_{diff}. \quad (9)$$

The difference between the internal heat production and loss,  $Q_{diff}$ , that occurs in a human body is calculated by,

$$Q_{diff} = M - Q_{work} - Q_{res} - Q_{sens} - Q_{evap}, \quad (10)$$

$$Q_{res} = 0.0014M(307.15 - T_{air}) + 1.72 \times 10^{-5}M(5867 - p_{vap}), \quad (11)$$

$$Q_{sens} = 39.6 \times 10^{-9} f_{clo} (T_{clo}^4 - T_{mr}^4) + f_{clo} h_{conv} (T_{clo} - T_{air}), \quad (12)$$

$$Q_{evap} = 0.42(M - Q_{work} - 58.15) + 3 \times 10^{-3} [5733 - 6.99(M - Q_{work}) - p_{vap}] \quad (13)$$

$$T_{clo} = T_{skin} - R_{clo} [f_{clo} h_{conv} (T_{clo} - T_{air})] - Ins_{clo} [39.6 \times 10^{-9} f_{clo} (T_{clo}^4 - T_{mr}^4)] \quad (14)$$

In the equation (9) – (14),  $M$  is the metabolic rate of a human being (W),  $p$  is air pressure (Pa),  $f_{clo}$  is clothing factor, and  $Ins_{clo}$  is clothing insulation (1 clo = 0.155 m<sup>2</sup>-K/W). The subscripts *clo*, *mr*, *vap*, *conv*, *sens*, *evap*, *res*, *skin* and *work* refer to clothing, mean radiant, water vapor, convection, sensible, evaporation from occupant skin, respiration of occupant, skin surface, and external work.

There are two nonlinear items, radiative heat transfer  $39.6 \times 10^{-9} f_{clo} (T_{clo}^4 - T_{mr}^4)$  and water vapour pressure,  $p_{vap}$ , in the PMV model. The radiative heat transfer term can be linearized by (Park, 2013),

$$Q_{rad} = 39.6 \times 10^{-9} f_{clo} (T_{clo} + T_{mr}) (T_{clo}^2 + T_{mr}^2) (T_{clo} - T_{mr}) = h_{rad} f_{clo} (T_{clo} - T_{mr}). \quad (15)$$

The water vapor pressure can also be calculated by the following equation, for air temperatures within 293.15 - 303.15 K covering the range of typical room temperatures,

$$p_{vap} = \psi_z p_z / (\psi_z + 0.622) \cong 1.598 \times 10^5 \psi_z. \quad (16)$$

In a scenario that the cloth factor, metabolic rate of the occupants, external work of the occupants and room pressure can be assumed constant, likely so in a typical office environment, the PMV equation can be reduced to one linear equation,

$$PMV = \left[ \frac{(0.68 h_{conv} + 0.0051 h_{rad} + 0.06) T_{air} + 0.68 h_{rad} T_{mr} + (35.7 h_{conv} + 35.7 h_{rad} + 419) \psi_z + 7.3 - 208 h_{rad} - 208 h_{conv}}{(h_{conv} + h_{rad} + 11.73)} \right] / \quad (17)$$

The equation is valid for a common office environment with air conditioning where room temperature is within 293.15 - 303.15 K.

### MPC formulation

A MPC controller for future study of building energy and indoor thermal comfort optimization with MPC could be modeled as

$$J = \text{Minimize} (\sum_{i=0}^M \sum_{k=0}^N Q_{i,t+k|t}^2 + \sum_{k=0}^N (W_{PMV} PMV_{t+k|t})^2 + \sum_{k=0}^N W_{\epsilon} (\epsilon_{t+k|t})^2), \quad (18)$$

where  $Q$ ,  $PMV$ ,  $W$  and  $\epsilon$  refer to normalized cooling power, normalized thermal comfort, weighting factor and slack variable.  $M$  and  $N$  refer to the number of cooling system and prediction horizon.

The objective function subjects to the building dynamics modelled in this section, limits of cooling power and acceptable indoor thermal comfort zone ( $-0.5 < PMV < 0.5$ ). In this study, the building dynamic model is linearized. This results into a convex optimization problem, which can be more efficiently solved compared to a nonlinear optimization problem with a nonlinear building model, for finding the optimal control strategies for building control (Cigler et al., 2013).

## CASE STUDY AND RESULTS DISCUSSION

The physical building studied in this work is the BCA SkyLab located in the BCA Academy in Singapore. SkyLab has two side-by-side identical experimental cells with full-height window façade on one side, as shown in Figure 2. The properties of the building envelope are described by Lamano et al., (2018), and Yang et al., (2018).

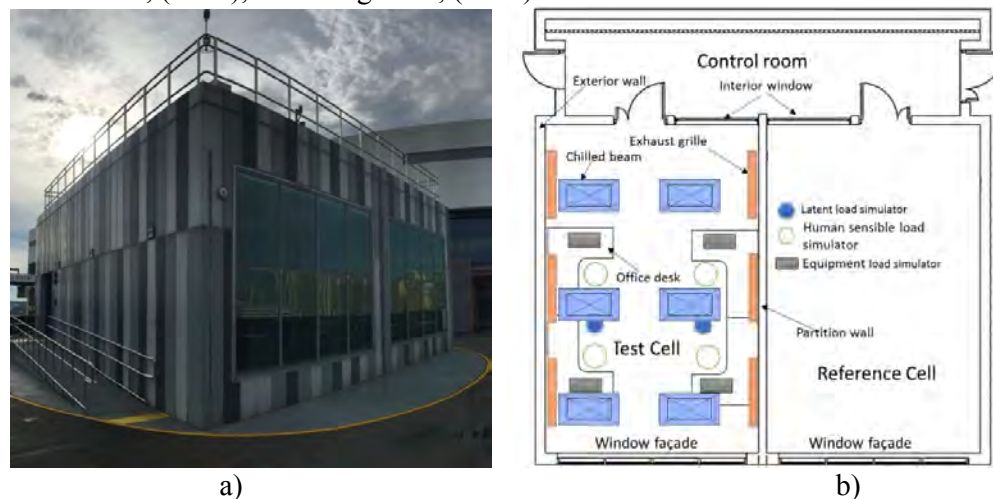

Figure 2 a) exterior view of BCA SkyLab, b) Schematic drawing of BCA SkyLab

An ACMV system that consists of one fan coil unit (FCU) and six active chilled beam (ACB) units was installed in the Test Cell of SkyLab, as shown in **Error! Reference source not found.** The chilled water valve in FCU was controlled by a thermostat according to pre-cooled air set point temperature. The pre-cooled air from FCU was supplied into the ACB units, meanwhile, induced some room air into the ACB units. The sensible load in the induced air was removed by the cooling coils in ACB. The conditioned induced air mixed with pre-cooled air and was distributed into the room space. A heat exchanger was installed to regulate the supplied chilled water temperature of ACB higher than dew point in the room space to avoid condensation. Thus, FCU is capable of dealing with all the latent load and partial sensible load and the rest sensible is removed by the ACB.

The Test Cell operates at a design condition during office hours (9 am – 6 pm of weekday). The design occupancy density, internal plug load and internal lighting load are 0.092 person/m<sup>2</sup>, 16 W/m<sup>2</sup> and 8.22 W/m<sup>2</sup> floor area, respectively. The ACMV system supplies constant 33 l/s fresh air and 147 l/s supply air into the room space.

Based on the modeling methods described earlier, an integrated linear model the Test Cell is developed in the MATLAB/Simulink environment. The RC models and heat/mass balance of

room air model are developed using SIMSCAPE language, which is an object-oriented physical modeling method (Miller & Wendlandt, 2010). The thermal comfort in SkyLab Test Cell is modeled with Equation (17) and measured three-day average velocity (0.09 m/s) in the occupied zone during office hours. The FCU in the AMCV system is modeled with Equations (7) and (8) under design conditions. The cooling coils in ACB system are treated as negative heat sources. The developed model is calibrated and refined using measurement data obtained in SkyLab. Fourteen days (8th to 21st January 2018) of experiment was conducted to measure the room temperature and humidity responses to different conditions.

Figure 3 Schematic drawing of the ACMV system in SkyLab Test Cell

In the Test Cell, there are some thermal masses (such as ducts, furniture and steel beams) inside the ceiling space, raised floor space and room space that are not included in the RC model. Thus, the R and C parameters of roof, floor and internal thermal mass are tuned in the calibration procedure. The thermal mass in room space is represented by a 1R1C node, separately, which is only connected to room air temperature node. The Trust-Region-Reflective Least Squares optimization method (Coleman & Li, 1996) is then employed to tune the RC model parameters in MATLAB environment to minimize the sum-squared error of room temperature as. After calibration, the parameter values of the SkyLab Test Cell are listed in Table 1.

Table 1 Tuned parameter values of liner model of SkyLab Test Cell

Envelope	Initial U value (W/m <sup>2</sup> K)	Initial C value (kJ/m <sup>2</sup> K)	Tuned U value (W/m <sup>2</sup> K)	Tuned C value (kJ/m <sup>2</sup> K)
Internal thermal mass	1.6	100	32	485
Roof	0.25	308.4	0.67	391.67
Floor	0.25	77.6	0.43	85.7

Figure 4 Comparison of simulated a) temperature and b) humidity ratio with measured data

Figure shows that there is good agreement between the simulated and measured results after the model calibration. The mean absolute percentage error (MAPE) of room temperature is 1.25% for the entire fourteen-day period. The MAPE of room humidity is 4.98% during office hours. The deviation of the humidity ratio prediction in non-office hours is because the model does not consider the moisture penetration from the ambient into room space.

## CONCLUSIONS

Methods to build a linear building model, which can be used to predict indoor temperature, humidity and thermal comfort for indoor environment control with linear MPC, are proposed. The RC model is adopted to represent the heat and moisture dynamic in the building. The heat transfer and dehumidification process in the ACMV system and PMV index calculation models are linearized by linear approximation of the nonlinear items in the theoretical models. A case study is conducted based on the BCA SkyLab in Singapore. After calibration, the developed linear model has high accuracy and the MAPE of predicted room temperature and humidity ratio are 1.25% and 4.98% compared to measured data, respectively.

### ABSTRACT

In recent years, probabilistic assessment of hygrothermal performance of building components has received increasing attention. Given the many uncertainties involved in the hygrothermal behaviour of building components, a probabilistic assessment enables to assess the damage risk more reliably. However, this typically involves thousands of simulations, which easily becomes computationally inhibitive. To overcome this time-efficiency issue, this paper proposes the use of much faster metamodels. This paper focusses on neural networks, as they have proven to be successful in other non-linear and non-stationary research applications. Two types of networks are considered: the traditional multilayer perceptron (with and without a time window) and memory neural networks (LSTM, GRU). Both are used for predicting the hygrothermal behaviour of a massive wall. The results showed that all networks are capable to predict the temperature profiles accurately, but only the LSTM and GRU networks could predict the slow responses of relative humidity and moisture content. Furthermore, the LSTM and GRU network were found to have almost equal predicting accuracy, though the GRU converged faster.

### INTRODUCTION

In recent years, traditional deterministic assessments in building physics have evolved towards a probabilistic framework (Annex 55, 2015; Vereecken et al. 2015). When evaluating the hygrothermal behaviour of a building component, there are many inherently uncertain parameters, such as the exterior climate, geometry, material... A probabilistic simulation enables taking into account these uncertainties, which allows evaluating the hygrothermal behaviour and the related damage risks more reliably. However, this often involves thousands of simulations, which easily becomes computationally inhibitive, especially when analysing more-dimensional component connection details. To overcome this time-efficiency issue, this paper proposes the use of metamodels, which aim at imitating the original hygrothermal model with a strongly reduced calculation time. Many different metamodeling strategies exist, of which multiple linear regression (MLR) or polynomial linear regression might be the most frequently used. MLR attempts to model the relationship between multiple input variables and an output variable by fitting a linear equation. It often performs well when predicting aggregated values such as the total heat loss (Van Gelder et al. 2014). On the other hand, many damage criteria, such as wood decay or mould growth, require evaluation over time, as such damage often has a long incubation time, whereafter it accumulates. Hence, more advanced metamodeling strategies that can handle time series prediction are needed. Furthermore, the model must be able to capture the highly non-linear and non-stationary pattern of the hygrothermal response of building components. Hence, this paper focusses on neural networks, as they have proven successful in other non-linear and non-stationary research applications.

The multilayer perceptron (MLP) is the most known artificial neural network. It has a feed-forward structure with one input layer, one output layer, and at least one hidden layer in between. Because the MLP can perform a non-linear mapping, it is a widely used (meta-)modelling method. In time-series prediction, it is sometimes used for predicting the next time step based on the current step (Soleimani-Mohseni et al. 2006). However, the MLP is static and has no memory of past time steps; hence, it cannot model input-output relations that span multiple time steps. When these temporal dependencies are short-term, often a time window is added (MLP TW), i.e. the current time step as well as a number of past time steps are used as input to the network (Kemajou et al. 2012). However, the MLP TW fails to capture patterns outside of this time window. Since the time window needs to be determined beforehand, a considerable number of experiments is required to identify the optimum time window.

Recurrent neural networks (RNN) overcome this problem by introducing memory. A simple RNN has a cyclic structure that feeds the output from previous time steps into the current time step as input. Hence, RNNs can model temporal contextual information along time series data. The simple RNN easily suffers from the vanishing or exploding gradient problem though, which makes it difficult for the network to learn correlations between temporally distant events. To deal with this problem, the long-short memory network (LSTM) was proposed by Hochreiter (1998). The LSTM model changes the structure of the hidden units to memory cells with gates. Via these gates, the LSTM unit is able to decide what information to keep from its existing memory, while the simple recurrent unit overwrites its content at each time-step. Hence, if the LSTM unit detects an important feature from an input sequence at early stage, it easily carries this information over a long distance, thus capturing potential long-term dependencies (Chung et al. 2014). Consequently, the LSTM has been widely used for many time-series forecasting and sequence-to-sequence modelling tasks. More recently, the gated recurrent unit (GRU) was proposed by Cho et al. (2014) to make each recurrent unit adaptively capture dependencies of different time scales. Similarly to the LSTM, the GRU has gating units that modulate the flow of information inside the unit, but without having separate memory cells. Both the LSTM unit and the GRU keep their existing memory and add the new content on top of it.

In this paper, the LSTM and GRU, as well as the MLP and MLP TW, are applied for predicting the hygrothermal behaviour of a massive masonry wall, as an explorative study. All network types are compared based on their prediction performance and training time.

## DATA AND METHODS

### Data description

As an example of predicting more complicated damage patterns, the hygrothermal performance of a massive masonry wall is evaluated for frost damage, wood decay of embedded wooden beam ends and mould growth. To estimate whether these damage patterns will occur, the temperature (T), relative humidity (RH) and moisture content (MC) are monitored at the associated positions for a period of 6 years (see Table 1). In this explorative study, the probabilistic aspect of the influencing parameters was not yet taken into account fully, as this allows for a more efficient exploring of several network architectures on a smaller dataset. The data was obtained via hygrothermal simulations in Delphin 5.8. The used input parameters are shown in Table 2; the brick material properties are given in Table 3. To account for variability in boundary conditions, different years of the external climate were used, as well as different wall orientations. Since the interior climate is calculated based on the exterior climate, this variability is also included. In total, 24 samples were simulated, of which 18 samples were used for training and 6 for testing. The neural networks are trained to predict the T, RH and MC time-series, given the time-series of the external temperature and relative humidity, the wind-driven-rain load, the short-wave radiation and the internal temperature and relative humidity.

Table 1. The monitored quantities for the damage patterns at different positions in the wall.

Damage pattern	Position	Quantity
Frost damage	0.5 cm from exterior surface	T, RH, MC
Decay of wooden beam ends	5 cm from interior brick surface	T, RH
Mould growth	Interior surface	T, RH

Table 2. Used input parameters for hygrothermal simulations of brick wall.

Input parameter	Value
Brick wall thickness	360 mm
External climate	Gaasbeek, Belgium
Internal climate	cfr. EN 15026 A
Wall orientation	U(0,360)
Rain exposure factor	1
Solar absorption	0.4

\* U(a,b): uniform distribution between a and b

Table 3. Properties of the used brick type.

Material property	Value
Dry thermal conductivity (W/m <sup>2</sup> K)	0.87
Dry vapour resistance factor (-)	14
Capillary absorption coefficient (kg/m <sup>2</sup> s <sup>0.5</sup> )	0.277
Capillary moisture content (m <sup>3</sup> /m <sup>3</sup> )	0.25
Saturation moisture content (m <sup>3</sup> /m <sup>3</sup> )	0.35

### Network architecture

Several hyper-parameters should be pre-set before building and training the networks, including the number of hidden layers and the number of neurons in these hidden layers. In this paper, all constructed networks have a single hidden layer, as comparative experiments showed no benefits using multiple hidden layers. Furthermore, networks with 32, 64, 128 and 256 hidden units were tested. In case of the MLP TW, a time window of 24 hours was explored. A larger time window, which would be required to capture long-term dependencies, resulted in an extensive input dataset which became too memory intensive. The networks are trained by minimising the mean squared error (MSE) via backpropagation (MLP and MPL TW) or backpropagation-through-time (LSTM, GRU). Based on the results of comparative experiments, the LSTM and GRU networks were trained using the RMSprop learning algorithm (Hinton, 2012) with a learning rate of 0.002. The MLP and MLP TW networks were trained using the Adam learning algorithm (Kingma and Ba, 2015) with a learning rate of 0.001. In general, before presenting data to the network, the data is standardised (zero mean, unit variance) to overcome influences from parameter units. In this paper, both the input and output data are standardised, as this was found to improve training speed and accuracy. The network's accuracy is evaluated by three indicators: the normalised root mean square error (NRMSE), normalised mean absolute error (NMAE), and coefficient of determination (R2), formulated as follows:

$$NRMSE = \frac{\sqrt{\frac{1}{n} \sum (y - y^*)^2}}{y_{max} - y_{min}} \quad NMAE = \frac{\frac{1}{n} \sum |y - y^*|}{y_{max} - y_{min}} \quad R2 = 1 - \frac{\sum (y - \bar{y})^2}{\sum (y - \bar{y})^2} \quad (1)$$

where  $y$  is the true output,  $y^*$  is the predicted output,  $\bar{y}$  is the mean of the true output and  $n$  is the total number of time steps. The RMSE and the MAE are normalised to remove the scale differences between the different outputs. Although the networks are trained to predict all outputs simultaneously, these performance indicators are calculated for each output separately. This allows assessing which outputs are more difficult to predict and which ones are easy.

## RESULTS AND DISCUSSION

Figure 1 presents the three performance indicators (rows) for all outputs (columns) and each network type. This graph shows that some outputs are easier to predict than others; all networks are capable to predict the temperature accurately, as well as the interior surface relative humidity. Since the wall temperature and surface relative humidity respond almost immediately to a change in boundary conditions, not much memory is needed to accurately predict these profiles; for these outputs, the MLP with a time window of 24 hours is about as accurate as the more complicated LSTM or GRU. The relative humidity and moisture content at 0.5 cm from the exterior surface (frost damage) and the relative humidity at the wooden beam ends (wood decay) appear less evident to model. As moisture is transported inwards only slowly, there is a large delay between a change in boundary conditions (e.g. a heavy rain shower) and the response in relative humidity in the wall. At the wooden beam ends, this response delay can go up to several months. Hence, the MLP and MLP TW, which have no or only limited memory, are incapable to capture these long-term temporal dependencies and perform poorly. The LSTM and GRU, on the other hand, are able to capture these complex long-term patterns because of their connections to information from long-past time-steps. Figure 2 shows the temperature and relative humidity at the wooden beam ends predicted by the GRU network with 256 hidden units, compared with the true value. The residuals  $\varepsilon_t$  show that that the error is very small.

Figure 1. The performance indicators show that the temperature patterns are easy to model, while only the memory networks types (LSTM, GRU) are able to model the moisture content and relative humidity patterns accurately.

Figure 2. The temperature (a) and relative humidity (b) at the wooden beam ends, predicted by the GRU network with 256 hidden units. The residuals  $\varepsilon_t$  show that the error is small.

Furthermore, it was found that the number of hidden units appears to have limited effect on the prediction performance in case of the MLP and MLP TW, though it increased the training time (Figure 3). In case of the LSTM and GRU on the other hand, more hidden units resulted in an improved prediction performance and a decrease in training time. It appears that the memory networks converge faster when they have more hidden units. Though prediction accuracy is very similar for both the LSTM and the GRU, the latter required less training time as it has fewer network parameters.

Figure 3. The training time for the memory network types (LSTM, GRU) decreases with increasing number of hidden units. The simulation time for one sample is 1 s for all network types. The reference simulation time for one sample in the original hygrothermal model is about 720 s.

## CONCLUSIONS

In this paper, the hygrothermal simulation model for a massive masonry wall is replaced by a much faster metamodel. Four different types of neural networks were considered as metamodel:

a traditional multilayer perceptron (MLP), a multilayer perceptron with a pre-defined time window (MLP TW), a long-short term memory network (LSTM) and a gated recurrent unit network (GRU). Only the last two types have dynamic memory. The MLP TW has only access to the past time steps within the pre-defined time window, and the MLP tries to predict based on the current time step only. It was found that all network types were capable to predict the temperature accurately. Since the temperature responds almost immediately to a change in boundary conditions, not much memory is needed to capture these patterns. By contrast, only the LSTM and the GRU were able to accurately capture the long-term dependencies needed to predict the relative humidity and moisture content, as these respond much slower to a change in boundary conditions. Both types of memory networks were found to have almost equal predicting accuracy, though the GRU converged faster and thus required less training time.

### ABSTRACT

This paper investigates if it is possible to optimize night cooling control setpoints and ventilation schedule regarding energy consumption and indoor climate. A retail store, located in Gothenburg, was used as a case study. The investigation was done by numerical modelling and simulations. It started with development and calibration of a building energy model for the store with data collected from the field. Afterwards, the calibrated model was used in the optimization of the night cooling. Initially, a genetic algorithm was applied to find the global minimum of the problem and further refined with a local search algorithm. The optimization speed was increased by neural networks, as they can approximate results faster than the building energy model.

The study suggests that the cooling and fan energy consumption can be reduced by 16% in the studied facility, compared to the currently used trial-and-error schemes. The project concludes that the use of logged control data in combination with genetic algorithms and neural networks are an efficient way for both calibration and optimization of building energy models. The industry moves towards an increase of available logged control data. As such, it is important to be able to properly utilize the data, for improving the accuracy of building energy simulations and improving the results.

### KEYWORDS

Night Cooling, Building Energy Modelling, Genetic Algorithms, Neural Networks and Optimization.

### INTRODUCTION

Cooling load has significant impact on energy cost in commercial premises in Sweden mainly due to the peaks in cooling power demand thus increasing the need for power generation. Ventilation at night with cool outdoor air is a wide-spread strategy for reducing and shifting the cooling peaks. Due to complex relations between the building's response to night cooling, the requirements on the thermal comfort and the weather, control setpoints for night cooling are often established on site, through trial-and-error methods. Hence, the opportunity for further optimization of night cooling is missed.

Monitoring of building performance in real time is becoming a wide-spread praxis due to reliable and affordable data acquisition techniques. Indoor parameters, electricity, heat and air flows are recorded continuously, on minute basis. Big data sets that are generated thereby can be used to identify opportunities for energy savings in buildings.

The purpose of the paper is to evaluate the use of genetic algorithms and neural networks with post-processed data from a building to improve the building energy simulations and to

optimize the control settings for night cooling. A store from a real commercial building is used as a case study to allow verification of the modelling results against the measured data. The building in question has a SCADA data logging system of control data such as; indoor temperatures, ventilation temperatures and ventilation air-flow rates. The data are saved every third minute. The records from the SCADA-system worked as a base for calibration of a building energy simulation.

## **OPTIMIZATION METHODS AND SCHEMES**

The work is conducted in several steps. Firstly, a building energy model of the store was created by using MATLAB (MATLAB, 2017). It is a dynamic model that considers the building's capacity to store heat, and where indoor temperature and cooling loads are calculated based on time-varying outdoor conditions, as well as ventilation, comfort and occupancy schemes (Dahlström & Rönn, 2017). This initial model was calibrated to better simulate the reality with the help of logged data from the actual building as shown in the next section. In addition, an optimization strategy was developed and used to improve the model calibration and the settings for the night cooling. This was done by means of genetic algorithms and neural networks as described below.

### **Genetic algorithm**

The optimization method for this analysis needs to be robust as the problems that are optimized can have a number of local minima. This makes a deterministic approach for the general optimization an unsuitable choice. Instead, a genetic algorithm is used as it is better suited to find a global minimum.

Genetic Algorithms (GAs) operate in a way that can be described similar to evolution (Aria, 2015) because they involve random inputs and stochastic search. A genetic algorithm uses a pool of variable-sets that makes it possible to search for the global minimum instead of a local one as multiple potential solution are kept in the pool. A variable-set contains individual values for all the parameters that are being optimized. Each variable-set is tested by an objective function and gets an associated fitness value produced by the objective function. The objective function is the function for which the global minimum is searched and the fitness value is a measure of the variable-sets suitability as a solution.

### **Neural network**

Neural networks can be used to approximate the results of functions that are relatively unknown and dependent on large numbers of input (Aria, 2015). So, called shallow neural networks (MATLAB, 2018) are used in the analysis as they can approximate the fitness value for a variable-set much faster than the building energy model, thus allowing the use of a much broader genetic function with larger pools and more iterations. One simulation by building energy model took 10 seconds, which was 1500 times slower than the neural network.

Shallow neural networks needs to be trained to do a specific job. The training is done by providing the network with examples of input variables and their respective outputs. It will then learn the relation between the inputs and the outputs and can then be used to approximate outputs with new inputs.

### **Optimization scheme**

Two optimization schemes were developed and used in the analyses, each employing a genetic algorithm as illustrated in Figure 1. The objective function for the first genetic algorithm is running the building simulation in MATLAB and calculating the fitness value.

All the variable-sets that are tested by the first GA with their respective fitness value are used as inputs and outputs to train a neural network. This trained neural network can then approximate the fitness value based on new input. The second genetic algorithm uses the neural network as its operative function.

The last step in the scheme is a local search algorithm that starts from the most optimized variable-set in Step 2. The purpose of it is to check if the minimum that was found could be further improved. A local search is used, as the genetic algorithm has very likely found a result close to the global minimum. For this purpose, a deterministic gradient-based method is used, as it will quickly converge to a minimum.

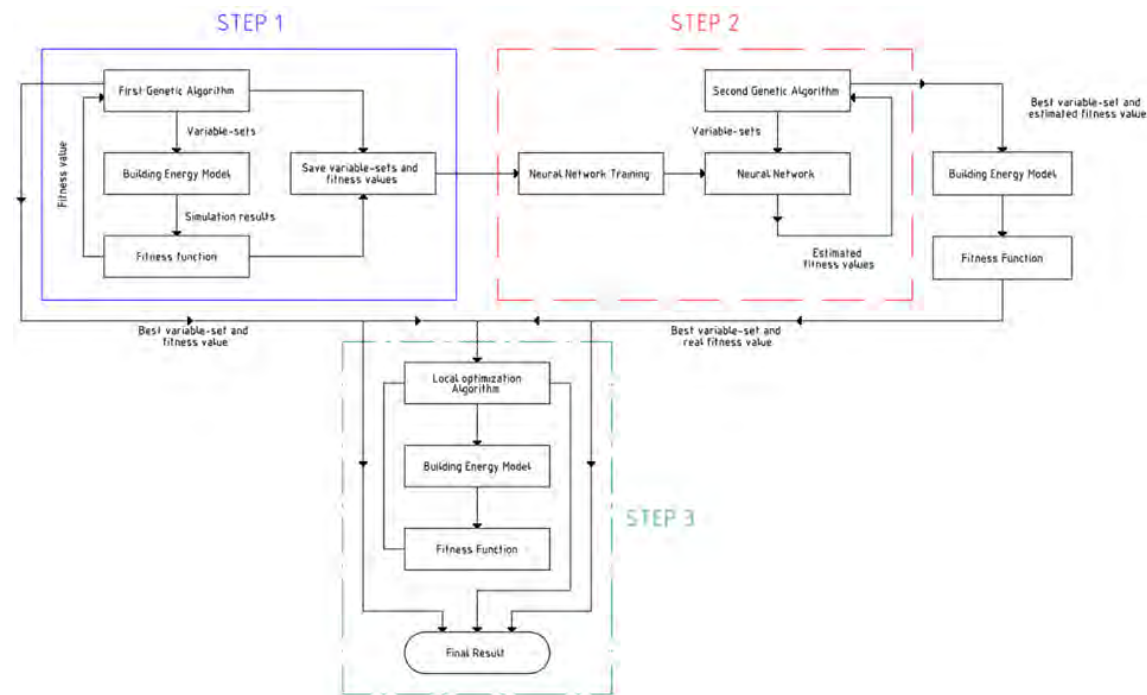

Figure 1: The optimization and calibration scheme used for the analysis.

## THE BUILDING MODEL CALIBRATION

The genetic algorithms are used to calibrate different building constants such as thermal masses of interest, heat transfer coefficients between the indoor air and the interior surfaces, magnitude of internal heat loads and how they are divided between the thermal masses. The aim of the calibration is to achieve as small difference as possible between the measured indoor temperature and the simulated temperature. The model was calibrated for the entire cooling season, from May 1 to September 30, 2016. With this long calibration period, most weather conditions are accounted for.

### Variable-sets and Fitness values

The calibration of the building energy model was done by making minor changes to the parameters that were initially either assumed or estimated by calculations, as the thermal masses and U-values of building envelope components, intensity of heat gains, occupancy schemes, etc. In the calibration, the fitness value is defined as a difference between the time integral of the measured indoor temperature and the simulated one, and presented in degree hours. By minimizing the difference in degree hours, the calibrated model more closely correlates with reality as the integral average between the real temperature and the simulated becomes smaller.

In the optimization of night cooling, new variable-sets, such as air flow rates, indoor and outdoor temperatures, are used instead of the building parameters that were found in the calibration. The fitness value is changed to represent the amount of energy used in the system instead of the difference between measured and simulated temperature. The energy use in the model considers the fan energy, cooling energy and the penalties, if the indoor temperature becomes too low, as described below.

To prevent the optimization to cool the facility below comfort levels in the morning, temperature requirements were inserted in the model. This was done by adding a penalty that starts if the temperature is below a thresholds value at specific times in the morning. The penalty is in form of an added energy usage. It is described as the temperature difference between the optimized indoor temperature and the threshold value, multiplied by a factor. The purpose of this is to train the system to not fall below these requirements.

### Simulation of ventilation

To calibrate the building parameters the measured ventilation data was used. This made sure that the ventilation was not a changing variable in the calibration, thus providing the same conditions for each simulation. However, for the optimization of night cooling, a simulated ventilation scheme was used in order to be able to change the ventilation set-points.

## RESULTS

The calibration results show that a decrease of the degree hours between the simulated and the measured temperature is possible. Table 1 and Figure 2a shows the improvements of the calibrations.

Table 1. Mean temperature and temperature difference for the simulation before and after the calibration for the period May 1 – September 30

	Measured	Uncalibrated Model	Calibrated Model
Mean Temperature	22.71 °C	22.94 °C	22.35 °C
Percentile error	-	1.03%	0.34%
Degree hour difference	-	2207 °Ch	1740°Ch
Average temperature difference		0.6°C	0.47°C

Figure 2b shows the difference in indoor temperatures between the original setpoints, taken from the SCADA-system, and the optimized setpoints.

Figure 2a: To the left a comparison between the uncalibrated model, calibrated and the measured temperature for 72 hours in mid-July. Figure 2b: To the right the temperature for the facility with optimized night cooling setpoints and the original setpoints.

The main differences between the optimized and the original setpoints are; 1) the optimized night cooling is allowed to start earlier, e.g. before business hours, 2) the longer active hours of night cooling make it possible for the indoor temperature to reach lower temperatures, 3) night cooling can be active during weekends.

The optimization reduced the total energy demand for the store by 16%, but only resulted in a daytime temperature decrease of 0.22 °C. Without night cooling the energy demand and temperature increases as shown by Table 2. The original setpoints taken from the SCADA-system.

Table 2. The energy demand for the case study.

	Original night cooling setpoints	No night cooling	Optimized night cooling setpoints
<b>Mean Temperature</b>	22.34°C	23.08°C	21.40°C
Day 08:00-20:00	22.32°C	22.77°C	22.10°C
Night 20:00-08:00	22.37°C	23.58°C	21.32°C
<b>Cooling Energy</b>	19.22 kWh/m <sup>2</sup>	22.58 kWh/m <sup>2</sup>	15.55 kWh/m <sup>2</sup>
Difference	-	17.4 %	-19.3%
<b>Fan Energy</b>	9.51 kWh/m <sup>2</sup>	10.49 kWh/m <sup>2</sup>	8.55 kWh/m <sup>2</sup>
Difference	-	10.3%	-9.7%
<b>Total Energy</b>	28.74 kWh/m <sup>2</sup>	33.06 kWh/m <sup>2</sup>	24.10 kWh/m <sup>2</sup>
Difference	-	15.1%	-16.1%
<b>Average Ventilation Flow</b>	1.19 m <sup>3</sup> /s	1.11 m <sup>3</sup> /s	1.33 m <sup>3</sup> /s
Day 08:00-20:00	1.80 m <sup>3</sup> /s	2.09 m <sup>3</sup> /s	1.41 m <sup>3</sup> /s
Night 20:00-08:00	0.59 m <sup>3</sup> /s	0.09 m <sup>3</sup> /s	1.27 m <sup>3</sup> /s

An increased ventilation during night leads to a decreased daytime ventilation as shown by the table above. This also leads to an overall increase in ventilation flow. An increase of total ventilation flow does not lead to an increase in fan energy due to the quadratic specific fan power (SFP) curve. A consequence of its polynomial shape is that peak flows have a significant increase in energy use. These peak flows are reduced with night ventilation as shown in the decrease of average ventilation flow during daytime. The temperature for the three results behave as expected, the overall mean temperature decreases with increased night-cooling but most of that decrease comes from the decrease in temperature during the night. Without night cooling the mean- and night temperature increase.

## DISCUSSIONS

In the study, the use of neural network is applied in the calibration of the building energy model and the optimization of night cooling, but not tested as a control system. To use a dynamic control system such as a neural network for controlling the ventilation could be an option. However, this would increase the "black box" effect of night cooling. Maintenance technicians and technical managers would have a harder time understanding and changing it and that would decrease its usefulness and flexibility. To train such a control system a genetic algorithm or another algorithm could be used to optimize the weights and transfer functions of the neural network. It would then optimize towards a goal of good indoor climate and less energy use. A neural network can also potentially be used instead of a building simulation model, if sufficient measured data would be available to train the network. However, this would require a complex network and a large number of examples to train it and, thereby, making it impractical to use.

During the analysis, we discovered some limitations and inaccuracies of the neural network. It was very useful and worked with good accuracy for the calibration of the building simulation. But when implementing the penalties for the optimization, the neural network had issues with accuracy. Without the penalty, the neural network would make an accurate prediction but the optimization would lead to an indoor climate that would be unacceptable. Testing showed that reducing the penalty would result in a better accuracy but colder indoor climate. Therefore, for our purpose the penalty was kept high to ensure a better indoor climate even though it counter act the results from the neural network and led to less optimization and testing.

Our reason behind the inaccuracies is that introducing the penalties leads to unexpected behavior. An example of this is a prolonged ventilation that leads to lower energy use until the system gets penalties, which would then quickly result in a larger energy use and a discontinuity in the results. Other configurations of the neural network and more examples to train the network could be a solution that could handle this behavior but it is not included in the scope of this analysis.

## CONCLUSIONS

The results show that genetic algorithms can be used for calibration and optimization of building energy simulations but with some limitations regarding both. For example, the genetic algorithm will always favor an increase in thermal mass and because of that, it would be better to only use it for thermal load calibration. The neural network has also proved to be useful for increasing the speed of the calibration but it had problems with the optimization due to the penalties from the temperature requirements.

## ACKNOWLEDGEMENT

We would like to thank Eric Eliasson and Jörgen Greek at Vasakronan for the support and the technical knowledge. Furthermore, the economic support provide by Torsten Janssons Stipendiefond was appreciated and used to further our research.

### ABSTRACT

Design activity regarding healthcare buildings must not only address the energy efficiency aspects but also account for the indoor thermal comfort conditions. Indeed, the occupants of this category of buildings are affected by different kinds of health issues. Thus, particular efforts are required in order to ensure conditions adequate for therapies and medical treatments. Simulation can be a helpful tool in designing new buildings, particularly in case of complex clinics and hospitals. When analyzing existing facilities, a proper calibration is a necessary step to reduce discrepancies between simulated and measured performance. This improves the reliability of the model itself and allows its use for many purposes, from the assessment of energy performance to the evaluation of indoor thermal comfort, under a broader range of operating conditions and use patterns. In the present contribution, a calibrated model of a healthcare facility in Vienna, Austria, was developed for the assessment of both thermal performance and comfort conditions. The facility, built in the early '90s with later expansions, consists of different rooms and spaces in which several therapeutic activities are performed. Long-term measurements of the air temperature were conducted every 10 minutes for the period between March and June 2015 and used for calibrating the model. During the same period, occupants were interviewed concerning their thermal comfort sensations and detailed short-term measurements were collected to calculate thermal comfort indicators, including Fanger's Predicted Mean Vote and Predicted Percentages of Dissatisfied. The same indices were also calculated through the calibrated simulation model and compared to experimental results and subjective evaluations. The resulting model is finally used to extrapolate the assessment of thermal comfort conditions beyond the measurement period.

Building simulation calibration

Thermal comfort

Healthcare facility

### INTRODUCTION

Ensuring high levels of indoor comfort to all occupants of healthcare facilities can be particularly critical since employees' and patients' comfort perceptions can differ significantly (Hwang *et al.*, 2007; Khodakarami *et al.*, 2012; Skoog *et al.*, 2005; Verheyen *et al.*, 2011). To this extent, building energy simulation, *BES*, can support designers' activity, but when it comes to existing buildings, calibration is required. As reported by Fabrizio and Monetti (2015), among *manual calibration methods based on iterative approach* and *automated techniques based on analytical and mathematical approaches*, also *optimization-based methods* can be

included. For example, Arambula Lara *et al.* (2017) exploited the genetic algorithm implemented in jEPlus+EA to calibrate an EnergyPlus model of an Italian school building. In this work, a portion of a healthcare facility in Vienna was analyzed. After collecting short and long-term measurements, global comfort according to Fanger's model (ASHRAE, 2013; ISO, 2005) was assessed and contrasted with the results by interviews submitted to occupants. An EnergyPlus model was developed and calibrated by means of two steps: first, by comparison with the collected air temperature measurements, and then against the calculated Fanger's indexes - predicted mean votes, *PMV*, and predicted percentages of dissatisfied, *PPD*. After calibration, the developed model was used to predict the comfort in the facility during the whole year, highlighting the extent of the discrepancies between the different occupants' perceptions. Further developments will focus on redesign tasks, based on the analysis of scenarios for long-term thermal comfort optimization, able to manage effectively the discrepancies among the different occupants' perceptions and to minimize overall energy costs.

## METHODS

**Case study and measurements** The study was conducted on the Physikalisches Institut Leopoldau, a private physiotherapy center located at the ground floor of a 20-year old building in Vienna. The analysed area, about 103 m<sup>2</sup>, includes 22 therapy rooms, where therapies are performed from 7:00 am until 8:00 pm, from Monday to Friday. Further details of the case-study, as well as the collected measurements and outcome of the survey on thermal comfort, are reported in a previous research (Zaniboni *et al.*, 2017), in which a new approach for calibration of TRNSYS energy model and cross-validation against calculated and measured Fanger's indexes was proposed.

**Simulation model definition** Since the technical details of the heating system (primary air system integrated with radiators) are largely unknown, it was decided to adopt a simplified model of an ideal air system active only during the occupancy time, with a simple control of air flow rate and temperature, the latter ranging from 22 °C to a 40 °C. EnergyPlus was chosen as simulation code, while the calibration was made partially manually and by means of jEPlus brute-force approach. The analysis included only one thermal zone and the 3D model was prepared using Rhinoceros and the Grasshopper plugin Honeybee. The same initial values and weather data, provided by ZAMG (Zentralstalt für Meteorologie und Geodynamik), used in Zaniboni *et al.* (2017), were set. The average daily occupational profile was calculated from the occupancy data, known from July 2<sup>nd</sup> 2014 to January 20<sup>th</sup> 2015. Shading devices, covering only part of the windows' areas, were simulated as a shading factor equal to 0.6. The EnergyPlus default specific infiltration rate for square meter of façade, equal to 0.0006 m<sup>3</sup>/(s m<sup>2</sup>) and representative of leaky buildings, was selected. Since it was observed that windows were quite often opened in the facility, a dynamic control for natural ventilation was modelled.

**Simulation model calibration** 14 variables were identified for calibration. The initial simulated air temperature profile resulted quite far from the measured one, therefore a first attempt manual calibration was made, considering a different interval of variation for each variable. A sensitivity analysis on *RMSD* (Figure 1) was performed to reduce the number of variables to calibrate in a second step, based on both manual and automatic brute-force calibration with jEPlus.

Figure 1. The sensitivity analysis results: percentages of variation of the *RMSD* in comparison with the initial value, using the maximum and the minimum limit values for each parameter reported on the right.

All the variables affecting the *RMSD* of more than the 5 % were considered. A manual calibration was made on these ones, i.e., thermostat setpoint temperature, the minimum outdoor temperature to open the window and the fraction of windows' area operable. At this point, a brute force calibration using jEPlus was applied to the internal thermal inertia, the air flow rate of the simplified ideal system and the equivalent average number of people present in the structure, the latter used to represent the thermal load by the occupants considering a load of 104 W per person, corresponding to the average between patients' and employees' metabolic rate. For each variable, new ranges were defined with a discrete number of levels from 5 to 7, and a total number of 175 simulations.

Comfort indexes *PMV* and *PPD* were derived from both measured and simulated data during occupancy time in order to validate the calibrated model. Considering the indexes determined from simulations, EnergyPlus air and mean radiant temperature outputs were used in calculations, together with average humidity and air speed by measurements. Finally, in both cases, the *PMV* evaluated at the same time in which votes were collected, were compared for both patients and employees.

**Prediction of the thermal comfort during the whole year** The calibrated model was used to calculate the indexes at each hour during the measurement period of three month, and also during the whole year. To do this last step, the Vienna typical year downloaded from the EnergyPlus Website (2018) was used.

## RESULTS

**Calibration** The first attempt of manual calibration halved the *RMSD* from 2.67 to 1.28 °C. The second attempt of manual and automated calibration made it furtherly decrease to 0.21 °C. The values of the variables after the first attempt manual calibration and at the end of the process are reported in Table 1.

The profile of the measured and simulated air temperature inside the thermal zone are reported in Figure 2, during the whole period and for the last month as an example. As it can be observed, the two profiles get along very well.

Figure 2. The comparison between the air temperature profiles (measured and simulated) during the whole period and for the last 20 days of March 2015.

Table 1. List of the variables varied in the second attempt manual and automated calibration

Variable	Initial	Final
Thermostat Setpoint Temperature [°C]	22	22
Internal Thermal Inertia [J/K]	20700	41400
Air flow rate of the simplified ideal system [m <sup>3</sup> /(m <sup>2</sup> s)]	0.0022	0.04
Equivalent average number of people [-]	22	13
Minimum Indoor Temperature to open the window [°C]	26	18
Minimum Outdoor Temperature to open the window [°C]	24	20
Fraction of window operable area [-]	0.5	0.5

**PMV and PPD indexes** The comparison between the *PMV* indexes at the time in which questionnaires were filled out by the occupants and the corresponding votes is reported in box and whiskers charts in Figure 3. Considering the patients, there is a good agreement between the average values of comfort indexes evaluated from measurements and votes collected by questionnaires and indexes calculated from the simulated model. On the contrary, the average *PMV* calculated from measurements and simulations overestimate the real employees' votes and dissatisfied percentage, which show also larger interquartile ranges. The wider dispersion of comfort sensation of employees can be explained by the large range of clothes and activities made. Figure 4 reports a comparison between average hourly *PMV* and *PPD* indexes calculated by measured and simulated data. The values are the hourly averages during the three months at which the measurements were taken, during the occupational time. In this case, the indexes do not refer to the time in which questionnaires were compiled by employees and patients but to the whole occupancy time. Also in this case, the two groups of indexes are similar, even if a slight underestimation of *PMV* and *PPD* calculated by simulation data can be registered.

The annual simulation results in Figure 6 show very low *PMV* for the patients. The image reports also a second solution, with a higher temperature thermostat setting. The too low *PMV* and *PPD* during the annual simulation are due to the fact that the period of measurements at which the model was calibrated, was a particular year, hotter than usually. This could be solved by the regulation of the thermostat. The lowest peaks are due to the fact that the plant is switched on at 7:00. A solution can clearly be to anticipate it, but at 7:00 not many patients are present in the structure.

Figure 3. Comparison among PMV indexes obtained by measured and simulated internal temperatures and real votes – box and whiskers chart.

Figure 4. Hourly and daily comparison between PMV and PPD indexes obtained by measured and simulated internal temperatures.

Figure 5. PMV calculated during the whole year, hour by hour, regulating the thermostat with 22 °C and 24 °C.

## DISCUSSION AND CONCLUSIONS

In this work, an EnergyPlus model of a thermal zone of a healthcare building in Vienna, Austria, was calibrated for the assessment of both thermal behavior and comfort conditions. Many properties of the building envelope and system were unknown and initial values were assumed from direct inspections and documentation on technical standards. Air temperature measurements taken from March to June 2015 were used for calibrating the model. During the same period, occupants were interviewed about their thermal comfort sensations and detailed short-term measurements were collected to calculate Fanger's Predicted Mean Votes and Predicted Percentages of Dissatisfies. Simulated air and mean radiant temperature profiles from the calibrated model were used to evaluate the same indexes, which were compared to the ones calculated from the short term measured data and people's votes for cross-validation purposes. With the calibrated and cross validated model, an annual simulation was made using the typical year. Thanks to these analyses, we observed that:

- Even starting with a limited number of monitored variables, it is possible to calibrate a simplified model able to simulate, with sufficient accuracy, the comfort indexes for the considered thermal zone.

- With a good synergy of manual and automated calibration, the calibration time can be significantly reduced. This is particularly true when, as in this case, the sensitivity analysis shows a strong dependence of the model on some variables, and also gives some clear indications on how to change these variables in order to minimize the objective function.
- The validated and calibrated model permits to extend the comfort analysis in the structure to time periods which are different from the one in which the measurements were taken for building management purposes. In this case, this allowed to observe that, using a typical year instead of 2015 data as weather file, a different building management is required to ensure proper thermal comfort to patients.

Possible further developments on this case study will be based on the calibrated model and deal with optimization techniques and solutions of model predictive controls. As a final consideration, the proposed method is expected to be applicable also to similar buildings, with the aim to assess the building management in order to optimize thermal comfort for occupants in various seasons and years.

## ACKNOWLEDGEMENT

This study has been funded by the project “Klimahouse and Energy Production” in the framework of the programmatic–financial agreement with the Autonomous Province of Bozen-Bolzano of Research Capacity Building. The authors kindly thank the Zentralanstalt für Meteorologie und Geodynamik (ZAMG) for providing the meteorological data.

### **ABSTRACT**

Applying air cleaning devices is an effective approach to control targeted indoor gaseous pollutants. It is important to understand the adsorption characteristics of filter media (e.g, activated carbon) at typical indoor application conditions as well as standard test conditions. Tests per ASHRAE Standard 145.1 for filter media performance evaluation can provide a relative comparison among different media. However, as the tests are conducted at elevated gas concentrations (1~100 ppm), they do not represent the media performance under lower concentrations typical of indoor applications (<0.1 ppm). Data are currently lacking for describing the correlation between the gas-phase filter media performance and the challenge concentration levels. In this study, single-pass adsorption tests were performed with smaller bed depth and pellet size than that specified in ASHRAE std 145.1 test protocol at four different concentration levels (50 ppb, 500 ppb, 5 ppm and 50 ppm). The data were used to determine the sorption isotherm and suggest a correlation between the partition coefficient and challenge concentration. Results revealed for the first time a linear correlation at log-log scale between the partition coefficient and the challenge concentration. Incorporation of this new correlation in a sorbent bed simulation model enabled the prediction of filter performance at low concentration based on the test data obtained from high concentration tests.

### **KEYWORDS**

Indoor air quality, adsorption, partition coefficient, activated carbon.

### **INTRODUCTION**

Poor indoor air quality has been statistically associated with occupants' health and performance (Seppänen & Fisk, 2006). Volatile organic compounds (VOCs) are found to be one of the major risk factors that are responsible for poor indoor air quality (Gallego et al, 2009). Ventilations, as a dilution method, has limitation in practice for removing targeted pollutants of interest because of its energy consumption and dependency on outdoor air quality. Thus, filtration through sorbent media (e.g., activated carbon) is considered as an effective alternative to reduce specific VOC concentration in an energy efficient manner (Fisk, 2008). Understanding and evaluating the performance of sorbent media become very important for designing a filtration system. ASHRAE standard 145.1-2015 has provided a laboratory test method to evaluate the performance of granular sorbent media (ASHRAE, 2008). However, the challenge concentration described in the test method is at 100±10 ppm, which is far above typical indoor concentration. Consequently, the results of the standard test cannot represent the actual performance of the sorbent media in the indoor environment. The goal of this study is to 1) investigate the performance of sorbent media at different concentration levels, from 100 pm down to 100 ppb (close to typical indoor concentration level of less than 50 ppb), and 2) develop a mechanistic model to simulate the sorbent media at real operation conditions.

## METHODS

An air-cleaning technology test system (ACTTS) was used to investigate the performance of sorbent media at different challenge concentration levels. The design of the test system is illustrated in **Figure 1**. The ACTTS could control and provide the same test conditions, e.g., flow rate, temperature, humidity and challenge concentration to each test column (Figure 2). The diameter of the test column was consistent with ASHRAE 145.1 standard test but the height of sorbent media was reduced to  $L=1$  cm to shorten the test period. Two test columns (sorbent column) were packed with sorbent media, and another one (reference column) was empty for inlet concentration monitoring.

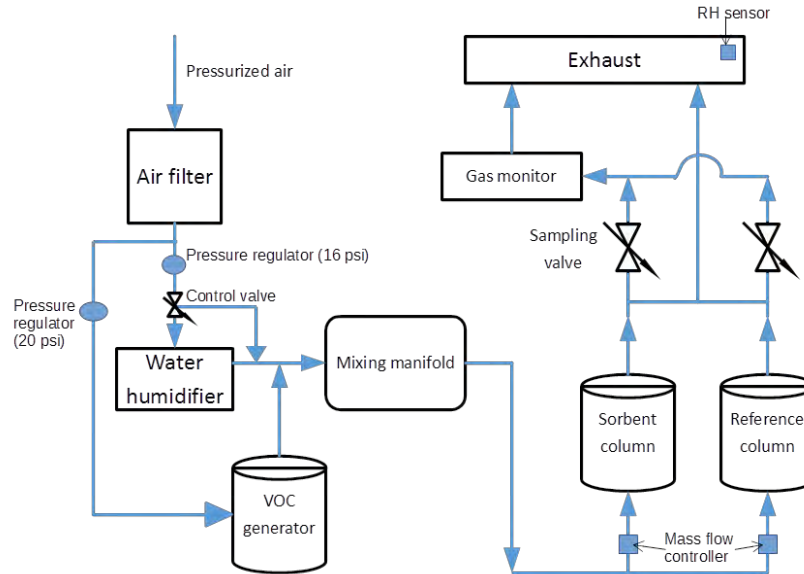

Figure 1 Schematics of the ACTTS

Figure 2 Schematic of the test column

Activated carbon is a widely used sorbent media in practice due to its high surface area and porous structure. Two types of virgin activated carbon were selected to test. The sorbent media were grounded into the particle size of 1 mm through ball-milling. The purpose of the

grounding procedure is to ensure the packing of the sorbent bed is uniform. The specifications of the selected media are listed in Table 1.

Table 1 Specifications of test media

Media ID	M#1	M#2
Material	Coconut base virgin activated carbon	Coal base virgin activated carbon
Apparent density*	0.45 g/cc	0.49 g/cc
Pellet porosity*	0.3	0.4

\* provided by manufactures

Toluene is one of the typical VOCs commonly found in the indoor environment. It has been widely used as a reference compound for total volatile organic compounds (TVOCs) in many studies. Bubbling method and heated permission tubes were used to generate high ( $\geq 5$  ppm) and low concentrations of toluene, respectively. A portable device, ppbRAE 3000 (1ppb resolution;  $\pm 3\%$  accuracy at calibration point), is used for toluene measurement. During the test, both the inlet concentration,  $C_i$  and outlet concentration  $C_o$  were monitored. The ratio between the adsorbed phase concentration and the gas-phase VOC concentration at equilibrium is defined as partition coefficient and used to represent the capacity of the activated carbon. The partition coefficient can be calculated through Eq-1.

$$K_{ma} = \frac{C_s}{C_i} = \frac{Q \cdot \int_0^t (C_i - C_o) dt}{\pi \cdot \frac{\phi^2}{4} \cdot L \cdot (1 - \varepsilon_b)} / C_i \quad (1)$$

where  $K_{ma}$  is the partition coefficient,  $C_s$  is the sorbent phase concentration,  $\varepsilon_b$  is the bed porosity,  $L$  is the height of the sorbent bed, and  $\phi$  is the diameter of the sorbent bed. Tests were conducted in this study to provide the partition coefficients of the two types of activated carbon under 4 different concentration levels ranging from 100 ppb to 50 ppm.

## MODELING AND SIMULATION

The mass transfer of VOC in the packed bed system includes: external convective mass transfer at the outer surface of sorbent particle, internal diffusion inside the pellet (within the pore air and on the internal surface) and adsorption of VOCs on the solid matrix of the sorbent, such as activated carbon. A mechanistic model has been developed to describe the mass transfer process in the sorbent bed in the previous study (He et al., 2014; Pei & Zhang, 2010). The same model was applied but a new method to determine the partition coefficient was used in the present study. Instead of using a constant partition coefficient gained from each experiment, the partition coefficient is considered as a variable that depends on the gas-phase concentration. The correlation between the partition coefficient and the gas-phase concentration, namely, P-C correlation, was found to follow the form of:

$$K_{ma} = a(C_p)^b \quad (2)$$

where  $C_p$  is the gas-phase VOC concentration, which is equal to the inlet concentration at 100% breakthrough.

The parameters used in the simulation are listed in Table 2. The methods to determine the mass transfer coefficient and diffusion coefficient were introduced in the previous study (Pei & Zhang, 2012).

Table 2 Summary of the simulation parameters

Packed-bed	Bed diameter, $D$ , cm	4.8	Measured
	Particle diameter, $d_p$ , mm	1	
	Bed length, $L$ , cm	1	
	bed porosity, $\varepsilon_b$	0.3	
	Pellet porosity, $\varepsilon_p$	0.3 (M#1), 0.4(M#2)	
	mass transfer coefficient, $h_m$ , m/s	0.076	Sh, Re, Sc
Environment	Inlet concentration, $C_i$ , ppm	42, 5, 0.58, 0.1	Measured
	Flow rate, $Q$ , m <sup>3</sup> /h	1.699	
	Superficial velocity, $u_s$ , m/s	0.26	
Media	Pore diffusivity, $D_p$ , m <sup>2</sup> /s	8e-6	Literature (Do, 2011; Khazraei, 2014; Pei, 2011)
	Surface diffusivity, $D_s$ , m <sup>2</sup> /s	5e-10	
	P-C correlation	$K_{ma}=2121.5 \cdot C_p^{-0.728}$ (M#1) $K_{ma}=1880.7 \cdot C_p^{-0.70}$ (M#2)	Measured and regressed

## RESULTS AND DISCUSSIONS

According to the experimental data from the breakthrough tests, the partition coefficient for two activated carbon at 4 different toluene concentration levels were obtained for Test M#1 and Test M#2 (**Figure 4**). The correlation of the partition coefficient and the corresponding challenge concentration was established by regression using Eq-2 (Figure 3). These two correlations for M#1 and M#2 were then used for determining the partition coefficient in each control volume in the simulation.

Figure 3 Correlation between the partition coefficient and the challenge concentration

In **Figure 4**, the simulation results were compared with the experimental data at 4 different concentration levels. The mechanistic model with the partition coefficient determined from the tests could generate results that have good agreement with the test data ( $R^2 > 0.9$ ). The P-C correlation for each activated carbon media could be used to simulate the tests at both high concentration and low concentration.

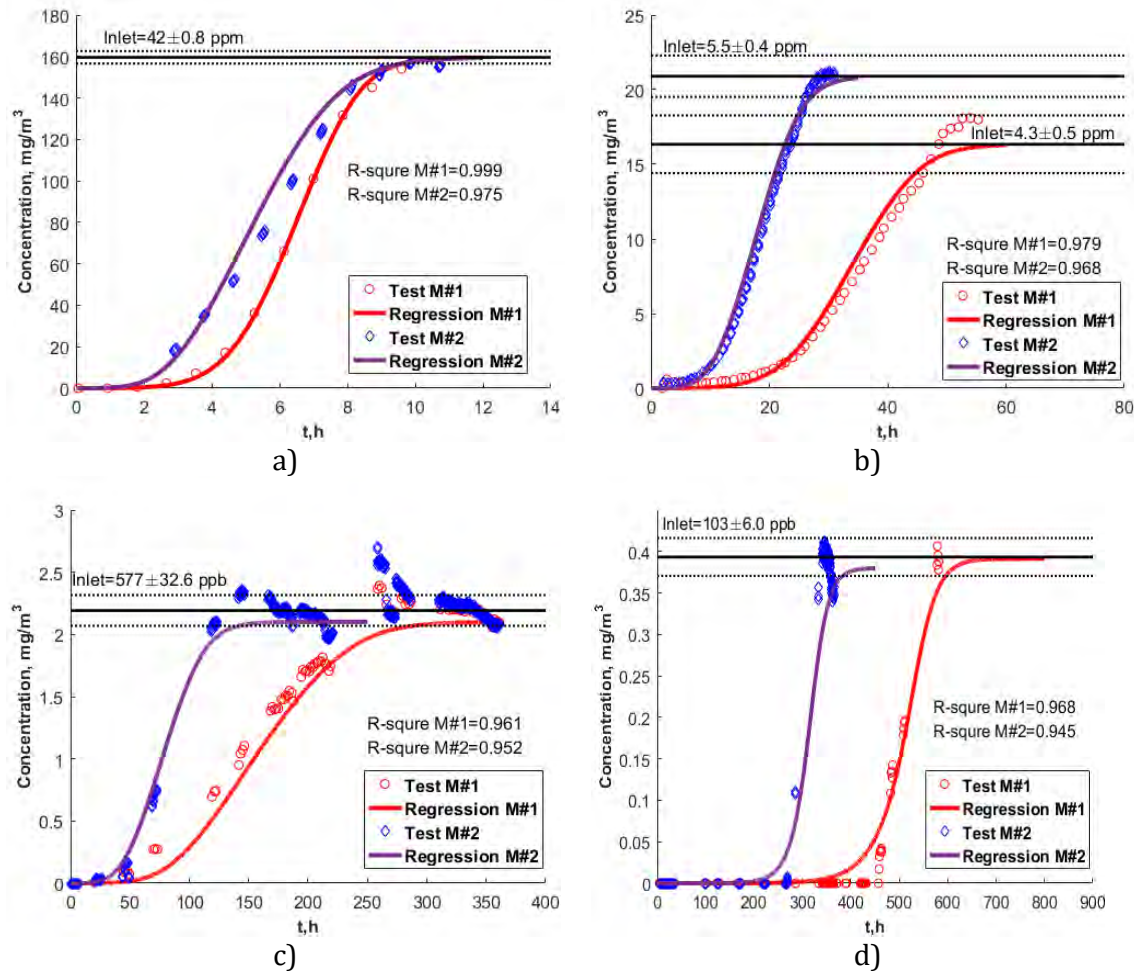

Figure 4 Breakthrough curve of toluene in activated carbon (M#1 and M#2) at four concentration levels

## CONCLUSIONS

Based on the experimental investigation, the removal capacity at 100% breakthrough depends on the challenge concentration significantly. Tests of two types of activated carbon at 4 different concentration levels of toluene show that the partition coefficient increases with decreasing inlet concentration. The correlation between the partition coefficient and the concentration can be represented by a power-law empirical equation (i.e., a linear relationship in the log-log scale). The empirical equation can be used to determine the partition coefficient in the sorbent bed and applied in the mechanistic model to simulate performance of the activated carbon at both high and low concentration of toluene. As a result, it would enable the prediction of the filter performance at low concentration levels typical of indoor environment based on the standard accelerated tests at high concentration levels.

### ABSTRACT

In order to evaluate the impacts of volatile organic compounds (VOCs) emissions from building materials on the indoor pollution load and indoor air quality beyond the standard chamber test conditions and test period, mechanistic emission source models have been developed in the past. However, very limited data are available for the required model parameters including the initial concentration ( $C_{m0}$ ), in-material diffusion coefficient ( $D_m$ ), partition coefficient ( $K_{ma}$ ), and convective mass transfer coefficient ( $k_m$ ). In this study, a procedure is developed for estimating the model parameters by using VOC emission data from standard small chamber tests. Multivariate regression analysis on the experimental data are used to determine the parameters. The Least Square and Global search algorithm with multi-starting points are used to achieve a good agreement in the normalized VOC concentrations between the model prediction and experimental data. To verify the procedure and estimate its uncertainty, simulated chamber test data are first generated by superposition of different levels of “experimental uncertainties” on the theoretical curve of the analytical solution to a mechanistic model, and then the procedure is used to estimate the model parameters from these data and determine how well the estimates converged to the original parameter values used for the data generation. Results indicated that the mean value of the estimated model parameters  $C_{m0}$  was within -0.04%/+2.47% of the true values if the “experimental uncertainty” were within +/-10% (a typical uncertainty present in small-scale chamber testing). The procedure was further demonstrated by applying it to estimate the model parameters from real chamber test data. Wide applications of the procedure will result in a database of mechanistic source model parameters for assessing the impact of VOC emissions on indoor pollution load, and for evaluating the effectiveness of various IAQ design and control strategies.

### KEYWORDS

Building materials, Volatile organic compounds (VOCs), Emission source model, Indoor air quality.

### INTRODUCTION

Indoor air quality (IAQ) plays an important role in human health because people typically spend 80-90% of their time indoors. To evaluate the effects of volatile organic compounds (VOCs) emissions from building materials, a physical mechanistic model was developed by Little and Hodgson (1994) and improved by Yang (2001), Huang and Haghighat (2002), Zhang and Xu (2003) with their specific assumptions and solutions. Deng and Kim (2004) successfully derived the analytical solution to the model that considering the convective mass transfer resistance across the boundary layer. The model in theory can be used to evaluate and predict the emissions of VOCs from dry building materials beyond the standard chamber test condition and test period. However, very limited data are available for the required model parameters including the initial concentration ( $C_{m0}$ ), in-material diffusion coefficient ( $D_m$ ), partition coefficient ( $K_{ma}$ ), and convective mass transfer coefficient ( $k_m$ ).

Little and Hodgson (1994) also performed a series of emission test for four kinds of carpets. Bodalal et al. (1999) tested three types of VOCs through typical dry materials. The correlation

for predicting  $D_m$  and  $K_{ma}$  based on molecular weight and vapor pressure were developed for each product and type of VOCs. These correlations were later verified and improved by Zhang et al. (2003) in the sorption and desorption experiments. Xu et al. (2011) implemented a Dual-chamber test that can measure  $D_m$  and  $K_{ma}$  directly. Xu's data were used for developing and verifying the method that can predict  $D_m$  and  $K_{ma}$  based on the similarity between water vapor and VOC transport in porous media. Cox (2001) measured the  $D_m$  and  $K_{ma}$  in vinyl flooring. Zhou et al. (2018) developed an alternately airtight/ventilated emission method for efficient determination of the key parameters from building materials. The measured  $D_m$  ranged across six orders of magnitudes from  $1E-14$  to  $1E-8$   $m^2/s$  and  $K_{ma}$  ranged from 1 to 450,000 (as shown in Figure 1), depending on the Media (materials)-Environment (T and RH)-Species (VOCs) combinations.

The objective of the present study is to develop a procedure for estimating the model parameters by using gas-phase VOC concentration data from standard small chamber emission tests and explore the feasibility of using the estimated parameters in the mechanistic diffusion model to analyse and predict the long-term emissions from building materials and their impact on indoor air quality.

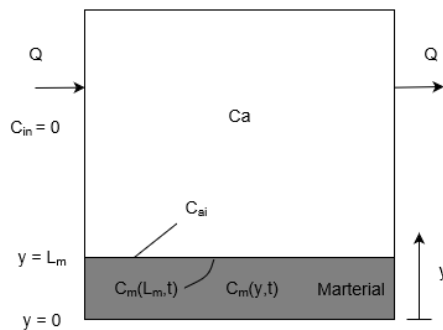

Figure 1 Summary of  $D_m$  (left) and  $K_{ma}$  (right) values from the literature

## METHODS

### Mathematical model

$$\frac{\partial C_m}{\partial t} = D_m \frac{\partial^2 C_m}{\partial y^2} \quad (1)$$

$$\text{The initial condition: } C_m(y, 0) = C_{m0}, 0 \leq y \leq L_m \quad (2)$$

The boundary conditions are:

$$\frac{\partial C_m}{\partial y} = 0 \text{ at } y = 0 \quad (3)$$

$$-D_m \frac{\partial C_m}{\partial y} = k_m \left( \frac{C_m}{K_{ma}} - C_a \right) \text{ at } y = L_m \quad (4)$$

Figure 2 Schematic of VOC emission in a test chamber and the governing equations

A schematic of emission testing and the equations governing the material diffusion process of a dry material in a ventilated chamber is shown in Figure 2, assuming that (1) the material is homogenous with a uniform initial concentration; (2) The diffusion process is one dimensional in the material; (3) The pollutant in the chamber air is perfect mixed; and (4) the interactions between different VOCs are negligible.

For the concentration in the chamber air, the governing equation can be represented as:

$$V \frac{dC_a}{dt} = -QC_a - AD_m \left. \frac{\partial C_m}{\partial x} \right|_{y=L_m} \quad (5)$$

$$\text{Initial condition: } C_a = 0 \text{ at } t = 0 \quad (6)$$

Where,  $V$  is the volume of the chamber,  $m^3$ .  $A$  is the top surface area of the material,  $m^2$ .  $Q$  is the air flow rate,  $m^3/s$ .

### Analytical solution

Deng and Kim (2004) derived an analytical solution derived the following analytical solutions to Eqs. 1-6:

Concentration in the material:

$$C_{m(y,t)} = 2C_{m0} \sum_{n=1}^{\infty} \frac{(\alpha - q_n^2)}{A_n} \cos\left(\frac{y}{\delta} q_n\right) e^{-D_m L_m^{-2} q_n^2 t} \quad (7)$$

Concentration in the gas-phase:

$$C_a(t) = 2C_{m0} \beta \sum_{n=1}^{\infty} \frac{q_n \sin q_n}{A_n} e^{-D_m L_m^{-2} q_n^2 t} \quad (8)$$

$$A_n = [K_{ma} \beta + (\alpha - q_n) K_{ma} Bi_m^{-1} + 2] q_n^2 \cos q_n + q_n \sin q_n [K_{ma} \beta + (\alpha - 3q_n^2) K_{ma} Bi_m^{-1} + \alpha - q_n^2] \quad (9)$$

$$Bi_m = k_m L_m / D_m \quad (10)$$

$$\alpha = N L_m^2 / D_m \quad (11)$$

$$\beta = L \cdot L_m \quad (12)$$

Where,  $Bi_m$  is termed as the Biot number for mass transfer, which represents the ratio of in-material to on-surface mass transfer resistance.  $\alpha$  is the dimensionless air exchange rate, which show the ratio of dilution rate in the chamber air to the in-material diffusion rate.  $L$  is loading ratio, area of material / volume of chamber.  $\beta$  is the ratio of the chamber air to the volume of the material.

$$\text{The } q_n \text{ are the positive roots of: } q_n \tan q_n = \frac{\alpha - q_n^2}{K_{ma} \beta + (\alpha - q_n^2) K_{ma} Bi_m^{-1}} \quad (13)$$

### Approach to the determination of the model parameters

The present model has four key parameters:  $k_m$ ,  $K_{ma}$ ,  $D_m$ , and  $C_{m0}$ . Due to the consistent flow patterns in the standard chamber test condition, the  $k_m$  can be pre-determined as part of the chamber characterization measurements. For example, the  $k_m$  of the small scale environmental chambers used to establish the material emission database (MEDB-IAQ) at the National Research Council Canada (NRC) were measured to be 1.0 and 1.5 m/h, respectively (Zhang et al., 1999). Some empirical relations were also adopted for the gas-phase mass transfer coefficient (Huang and Haghighat 2002). For laminar flow, there exists (White, 1988)

$$Sh = 0.644 Sc^{1/3} Re^{1/2} \quad (14)$$

Where,  $Sh$  is Sherwood number ( $Sh = \frac{k_m}{D_m / L_m}$ ).  $Sc$  is Schmidt number ( $Sc = \frac{\nu}{D_m}$ ),  $\nu$  is the kinematic viscosity,  $m^2/s$ .  $Re$  is Reynolds number ( $Re = \frac{v \cdot l}{\nu}$ ),  $v$  is the velocity of the fluid,  $m/s$ ,  $l$  is the characteristic dimension,  $m$ .

The remaining three key parameters ( $C_{m0}$ ,  $D_m$  and  $K_{ma}$ ) need to be obtained from the emission test data. From Deng's analytical solution of gas-phase concentration (Eq.8),  $C_{m0}$  does not affect the shape of concentration curve  $C_a(t)$ , though it affects the magnitude of  $C_a(t)$ . So we first

estimated the initial value of  $C_{m0}$  ( $C_{m0,ini}$ ) by using a first-order evaporation model (Zhang et al, 1999) and then use it in the regression analysis of normalized concentration to estimate  $D_m$  and  $K_{ma}$ . Since the gas-phase concentration is proportional to  $C_{m0}$  for the same  $D_m$  and  $K_{ma}$ , the final value of  $C_{m0}$  can be obtained by:

$$C_{m0} = C_{m0,ini} \frac{\int_0^{t_n} C_{a,data} dt}{\int_0^{t_n} C_{a,sim} dt} \quad (05)$$

Where,  $C_{m0,ini}$  is the initial guess of  $C_{m0}$ .  $t_n$  is the time of the last data point.  $C_{a,data}$  is the measured gas-phase concentration from chamber test data.  $C_{a,sim}$  is the simulated gas-phase concentration calculated by the analytical solution with  $D_m$  and  $K_{ma}$  from the regression analysis with initial guess of  $C_{m0}$  ( $C_{m0,ini}$ ).

### Procedure for the determination of the model parameters

The chamber data are first pre-processed by curve fitting with a power law model, which is then used to generate the data with the same “sampling” time interval. The initial guesses of the three key parameters are obtained from the generated data. To minimize the distortion of normalized curve due to measurement error of maximum concentration, we used the average concentration over the test period ( $C_{a,avg}$ ) to normalize the measured concentrations in the chamber. Then the regression analysis with global minimum algorithm that could find the minimum least square of error in the concentration (target function:  $F(D_m, K_{ma}) = \sum (C_{a,estimate}(t) - C_{a,data}(t))^2$ ) is performed on the normalized data ( $C_a/C_{a,avg}$ ), which is followed by the re-calculation of the  $C_{m0}$  by Eq.15. If the results of  $D_m$  and  $K_{ma}$  are in the range of  $K_{ma}$  dominated state (i.e.,  $K_{ma}$  is so large that there is abundant VOC mass on the surface that the in-material diffusion resistance is inconsequential comparing to the convective mass transfer resistance over the surface), the upper limit of  $D_m$  were accepted as final estimation of  $D_m$  as the conservative estimate. Otherwise, the results of the regression are used as the parameter estimates.

## RESULTS

### Verification of the procedure from measured parameters

A reference emissoin test with 840 hours of experimental data for a particleboard (PB1) obtained by NRC (1999) are used to examine the effect of the elapsed time on the regression results. In this test, VOC concentrations were measured at  $t=94, 120, 168, 240, 336, 504, 672$  and 840 hours. The data are well represented by Deng’s analytical solution (2001) with the parameters:  $D_m=7.65 \times 10^{-11} \text{ m}^2/\text{s}$  and  $K_{ma}=3289$  for toluene (note that the volume of the small-chamber is 50 L, the air change rate is 1 ACH, the loading ratio is 0.729, the thickness of the material is 0.0159 m). We use analytical solution to generate simulated concentration data with a “sampling” interval of 24 hours, which were then used to test the effects of the test period (i.e., the simulated test peiord or elapsted time). The relative error in estimating the three parameters decreases with the increase of the simulated test period. 96 h and 120 h tests would give 150%-200% overestimate of  $D_m$  and 30%-20% underestimate of  $C_{m0}$ . A test period of longer than 240 h would give reduce the relative error to be less than 1%.

Gas-phase concentration of 94 measured cases (only  $D_m$  and  $K_{ma}$ ) shown in Figure1 were generated by analytical solution. 80% of  $D_m$  and 90% of  $K_{ma}$  ranged from 20% - 500% that coverd most the compounds in the materials except vinyl flooring from Cox and carpet3 from John Little. All the out of range cases have very small  $D_m$  ( $<1\text{E-}12$ ) and  $K_{ma}$  ranged from 810 to 450,000. The  $D_m$  of these cases converged around  $1\text{E-}12 \text{ m}^2/\text{s}$  by the global minimum algorithm with 300 multi-start points, which is one of the local minimum but not the global minimum of target function. 7 of these cases can find the global minimum by increasing the multi-start points to 1000. Genetic algorithm will be tested in the future to increase the speed of convergence to global minimum.

### Effects of experimental uncertainty of chamber measured concentration

All the previous discussion or verification of procedure are based on simulated data by analytical solution without any uncertainty of measured chamber concentration which is ideal condition. The experience value of uncertainty in the standard chamber test is 10% from NRC database. To test the effect of uncertainty, 100 cases of PB1 were generated by analytical solution by adding 10% uncertainty which follow the normal distribution on each data points.

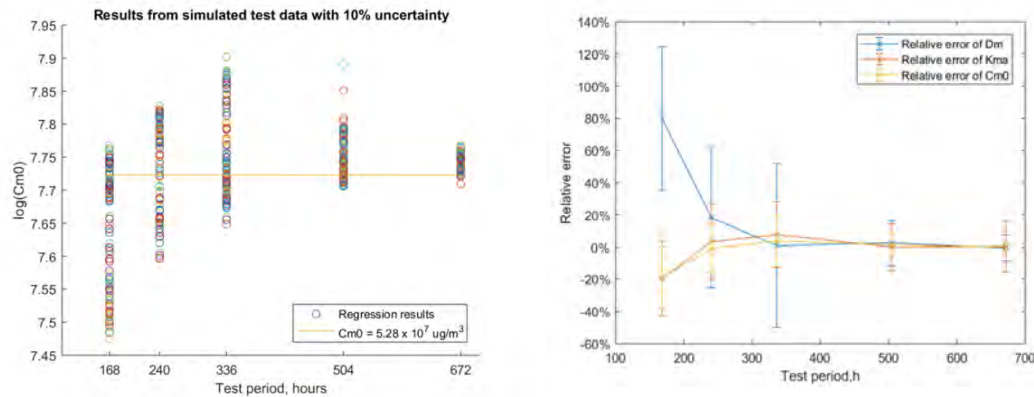

Figure 3 Results of  $D_m$  for 1000 cases with 10% uncertainty

From the above figures, the uncertainty of measured data has a significant impact on the results of key parameters for any one case. The statistic results show the similar behavior as discussion of effect of test period. For the above case, the test period less than 120 hours do not have enough data points to eliminate the influence of uncertainty. In other words, the uncertainty has a larger impact to the shorter test period.

The relative error between mean value of 100 cases and given parameters vary with test period. (Figure 4, right). Based on the relative errors of the three key parameters, the prediction of  $D_m$  is higher at 168 h and 240 h, but less than 3.02% after 336 h. The prediction of  $K_{ma}$  is less than 2.36% with test period longer than 240 h. The prediction of  $C_{m0}$  is under 3.72% with the test period longer than 240 h. The standard deviation of the prediction ranged from 54.17% to 2.47% for all the three key parameters. The procedure can give the same order prediction with test period between 168 h to 240 h and less than 1%  $\pm$  16.01% with 672 h test. Based on the analytical solution (Deng, 2004), the errors in  $C_{m0}$  transfer directly into the model prediction errors in  $C_a$  and has the largest influence on the model prediction (Wei and Xiong, 2013).

### Application of the Procedure on particleboard

Figure 4 Chamber concentration of PB6

One material (particleboard ID: PB 6) was selected from the NRC database to investigate the application of the procedure. Figure 5 gives the results of PB6 when implement this procedure. For PB6, when the time is longer than 336 h, this procedure gives good result to approach the test data. Using all 840 h data resulted  $D_m$  and  $K_{ma}$  that gave the best curve fitting for the long-term prediction, but the initial concentration data points were not as well represented.

### CONCLUSIONS

Based on the standard chamber test and analytical solution of diffusion model, a

procedure has been developed, which can obtain the key parameters of the diffusion model by multi-variance nonlinear regression analysis. The concentration curve generated by estimated key parameters shows a good agreement with the real chamber test data. Uncertainty of measurement affects the accuracy of estimated key parameters very much, but the statistic results show convergence to the true value when applied the procedure to 1000 cases. Further studies will focus on weight factor to enhance the matching of long-term concentration and more efficiency global search algorithm (e.g., genetic algorithm) in the future. Wide applications of the procedure will result in a database of the required emission model parameters for predicting the impact of VOC emissions on IAQ.

### **ABSTRACT**

Identifying building envelope thermal properties from the calibration of a lumped model raises identifiability issues. Not only needs the simplified model to be structurally identifiable, i.e. deliver unique estimates after calibration, but also the data used might not be informative enough to result in either or both accurate estimates and physically interpretable values. This could particularly be the case when data is extracted from non intrusive in situ measurements, in the sense not disturbing potential occupancy. In this frame, this paper develops a method to investigate the physical interpretation of the parameters of lumped models through a numerical tests procedure. Each test runs a simulation of a comprehensive thermal model of a building, with variations in thermal resistance properties of the envelope. Each simulation delivers data used to calibrate a lumped model. The parameters of the lumped model are then physically interpretable if their value vary according to the variations of the comprehensive model. The overall test procedure is applied to the study of a 2R2C model. Results show that the calibration of this model delivers robust calibration results for all parameters but one and also shows satisfactory robustness of the estimation of the overall thermal resistance. This paper concludes that the numerical test procedure does allow to evaluate practical identifiability of lumped models, and will in future work be used to examine more complex lumped models.

Practical identifiability, Parameter estimation, Model calibration, Lumped models

### **INTRODUCTION**

A major lever for decreasing energy consumption in both newly built and existing buildings would be to accurately estimate, in situ, the building envelope thermal performance. Delivering valuable information on that performance relies then on an accurate, detailed and robust analysis of the building's envelope. Methods such as the coheating test, QUB or ISABELE methods (Sonderegger 1978; Mangematin et al 2012; Schetelat and Bouchié 2014) deliver a satisfyingly accurate Heat Loss Coefficient of the envelope, but cannot identify weaker parts of the building's envelope on which concentrate retrofit efforts. Furthermore, these methods are hardly applicable for in-use buildings as they rely on a lot of measurement equipment and require inoccupancy for a period from a few days to a few weeks. Recent literature (Reynders, Diriken, and Saelens 2014; Deconinck and Roels 2017; Menberg, Heo, and Choudhary 2017) has focused on calibrating dynamic simplified thermal models in the hope of physically interpreting calibrated parameters. It showed that the overall Heat Loss Coefficients may be robustly estimated, but that in the particular settings studied, thermal properties of each layer of the envelope could not. This paper presents a method that assesses how each parameter of a lumped model truly represents the building envelope. The method is first described and then applied to a 2R2C lumped model.

## METHODS

### Overview of the numerical test procedure

To test different envelope settings, the method is based on an entirely numerical study. Given known weather boundary conditions, a comprehensive model defined in EnergyPlus (Figure 1 : I) is written in  $N$  versions representing as many envelope settings to test. Each setting generates a thermal dynamic simulation. Each simulation returns an indoor temperature profile (Figure 1 : II) from which 5 days data in January are extracted. Noise from a normal distribution  $N(0,0.2)$  is then added to the data. The third step is to calibrate the selected lumped model, i.e. fit it to the noisy data (Figure 1 : III). The objective of the overall procedure is then to study the variability of the calibrated parameters (Figure 1 : IV) : do the estimations of the parameters vary according to the changes made in the original complete thermal model? In other words, to what extent are the parameters of an RC model representative of the physical thermal properties of the original comprehensive model?

Figure 1: Numerical test procedure

### Specific settings of this case study

The comprehensive model used in this work is based on a Bestest 600 case (Judkoff and Neymark 1995) equipped with a convective electric heater and no air infiltration nor ventilation. Window area is  $3 \text{ m}^2$  to avoid the overheating from the original Bestest scenario. Indoor temperature setpoint schedules are set to reach  $17^\circ\text{C}$  at night and  $20^\circ\text{C}$  during the day.

Table 1: Design of experiments used in this study. From left to right, the envelope is poorly to highly insulated

Experiment number	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16
Wall insulation (cm)	5	5	5	5	5	5	5	5	20	20	20	20	20	20	20	20
Roof insulation (cm)	5	5	5	5	20	20	20	20	5	5	5	5	20	20	20	20
Window air gap (mm)	4	4	20	20	4	4	20	20	4	4	20	20	4	4	20	20
Floor insulation (K/W)	10	25	10	25	10	25	10	25	10	25	10	25	10	25	10	25

We choose for a design of experiments, as suggested in (Iooss 2011). The thermal comprehensive model therefore undergoes four different changes in insulation thicknesses, ground floor thermal resistance and double pane glazing air gap thickness. This design of experiment is therefore intended to only assess the influence of thermal resistance properties. Each parameter takes two possible values as shown in Table 1 and a full factorial design is run, i.e. 16 different configurations.

In the present paper, we apply the method to the calibration and study of a 2R2C model (Figure 2). As for any model calibration, the structural identifiability of the 2R2C model has to be checked and it has been found structurally identifiable (Bellu et al. 2007). This means that, in theory, there exists only one set of parameter values towards which the calibration algorithm will converge.

Figure 2: Model 2R2C. In blue the model output, in orange the model inputs, in black the unknown parameters and state variables

Each model is calibrated by bayesian inference (Figure 1 III), where the parameters and the unknowns are considered to be probability distributions. Calibrating the model then means determining the parameters probability distributions given the available data, also known as posterior distributions. The literal expressions of the posterior distributions cannot be known and are therefore sampled by an adaptive Metropolis algorithm (Haario, Saksman, and Tamminen 2001). Each parameter distributions can then be plotted with a boxplot as in Figure 1 IV, showing the most probable value, its standard deviation and its 95% confidence intervals.

## RESULTS

### Contribution of envelope properties to the calibrated parameters

Estimations of all five parameters of the 2R2C model for each experiment setting are shown in Figure 3.

Resistance parameters  $R_{ext}$  and  $R_{int}$  in Figure 3 (a) vary differently.  $R_{ext}$  shows a significant correlation with the thermal properties variations in the experiment, whereas  $R_{int}$  is quite steady and takes values between  $4 \cdot 10^{-4}$  and  $9 \cdot 10^{-4}$  K/W. From this experiment could be inferred that  $R_{ext}$  actually represents the thermal resistance of the envelope itself.  $R_{int}$  might rather represent the resistive air layer at the indoor surface, which is theoretically in the range [ $8 \cdot 10^{-4}$  K/W ,  $13 \cdot 10^{-4}$  K/W].

The solar coefficient  $A_{sol}$  estimation in Figure 3 (b) is also significantly correlated to the thermal resistance properties of the building envelope. The better the insulation, the lower the parameter estimation. Ground floor insulation or window air gap show however no significant influence on the value taken by the solar coefficient  $A_{sol}$ . This result is not coherent with the expectation that this parameter should not vary with thermal properties. We indeed expect it to be physically related to window orientation and size, that are not changed in this design of experiments. We explain this unexpected result first by the fact that the 2R2C lumped model is quite simplistic and might not be entirely interpretable when fitted to data. Also, the solar irradiation and the indoor-outdoor temperature differences are probably partially correlated to begin with. A different indoor temperature setpoint schedule and/or adding a shading schedule might give better interpretability of the  $A_{sol}$  parameter.

Figure 3 (c) shows that the thermal capacity parameter  $C_{ext}$  is not significantly varying with the different experiment settings, which is the expected result. Indeed, the comprehensive model is one of the Bestest low thermal inertia scenarii and has indoor insulation. As the

experiments only varied thermal resistance properties, the thermal capacity is expected to remain steady. Compared to the values taken by the thermal capacity  $C_{int}$  in Figure 3 (d),  $C_{ext}$  seems to represent the thermal capacity of the envelope itself. Noteworthy is that  $C_{int}$  takes values indicating that it could represent the indoor air thermal capacity, but with extremely large confidence intervals. This shows that this parameter is poorly identifiable, meaning that its exact value cannot be inferred from these results. Data with more frequent measurements, every 1 to 5 min instead of 10 min, might enhance its identifiability though.

Figure 3: Variation of all 5 parameters of the lumped model with the experiments settings

### Robustness of overall thermal resistance of the envelope

An equivalent resistance  $R_{eq}$  can be calculated from the estimation of both resistances of the 2R2C model :  $R_{eq} = R_{ext} + R_{int}$ . The equivalent resistance  $R_{eq}$  may then be compared to a theoretical overall thermal resistance  $R_{th}$  of the comprehensive model envelope.

From Figure 4 can be seen that fitting the 2R2C model gives a satisfactory estimation of  $R_{eq}$  (mean error up to 6,5 %). In the case of a highly insulated envelope (experiments 9 to 16), the error to the theoretical value is higher than with poorly insulated envelopes (experiments 1 to 8), especially when the ground floor is poorly insulated, for example in the experiments 13 or

15. The 2R2C model does not include any term representing the losses to the ground to differentiate them from the losses to the ambient air. So as soon as losses to the ground become significant compared to losses to the ambient air, the resistances of the model take the losses to the ground into account. This needs to be considered when comparing the estimated equivalent resistance of the building to a target value from a norm or a regulation, as in theory losses to the ground are not taken into account in the theoretical calculations.

Figure 4: Estimation of the overall thermal resistance : agreement to the theoretical value

## DISCUSSION

First of all, the methodology applied to a 2R2C model showed that the parameter estimation converged towards unique estimates, except for parameter  $C_{int}$ . This stresses out that theoretical identifiability is necessary but not sufficient. The data here is not informative enough for the parameter  $C_{int}$ . It is however sufficient to uniquely estimate values for the other parameters, which is promising for future work where data from occupied buildings are used. Indeed, this shows that major temperature differences, as seen in Schetelat and Bouchié (2014) or in Mangematin et al (2012) are not necessary to identify thermal properties of a building envelope. Additionally, it would be interesting to study the robustness of the results with fewer days data. In particular, one could study the influence of outdoor conditions which might particularly affect the results when the model is fitted on fewer days. We refer here to (Juricic et al. 2018).

Secondly, the study showed that the estimates could be, to a certain extent, identified with true thermal properties of the envelope.  $R_{ext}$  and  $C_{ext}$  have been found representing the envelope thermal properties itself, whereas  $R_{int}$  and  $C_{int}$  were found rather related to properties of the indoor air. It seems though that this model cannot identify thermal properties of layers inside the envelope. It would be interesting to study how parameters of more complex models can be identified to different envelope layers, starting with 3R3C models. At the same time, estimating the overall thermal resistance in these conditions shows satisfactory robustness, unless ground floor insulation is much poorer than envelope insulation, which would rarely happen in existing buildings though. This result is promising when considering testing existing buildings for regulatory purposes. Compared to Deconinck and Roels (2017) who found poor identifiability in all of the tested RC models for a cavity wall in winter, this case study studies the whole envelope has quite different boundary conditions which is probably why the parameters here were found to be identifiable even in winter. The work of Deconinck & Roels however suggests, by extrapolation, that estimations from the 3R3C model should be more trustworthy.

Finally, if a design of experiments approach was coherent with the goal of this study, further work should focus on variations of many more envelope properties of the reference building. A preferable approach will be to use sensitivity analysis tools, namely the RBD-FAST variance decomposition approach, allowing at the same time an efficient parameter space exploration and a more detailed study of the parameters interactions.

## CONCLUSIONS

This paper shows how the numerical tests procedure allows to evaluate practical identifiability, i.e. interpretability of model parameters. Future work will focus on different comprehensive models, starting with scenarii with heavier thermal mass, on more complex lumped models in the hope of distinguishing contributions of separate parts of the envelope and finally on combining this methodology with a study of the influence of boundary conditions on identifiability.

## ACKNOWLEDGEMENT

The authors would like to thank the ANR-15-CE22-0003 BAYREB funding which has made this work possible. All results of the project are online at [locie.github.io/bayreb](https://locie.github.io/bayreb).

### **ABSTRACT**

Some part of indoor space components such as furniture and surfaces (like walls and floor carpet) contains contaminants and emit them over time. The emission is affected by different environmental factors like temperature, relative humidity, and solar radiation. As a result, three field experiments are conducted to assess the impact of these environmental factors on Formaldehyde emission. This study referred to previous literature on measuring volatile compound emission from wood stain using balance scale. Consequently, a similar test setup (balance scale) is adopted to investigate formaldehyde emission from test sample which is exposed to solar radiation in fully controlled test buildings. Two identical particle-board test samples are prepared and one of them placed inside a test building in which the window is fully covered whereas the other test sample is installed in a building which is not covered so that it is exposed to solar radiation to the maximum extent. Moreover, Formaldehyde meter captures the concentration inside the test room release from the test sample. The result shows that the test room with 23°C depicts slightly more formaldehyde in comparison to a room with 18°C. Whereas, both rooms with 50% and 70% RH shows similar Formaldehyde concentration between 20 ppb and 25 ppb.

### **KEYWORDS**

Formaldehyde, solar radiation, RH, Temperature, emission rate.

### **INTRODUCTION**

The indoor environment is consisting of different components which contains chemical compounds harmful to the dwellers [1]. Although various measures are taken to minimize the indoor components with high pollutant sources, there are still some components such as particle board that produce formaldehyde which is deemed harmful [2]. The emission rate is found impacted by different indoor environmental elements such as temperature and relative humidity [3]. The impact of these environmental elements has been investigated by various studies [4].

The impact of temperature on formaldehyde emission from a laminated particleboard floor was found low at both 23°C and 29°C; however, the high initial concentration found influencing the emission which gradually decreased at 50°C [5]. Moreover, the impact of temperature on the emission further extended to investigate the impact on components of parameters that depict the emission of formaldehyde from particle board and found to have a significant effect on both diffusion coefficient and partition coefficient [6]. Whereas, the remaining component initial (imitable) concentration found affected by the relative humidity [7]. The combined effect of temperature and relative humidity studied and found having a significant influence on formaldehyde emission [8].

However, most of these researches were done in a climate chamber which is different from the field experiment where the measurement is conducted under a real environment (more

dynamic). Besides, there is insufficient research in the area where solar radiation is influencing particle emission. Therefore, this study incorporates the effect of solar initiated formaldehyde emission in addition to temperature and relative humidity to get insight on formaldehyde emission in a full-scale test building simulating study room or small office.

## METHOD

Field experimental measurement method is used to conduct this study. Two identical experimental test buildings with an overall dimension of 12 ft x 16 ft x 10 ft are used to carry out these tests. Both buildings have two (3 ft by 4 ft) windows on their south and north walls. These two buildings are exposed to a similar climatic environment as shown in Figure 1. The indoor condition in both buildings are set to maintain 21°C room air temperature, and 50% RH in 100% recirculated air ventilation at 5 cfm. Then three separate measurements are conducted to study the impact of solar radiation, temperature, and relative humidity on Formaldehyde emission from particle board. Two type of measurement is conducted in the test rooms. First, the Formaldehyde concentration in the air, the second weight loss of the test samples as a result of mass exchange using balance scale. Moreover, two-weeks of data measurement is reviewed, and single day data is reported for each case in the result and discussion section.

A) South Test Building (STB)

B) North Test Building (NTB)

**Figure 1: Whole Building Research Laboratory (WBRL).**

The experimental set up for the first test case arranged to examine the impact of solar radiation on Formaldehyde emission from particle board test sample. Two test samples are prepared from a single sheet of particle board, a building material which is known to have and release formaldehyde. The samples have similar dimensions and size. Due to the balance maximum weight capacity, the test samples are limited to have 0.7 m x 0.7 m surface area and 11 mm thickness. One of the test samples is exposed to solar radiation inside south test building (STB) where the window is not covered as shown in Figure 1 (A). The other test sample is placed inside the north test building (NTB) in which the window is fully covered with aluminum foil to block solar radiation reaching inside the test room as shown in Figure 1 (B). Besides, the mass loss from the test samples due to formaldehyde emission is measured using balance scale as shown in Figure 2 B. The off-gassed formaldehyde concentration in the test room is measured using formaldehyde sensor as illustrated in Figure 2 A.

A) Formaldehyde meter

B) A test sample (window not covered)

**Figure 2: Formaldehyde meter and Thermocouples on the surface of test sample: Window not covered**

The buildings are first flushed with high ventilation rate 1.1ACH (30 cfm) before each test. The ventilation rate then changes to 5 cfm and the background Formaldehyde concentration is measured. Following that the two samples are introduced into the test room, and the measurement carried out. The test samples are prepared and installed as illustrated in Figure 2. As illustrates in Figure 2 B, two balances are used to measure the mass change over the measurement period. The maximum capacity of the balances is 4100g for the balance in the NTB and 6100g in the STB. The initial mass of the samples is 3257.922 g in STB and 3261.722 g in NTB. In addition, five thermocouples are installed on the surface of the sample to identify the part of the sample under solar radiation as shown in Figure 2 B.

The experimental set up is rearranged for the experiments to investigate the effect of indoor air temperature and relative humidity on Formaldehyde emission separately. As a result, a full-size particle board (5/8'' x 49'' x 97'' CARB II / E1 PB) is mounted in both test rooms as shown in Figure 3 B, where the windows of both test buildings are not covered but the solar radiation doesn't reach on the samples. In the test where the impact of temperature is investigated, the setpoint temperature in North Test Building (NTB) is at 18°C and in the South Test Building (STB) is at 23°C keeping the same relative humidity (50%). For the last test in which the effect of relative humidity is investigated involves setting both test rooms at 21°C but different relative humidity (NTB at 50% and STB at 70%). Moreover, a single formaldehyde meter is used to measure the formaldehyde concentration in the test room by switching the sensor between the test buildings. The sensor is switched every other day for the second test which investigates the impact of temperature; whereas, for the last test case, it is switched every three and half days.

## RESULTS and DISCUSSIONS

### Temperature distribution

Figure 4 shows the temperature reading from five thermocouples on the surface of the test sample over 24 hours period where the impact of solar radiation on formaldehyde emission measurement is conducted. As depicted in the figure the temperature raised during the daytime when the sun radiates on it. The maximum temperature reading on the sample was over 30°C. Whereas, the average sample temperature at the pick is over 26°C which is more than 5°C relative to the average room temperature (20°C).

Figure 4: Sample surface temperature distribution: window not Covered.

### Case 1: Impact of Solar radiation on formaldehyde emission

The formaldehyde meter measurement shows the formaldehyde concentration in the test room is between 10 ppb and 12.5 ppb throughout the measurement period as illustrated in Figure 5, despite the average sample surface temperature rise 5°C more than the room temperature due to solar radiation. This finding suggests that the sample in this test is discharging a small amount of particle (Formaldehyde) into the test room. As a result, the attempt to measure the emitted particle is not successful. It is because the maximum capacity of the balances limits the sample size. Moreover, since the sample size relative to the test room volume and temperature rise on the sample surface is small, that might explain why the balances do not capture the mass change.

Figure 5: Formaldehyde emission due to solar radiation.

### Case 2: Impact of Temperature on formaldehyde emission

The formaldehyde concentration in the test rooms with 23°C and 18°C both rooms with 50% RH is illustrated in Figure 6. As indicated in the figure the average formaldehyde concentration is around 15 ppb in a test room with 23°C. Whereas, the average formaldehyde concentration in a test room where the temperature is 18°C, is around 12.5 ppb. Overall, the room with 23°C show marginally more formaldehyde concentration compares to a room with 18°C. This result indicates that the formaldehyde emission is slightly affected by the temperature.

Figure 6: Formaldehyde concentration profile with two different indoor temperature (18°C and 23°C).

### Case 3: Impact of RH on Formaldehyde Emission

Figure 7 shows the formaldehyde concentration in test rooms both with similar room temperature (21°C) and different relative humidity (50% and 70%). The formaldehyde measurement in a room with 70% relative humidity shows slightly scattered values. Whereas, in a room with 50% relative humidity depicts smooth trend. However, the formaldehyde concentration in both rooms remains between 20 ppb and 25 ppb. Overall, both test rooms demonstrate similar formaldehyde concentration despite their relative humidity difference.

Figure 7: Formaldehyde concentration profile with two different RH (50% and 70%).

## CONCLUSIONS

This project conducts three set of experiments investigating the effect of temperature, relative humidity and solar radiation on formaldehyde emission from a particleboard test samples in full-scale field experimental test buildings. Similar formaldehyde concentration (between 20 ppb and 25 ppb) is found in both test rooms with 50% and 70% relative humidity. Whereas, in the case of temperature, the formaldehyde concentration in the test room with 23°C is slightly higher than the room with 18°C. The preliminary study indicates that the mass change measurement is found very low and further study is recommended to find material that yields measurable mass change due to emission.

Microporous surface materials are put forward to prevent condensation on subfloor in some building design standards and specifications in China. However, in the current study there are mostly applied cases, lacking of quantitative research. This paper simulated and compared the surface wet condition of three different surface materials by WUFI software: solid brick, hardwood and glazed tile brick. The results shows that the time on surface relative humidity that above 95%, hygroscopic subfloor reduces by more than 20% over non-hygroscopic subfloor, and the improvement is over 45% in relative humidity range of 99% to 100%. In high-humidity areas such as Chongqing, it is suitable to use the porous hygroscopic material which moisture absorption capacity rapidly increases when the environment humidity exceed 80%, and absorbs little moisture lower than 80%.

### **KEYWORDS**

Hygroscopic material, Hot and humid area, Floor condensation, Heat and moisture transfer

### **INTRODUCTION**

China is a big agriculture country and put forward New Rural Construction as a major strategy. After more than ten years of development, rural buildings have greatly improved in terms of functions, sanitation and indoor lighting, etc. The investigation and test of indoor thermal environment in rural buildings have been took widely to various climatic regions (Wang X.P et al., 2009; Zhu W. et al., 2009; Zhu Y. Y et al., 2010; Wang Z.J et al., 2014; Yang L. et al., 2014). Many optimization programs have been put forward and practical demonstration projects have been build (Zhu XR and Liu JP, 2009; Xie MD and Shi YL, 2011; Shao, NN. et al., 2017) However, most of the investigations, tests and improvement measures focus on temperature, but few consider humidity.

There is a large land of China in hot-humid area, the annual average humidity there is about 80% and even 90-100% in rainy season. Therefore, moisture proof and anti-condensation is an important factor in creating a good indoor environment in this area. Rural houses are low-rise building, and mainly surface materials of subfloor that adjacent to the ground is cement or glazed tiles or other little hygroscopic materials. Subfloor connects to the earth that has a large thermal inertia, so moist air is likely to condense on the floor in the humid season. Therefore, the issue of floor condensation brings inconvenience to the residents' lives, affects health (Lotz W A. 1989), and causes economic losses become more serious.

In current engineering practice, enhancing the insulation properties, suspended timber or concrete slab floor are usually used on anti-condensation of subfloor. However, the methods above are not conducive to the use of ground temperature in passive houses to improve indoor comfort in the summer and winter. Chinese traditional buildings commonly used breathable materials that have rich microcellular structure, such as earth, wood, brick, clay brick. They can absorb moisture in the humid weather, and then release it in the dry. Due to these materials, the surface of the traditional building rarely dews. Modern building technology can draw wisdom from traditional architecture and use its advantages to meet the development needs in the new age. At present, only proposal of the breathable material as subfloor surface

materials was put forward (*Code for design of building ground*, 2013; *Design standard for energy efficiency of rural residential buildings*, 2013), and direct use without parameter selection and evaluation, lack of quantitatively studies on improvement. In order to provide reference for practical projects, this paper simulated and quantified the improvement effect of hygroscopic subfloors, and analyzes the characteristics of hygroscopic materials suitable for use in hot and humid areas.

## METHODS

This paper established subfloor model by one-dimensional heat-moisture transfer simulation software WUFI, simulated and compared the heat and moisture performance by several different surface materials. The specific method is as follows.

Nowadays, the construction method to isolate the rising effect of groundwater has matured. Therefore, this paper only considered the underground temperature as the lower boundary of ground components by taking advantages of the fitted data provided by the Special Meteorological Data Set for Thermal Analysis of Indoor Buildings in China (Xiong A Y. et al., 2005). The upper boundary condition is the indoor thermal environment. This paper got the whole year indoor temperature and humidity through simulation, while the model has been verified by field measurement date. The simplified model (shown in the figure 1.a ) was created using DesignBuilder which is a user interface for Energy+, with reference to the actual rural house according to its actual size and construction practices in Chongqing, who is typical hot and humid climate. The average error between simulations and measurements were shown in the figure2, while the average error of the indoor air temperature is 3.5%, 3.4% on relative humidity and 5.5% on surface temperature of the subfloor. So this model is reliable.

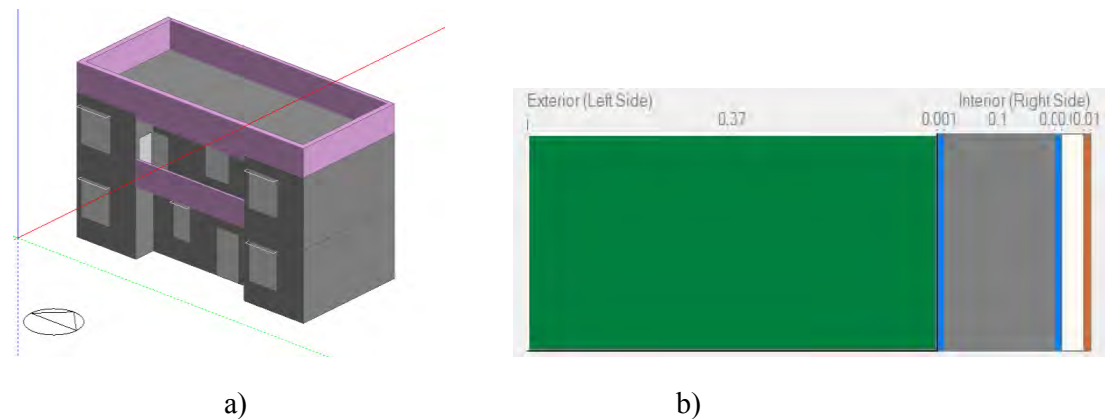

Figure 1. Simulated model by software

a) Simulated building model by DesignBuilder b) Subfloor structure diagram by WUFI

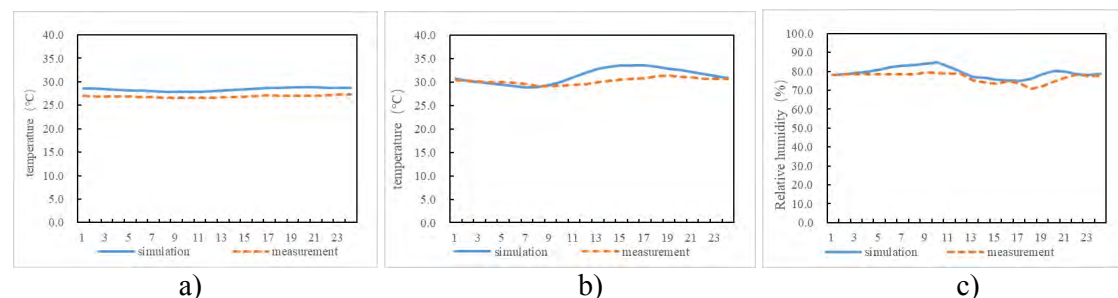

Figure 2. Comparison between simulated and measured.

a) Subfloor surface temperature b) Air temperature c) Relative humidity

A subfloor model consistent with DesignBuilder on structural hierarchy and material parameters was established in WUFI (shown in the figure 1.b). The average error of surface subfloor temperature between the two software was only 0.5%. The WUFI subfloor model can be used for the next comparative study.

The simulation focused on the surface material, so the other factors that may affect the heat and moisture performance of the surface material were simplified. In order to make the contrast of the thermal characteristics of the surface layer more obvious, a waterproof layer was added between the cushion layer and the tamping layer based on the verified concrete floor above, while the material parameters of each structural were shown in table 1. Three different surface materials were selected, they are Brick ZI that is one kind of solid -bricks, hardwood and Brick H which is one kind of glazed tile brick. Solid Brick and Hardwood are hygroscopic, while glazed tile brick is little hygroscopic. The physical properties of the three in the dry state shows in Table 2, and the isothermal moisture sorption isotherm shows in Figure 3 from WUFI Material library.

## RESULTS

The annual average relative humidity of indoor environment is 78%, and the room maintained at a high damp level from April to June. The hours on different surface relative humidity of the three were categorized into statistics throughout the year shown in Figure 4. The time of the three on surfaces relative humidity that less than 80% are almost equal. The difference

increases in the high humidity range. The accumulated time when the surface humidity above 95% of Brick H is 1512 hours, while Hardwood and Brick ZI decreases by 504 hours and 319 hours respectively, and the improvement ratios are 33.3% and 21.1% respectively. Among them, in range of 99%-100% on the humidity, the time value of Hardwood and Brick ZI are significantly smaller than that of Brick H, while the accumulated time of Brick H is 944 hours, and the improvement ratios of Hardwood and Brick ZI are 50.3% and 46.8% respectively. At the same time, the comparison shows that solid brick (Brick ZI) is better than Hardwood in the high humid condition, cause the hours for the Brick ZI approaching 100% (99.99% bound) is 0, Hardwood is 118 hours, while Brick H is 829 hours.

Figure 4. Surface Relative Humidity Hours Statistics Comparison Chart

This paper selected May 24 to May 29 for a typical humid period time on heat and moisture analysis. Figure.5a shows the surface wet-flow accumulation. The wet flow is overall negative means the moisture absorption, and the cumulative moisture absorption of solid brick (Brick ZI) is greater than that of hardwood, while glazed tile brick (Brick H) is the smallest. Since the material releases energy when it absorbs moisture, the surface temperature increases to reduce the possibility of condensation. As shown in Figure.5b, the surface temperature of Brick H is the lowest, followed by Hardwood, and the surface temperature of Brick ZI is the highest, which with the largest wet flow. Figure.5c showed the surface relative humidity of Brick ZI the lowest. With humid weather continues, surface humidity of Brick ZI continues to increase, with an average value of 93%, Hardwood following by an average humidity of 97%. The surface humidity of Brick H is the highest with an average value of 98.5%. What more, from May 28 to May 29, the value of Brick H reaches 100%, resulting in condensation. In general, the wet conditions of the hygroscopic subfloor are clearly better than non-hygroscopic subfloor, and the Brick ZI used in the simulation is better than Hardwood.

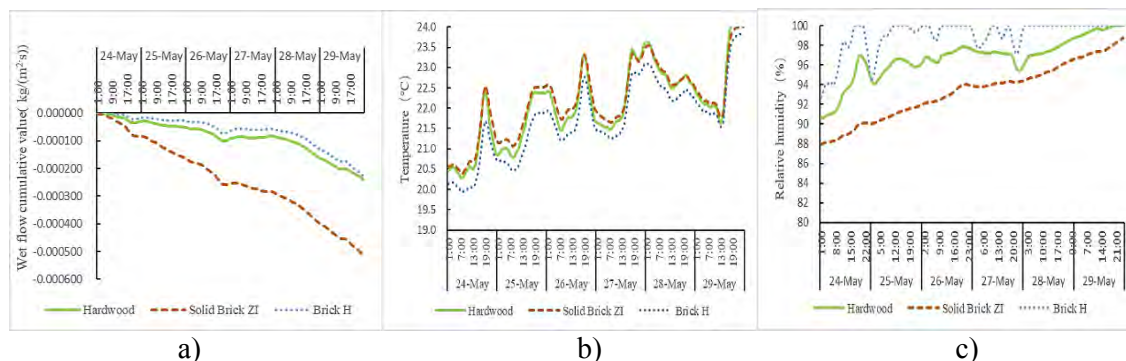

Figure 5. Heat and moisture performance contrast a) Surface wet flow cumulative b) Surface temperature c) surface relative humidity

Figure 6 shows the change in moisture content throughout the year. The fluctuations occurred during the humid months from April to July, indicating that moisture absorption and release are seasonal. The moisture content of Brick H varies little and it is almost 0 in autumn and winter. The moisture content of Brick ZI varies the largest, the minimum value is  $9.48 \text{ kg/m}^3$ , the maximum of  $245.45 \text{ kg/m}^3$ , and the elasticity is  $235.81 \text{ kg/m}^3$ . The maximum moisture content of Hardwood is similar to Brick ZI, but higher in autumn and winter, the minimum value is  $71.46 \text{ kg/m}^3$ , the maximum of  $238.51 \text{ kg/m}^3$ , and the elasticity is  $167.04 \text{ kg/m}^3$ .

Figure 6. Daily average moisture content comparison chart

During the humid season, the material is in a period of moisture absorption and desorption. As the hygroscopic equilibrium curves showed, Brick ZI has a faster moisture absorption capacity with humidity changing when relative humidity above 80%. The moisture absorption elasticity is about  $200 \text{ kg/m}^3$ , and the moisture content growth rate is 5.56, so there is no condensation on the surface. Hardwood has the moisture content of  $98 \text{ kg/m}^3$  at relative humidity of 80% and  $92 \text{ kg/m}^3$  of elasticity at 80% to 97%, with the growth rate of 0.93 that lower than Brick ZI. The moisture content of Hardwood increases from  $190 \text{ kg/m}^3$  to  $370 \text{ kg/m}^3$  in the humidity range of 97% to 100% which is Hardwood's hygroscopic and supersaturation range that prone to condensation, so there are 118 hours when the relative humidity is greater than 99.99%. From the isothermal moisture absorption curve of Brick H, the moisture content is  $1.2 \text{ kg/m}^3$  when the ambient humidity under 80%. Only when ambient humidity closes to 100%, the moisture content increases fast to  $180 \text{ kg/m}^3$ . In the humidity range from 80% to 100%, the increase in moisture content is less than  $5 \text{ kg/m}^3$ . Therefore, there are 829 hours of Brick H when surface humidity greater than 99.99% with condensation for a long time.

In summary, in order to reduce the wetness of the subfloor in humid season, the hot and humid areas, represented by Chongqing, is suitable to use porous hygroscopic materials that have hygroscopic behavior that absorption capacity rapidly increases when the environment humidity exceeds 80%, and absorbs little moisture when the environment humidity is lower than 80%.

## DISCUSSIONS

The materials in this paper were taken from the WUFI material library which may has some differences between hygroscopic materials in China. Since the standard database of wet physical properties of construction materials in China has not been established yet, the paper uses existing databases to simulate the effects of differences in material properties, and to find the characteristics of hygroscopic materials suitable for high humidity areas from the analysis and comparison. Evaluating building materials or recommendation material selection through experimental measurement or after the establishment of a domestic wet material property standard for building materials may can be the follow-up work.

## CONCLUSIONS

This article draws on the fact that most of China's traditional building materials have rich pore structure, which reduces subfloor condensation through the ability to absorb moisture, and also conducive to the use of ground temperature. Through simulations, the improvement effect of wet condition on hygroscopicity was quantified. By comparing the surface wetness and moisture content of different materials, the characteristics of hygroscopic subfloor surface materials in hot and humid areas was summarized. Take Chongqing as a case, it is suitable to have hygroscopic behavior that absorption capacity rapidly increases when the environment humidity exceeds 80%, and absorbs little moisture when the environment humidity is lower than 80%.

### **ABSTRACT**

Flow and transport phenomena in porous media play a significant role in various fields of science and technology, comprising a spectrum from medical sciences over material sciences to soil and rock sciences. Also in building materials, the transfer of moisture and heat play a crucial role when assessing their properties and performances. Hence, three-dimensional analyses of the pore structure of building materials are becoming progressively more important in recent years, to obtain more accurate interpretations and simulations of their characteristics. Computed tomography has proven to be an excellent and versatile tool to perform these analyses non-destructively. The reconstruction of the pore structure is of high importance for establishing accurate models, as it plays a crucial role in determining important characteristics of building materials. These models allow to better understand the results of corresponding laboratory tests and in the near future might replace these time consuming experiments. In this paper the added value of Computed Tomography characterization will be demonstrated based on two case studies. The first will focus on the accurate simulation of moisture transfer while in the second one CT datasets are used to overcome a multiscale problem regarding the simulation of the effective thermal conductivity.

### **KEYWORDS**

Micro-CT, Pore network properties, Hygric properties, Heat transfer simulation

### **INTRODUCTION**

Three-dimensional characterizations of the pore structures of building materials are becoming progressively more important in recent years, in order to obtain more accurate interpretations and simulations of their properties and performance characteristics. This study focuses on two applications where pore-scale-based simulation is distinctively an added value: moisture flow and heat transfer. In both cases the accuracy of the pores-scale models greatly depends on the input parameters i.e. the geometry of the solid matrix material or the corresponding pore network. This paper will focus on the data acquisition part of the process and show the possibility's regarding pore shape description and the incorporation of multi-scale datasets.

Storage and transport of moisture in porous media play a significant role in the performance characteristics of building materials. Moisture is therefore often a critical factor when judging the durability and sustainability of built structures and the health and comfort of building occupants, and a reliable evaluation of moisture transfer in building materials is crucial for correct performance assessments. In order to determine the moisture behavior of building components, numerical simulation models are commonly used. However, these models require a good description of the moisture retention and moisture permeability functions, as these are crucial input data for a dependable simulation (Dong and Blunt, 2009).

Heat transfer through building materials and building components equally is important. These transfers make up a crucial part of the energy consumed for the conditioning of residential buildings. Porous building blocks, consisting of gas-filled pores in a solid material matrix, are therefore increasingly used in residential buildings, combining ease of construction and adequate mechanical properties with a relatively high thermal resistance. However, due to increasingly stringent energy requirements, further reduction of the thermal conductivity of these materials is needed to improve their performance and boost their application (Coquard and Baillis, 2009).

## DATA ACQUISITION

### Micro-CT

The working principle of CT scanners is schematically depicted in Figure 1. The attenuation of X-rays when passing through the material is recorded for multiple rotation angles. Because the attenuation depends on the interior composition of the sample, it is possible to reconstruct this internal information from X-rays that have travelled a different path through the sample. The generated X-rays are attenuated by the components of the sample and captured by the detector, generating projection images. Image reconstruction is a mathematical process, which calculates the CT slices based on the projection images using a back projection algorithm. The data at one pixel in one projection image comes from the attenuation of the object along the entire path from source to detector, explaining the need for multiple rotation angles and projections. The result of the reconstruction process is a 3D image stack of gray-scaled voxels.

Figure 1. Schematic overview of the working of a CT scanner. The X-rays are generated in the source, travel through the object where they are attenuated and are captured by the detector.

### Segmentation

In order to differentiate gas pore from solid matrix voxels, an image segmentation needs to be performed. Quantitative analysis of the porosity requires a voxel by voxel determination of it belonging to pore or solid phases. For segmentation an in-house dual-thresholding algorithm is used. This method is an adaptation of the single-threshold approach, which typically selects

pixels/voxels on the basis of their unique histogram range. However manually determining the boundary values is not straightforward in the case of insufficiently ideal histograms, with peaks that are not obviously separated. The applied dual or hysteresis thresholding uses two intervals of the histogram in order to determine the segmentation. Voxels corresponding to the first ‘strong’ threshold are classified as foreground voxels, while voxels selected by the second threshold are only considered foreground if they are connected to voxels already selected by the ‘strong’ threshold. The advantages of this algorithm are the reduced sensitivity to residual noise in the dataset and the selection of less insulated foreground voxels. However this method does not exclude operator bias when determining the threshold values which will have a significant influence on the results. Baveye et al. (2010) provide an excellent illustration on how inter-operator bias can influence the thresholding results. 13 experts were asked to segment a micro-CT image of a soil sample and the obtained porosity results varied between 0.13 and 0.72 with a standard deviation of 0.14. Hence, this inter-operator bias will have an important influence on the characterization of the studied material or interpretation of the results.

Figure 2. Dual thresholding: a) Original slice, b) Histogram of the attenuation coefficients; the strong threshold is indicated in red; the weak threshold is indicated in green, c) Matrix selection using only the strong threshold, d) Resulting slice using both the strong and weak threshold.

## APPLICATIONS

The segmented images provide the input information for both applications. When simulating moisture flow, the pore space needs to be characterised as accurately as possible by generating a pore network model (PNM). For the simulation of heat transfer, the pore space as well as the solid matrix need to be incorporated in the model. Both applications are discussed below.

### Fluid flow

The pore space in a sample can be represented as a network of pores (larger void spaces) and throats (smaller void spaces connecting the larger pore spaces). CT datasets form the ideal tool to characterise both components up to the scan resolution. The visualised pore network is

transformed into a pore network model (PNM) which represents the studied pore structure as accurately as possible while retaining a certain simplicity by representing each component of the network by a set of parameters such as volume, surface area and shape descriptors. Hence, the PNM tries to capture local features of the pore-space which are important for the fluid storage and transport processes under investigation.

Subsequently these PNMs are subjected to invasion algorithms that replicate different (de)saturation procedures: absorption, desorption, imbibition and drying. For unsaturated moisture storage and transport in building materials, Islahuddin and Janssen, (2017) developed a multi-scale hygric pore-scale simulator comprising the coexisting liquid and vapor phases of water. Hence in theory, PNMs form the basis of simulations which determine the moisture storage and moisture transport in building materials over the whole capillary range, allowing a complete and accurate determination of the hygric properties of building materials.

As an example a PNM has been generated for a sintered glass volume. This material is chosen because the entire pore size distribution can be captured by a  $2.5\ \mu\text{m}$  resolution micro-CT scan (Figure 3 A). The CT dataset also allows to mathematically describe the shape of the pore bodies based on the length of the three principal axis (Figure 3 B) (Claes, 2015). Because the pore shape distribution in the sample is homogeneous a PNM can be used to determine the hygric properties of the sintered glass. Based on the code of Islahuddin and Janssen, (2017) the permeability and adsorption curves can be calculated for the entire water saturation range (Figure 3 C and D).

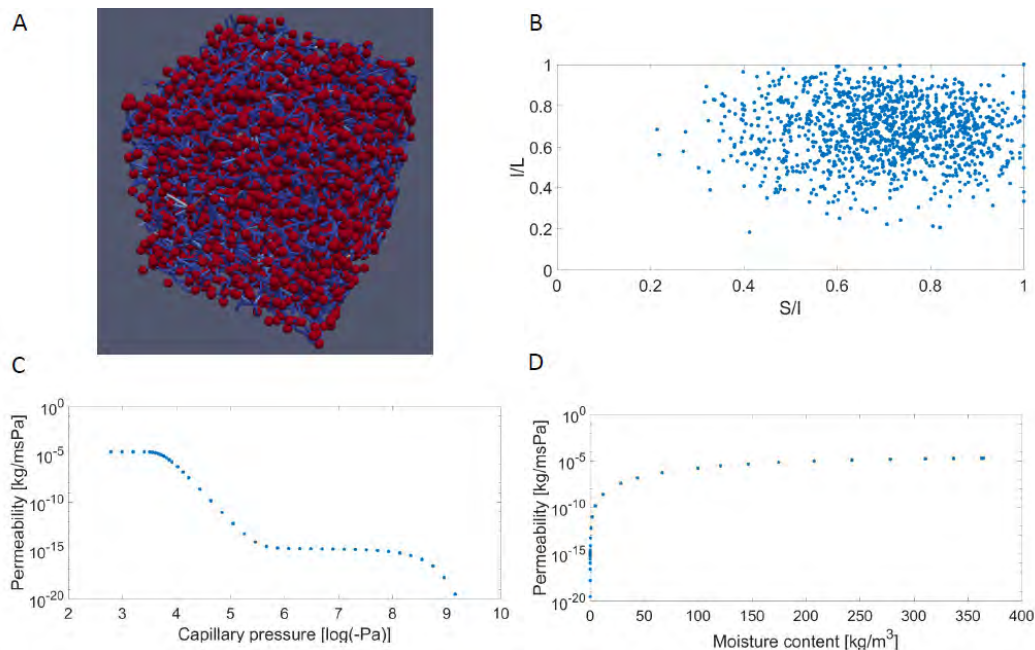

Figure 3. Sintered glass: a) Pore Network Model, b) Pore shape analysis, c&d) Adsorption permeability curve.

To assess the accuracy of the simulation, the obtained saturated permeability is compared with lab measurements. The simulated and measured saturated permeability are in the same order of magnitude, but the simulated one is slightly higher than the measured one:  $1.86 \cdot 10^{-5}$  vs  $1.25 \cdot 10^{-5}$  kg/m s Pa respectively. This trend was also observed by Oren & Bakke, (2003) and Dong & Blunt (2009), who performed simulations on the Berea sandstone and noticed a discrepancy around a factor 2 between simulations and measurements. This factor can be explained by the

heterogeneity of the sample and the uncertainty associated in the course of imaging and image processing.

### Heat transfer

One of the main advantages of micro-CT is its flexibility regarding sample size. Optimal sample diameters range between 1 mm and 4 cm. However, an inherent characteristic of CT is the negative relationship between scan resolution and sample size. The larger the sample, the bigger the voxel size becomes. Several materials, including building materials, often have a broad spectrum of pore sizes, ranging from nanometers to millimeters. The presence of multiple pore-scales in the studied sample can severely influence its physical properties. In order to test the applicability of CT on different scales, Reapor is chosen as a test case. Reapor is a highly-porous material mainly applied for acoustic absorption. The production process is based on recycled glass and consists of sintering together expanded granules, hence leading to a pore structure with a two-scale type of pore volume distribution: a cellular structure inside the granules and a granular structure overall. As there is a clear separation between the intra- and intergranular pore structures, a hierarchical approach is adopted to overcome the two-scale nature of the material: simulation results obtained on the intragranular level are averaged and used in the simulations performed on the intergranular scale.

Figure 4. a) Photograph of sample pore structure with the bimodal pore volume distribution clearly visible, b) Measured pore volume distribution of the Reapor material, c&d) Micro-CT slice scan result of the intra- and inter-granular scale, e&f) Segmented 3D image of intra- and inter-granular scale scans (after Van De Walle et al, 2018).

In order to characterise the intra-granular scale a 2 mm diameter sample is scanned at a resolution of 1.2  $\mu m$ . Based on these results simulations were conducted and the results are shown in Figure 5 A. A power-law trend-line is fitted through the results, showing an expected decrease of the thermal conductivity with increasing porosity.

Subsequently these values are used to characterize the matrix material when analyzing the inter-granular pore network. The configuration of the matrix material is characterized by a 12  $\mu m$  resolution scan. The results of these simulations are shown in Figure 5 B. In order to assess the quality of the simulations, the results are compared to lab measurements and information provided by the manufacturer. On average, the simulations show a relative deviation of about 5 % with the experimental measurements, indicating a good performance of the model framework even when using a two-scale hierarchical simulation approach.

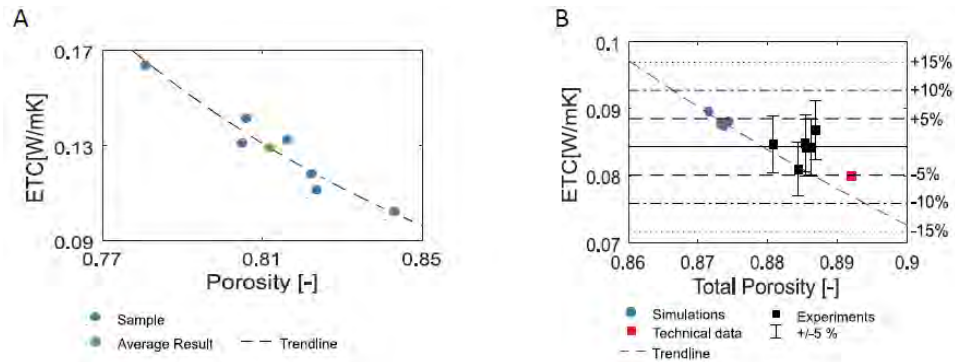

Figure 5. a) Simulation results on the intra-granular scale in the air-dry case, b) Comparison of simulations, experiments and analytical models for the air-dry case of the Reapor material (after Van De Walle et al, 2018).

## CONCLUSIONS

The overall goal of this research is to come up with a more accurate description and characterization of the pore structure of building materials. Computer tomography (CT) proves to be an excellent tool for achieving this objective. Because of its inherent 3D data acquisition, the complete internal structure of the scanned sample can be evaluated at different resolutions. The visualization of the connectivity of the pore network and the detection of additional phases results in a detailed characterization of the building material. The generation of 3D datasets also permits a more quantitative description and calculation of different important parameters such as porosity, hygric properties, heat transfer and spatial variability of these parameters.

## ACKNOWLEDGEMENT

This project has received partial funding from the FWO Odysseus grant ‘Moisture transfer in building materials: analysis at the pore-scale level’. W. Van De Walle’s research is funded by a Ph. D. grant of the Agency for Innovation by Science and Technology (IWT - Vlaio). Their support is kindly acknowledged.

## **A DYNAMIC THERMAL NETWORK MODEL APPLIED TO VENTILATED ATTICS**

Johan Claesson, Petter Wallentén

Dep. Of Building Physics, Lund University, Sweden

*Johan.Claesson@byggtek.lth.se, Petter.Wallenten@byggtek.lth.se*

### **ABSTRACT**

The need for tools to analyze heat and moisture behavior in wooden constructions is increasing with the increasing awareness of the moisture problems. An example of a construction with a history of mould problems is cold attics. Most heat models of attics use a lumped node technique for energy balance and ignore the variation in heat transfer coefficients. A model based on so called dynamic thermal networks has been developed that takes into account radiation between the interior surfaces and the different boundary conditions at the outside and inside surfaces. The first step is to develop analytical solutions for the step responses for the whole attic including a composite roof. The second step is to create a dynamic thermal network based on these solutions. With the thermal network it is possible to do hourly (or any given time step) calculations for several years in a very short computer time which makes it possible to easily test different parameters: ventilation rate, insulation thickness, solar insolation etc. The analytical response solutions also provide good insight into the physics of the thermal problem. A simple parameter study of exterior roofing insulation is presented as an example. The work is part of a large project in Sweden investigating wooden constructions.

### **KEYWORDS**

Heat transfer, Analytical solution, Attics, Transient.

### **INTRODUCTION**

The points of interest for mould problems in a cold attic are e.g. the attic air and the interior attic roof surface. This is because one reason for the moisture problems is the cooling of ambient air when entering the attic. There are many possible ways to implement a thermal model of an attic. Using a one-dimensional model where the ventilated air space is modeled as a space between two parallel plates is especially common when the model includes moisture transport, Vahid (2012). Since even the thermal problem is quite complex given that the attic has many layers the methods used to solve the problem are typically numerical. The paper presented here deals with an analytical solution of the transient heat transfer problem of an attic based on a thermal network. With this solution it is possible to do fast parameter studies with hourly climate data. This includes the effect of shortwave absorption coefficients, insulation thickness, ventilation rate etc.

### **THERMAL MODELING OF AN ATTIC**

The model consists of an attic floor, roof and a ventilated space in between. The heat transfer in the floor and roof is one dimensional but the radiation exchange between the surfaces takes into account the two dimensional view factors between the floor and roof. The floor consists of insulation. The composite roof consists of wood, insulation, a non-ventilated air gap and roof tiles. This is described in Figure 1. The heat transfer process is a linear one, which therefore includes linearization of the convective and radiative heat transfer at the surfaces.

Figure 1. Left: Notations for an attic with radiation heat exchange between floor and roof. Right: Details of the composite roof involving two material layers and an air gap below roofing tiles.

The following subscripts will be used:  $a$  = attic air,  $f$  = attic floor surface,  $r$  = attic roof surface,  $v$  = ventilation air temperature,  $e$  = exterior air temperature,  $i$  = interior air temperature,  $rad$  = effective outdoor air temperature due to radiation, 1 = insulation slab in attic floor, 21 = wood slab in attic roof, 22 = insulation slab in attic roof,  $rt$  = roofing tiles.

The model can be represented as thermal network which is described in Figure 2. It is easy to see the possible paths of the heat flow.

Figure 1. Network to represent the thermal interactions and equations in the attic components

The thermal process is governed by the three prescribed boundary functions for ventilation, exterior and interior temperature:

$$T_v(t), T_e(t), T_i(t). \quad (1)$$

These particular boundary conditions are chosen because they are simple but allow for a realistic treatment of the climate. Obvious simplifications are: constant ventilation rate, constant convective and radiative heat transfers coefficients, well mixed air in the attic space and that the influence of short and longwave radiation on the exterior surface can be simplified as an equivalent exterior temperature. The task is to calculate temperatures as functions of time at the four nodes ( $a, f, r, rt$ ) and the temperature field through floor and roof:

$$T_a(t), T_f(t), T_r(t), T_{rt}(t), T_1(x, t) \quad 0 \leq x \leq D_1, T_2(x, t) \quad 0 \leq x \leq D_2 \quad (2)$$

The temperature of the attic air,  $T_a(t)$ , and the interior surface of the attic roof,  $T_r(t) = T_2(0, t)$ , are of particular interest for studies of moisture problems. There is a heat balance equation at each node ( $a, f, r, rt$ ). The equation for the air node,  $T_a(t)$ , is:

$$C_a \frac{dT_a}{dt} = \frac{T_v(t) - T_a(t)}{R_v} + \frac{T_r(t) - T_a(t)}{R_{ar}} + \frac{T_f(t) - T_a(t)}{R_{af}}. \quad (3)$$

The equation for the node at the surface of the attic roof,  $T_r(t)$ , is, Figure 2:

$$\frac{T_a(t) - T_r(t)}{R_{ar}} + \frac{T_f(t) - T_r(t)}{R_{fr}} = q_2(0, t) = L_2 \cdot (-\lambda_{21}) \frac{\partial T_2}{\partial x} \quad x=0 \quad (4)$$

The heat equation for the temperature  $T_1(x, t)$  in the insulation slab of the attic floor reads:

$$\frac{1}{a_1} \cdot \frac{\partial T_1}{\partial t} = \frac{\partial^2 T_1}{\partial x^2}, \quad 0 \leq x \leq D_1, \quad a_1 = \frac{\lambda_1}{\rho_1 c_1} \quad (5)$$

The heat equation for the temperature  $T_2(x, t)$  of the composite roof is similar. The basic input data with values for the reference case are chosen as a relatively small attic:

$$\begin{aligned} L_1 &= 8 \text{ m}, \quad H = 3 \text{ m}, \quad n_v = 2/3600 \text{ s}^{-1}, \quad r_a = 1.29 \text{ kg/m}^3, \quad c_a = 1000 \text{ J/kg}, \quad e = 0.9, \\ T_{av} &= 283 \text{ }^\circ\text{C}, \quad a_f = 4 \text{ W/(K}\cdot\text{m}^2), \quad D_1 = 0.4 \text{ m}, \quad l_1 = 0.04 \text{ W/(K}\cdot\text{m}), \quad r_1 = 20, \quad c_1 = 800, \\ a_i &= 8, \quad a_r = 4, \quad D_{21} = 0.02, \quad l_{21} = 0.14, \quad r_{21} = 500, \quad c_{21} = 1200, \quad D_{22} = 0.05, \quad l_{22} = 0.04, \\ r_{22} &= 50, \quad c_{22} = 800, \quad a_{2-rt} = 15, \quad D_{rt} = 0.015 \text{ m}, \quad r_{rt} = 1500, \quad c_{rt} = 800, \quad a_e = 15. \end{aligned} \quad (6)$$

### STEP RESPONSES FOR THE THREE BASIC CASES

The determination of the attic temperatures is based on the solutions for three basic cases, one for each boundary condition. In the first case associated with the ventilation boundary, the ventilation temperature experiences a unit temperature step from 0 to 1 at  $t = 0$ . The exterior and interior boundary temperatures are zero for all times. The temperature at the start  $t = 0$  is zero in the whole attic. The three basic step-response problems (ventilation, exterior, interior) are defined by the following boundary conditions:

$$\begin{aligned} \text{Ventilation:} \quad & T_v(t) = H(t), \quad T_e(t) = 0, \quad T_i(t) = 0; \\ \text{Exterior:} \quad & T_e(t) = H(t), \quad T_v(t) = 0, \quad T_i(t) = 0; \\ \text{Interior:} \quad & T_i(t) = H(t), \quad T_v(t) = 0, \quad T_e(t) = 0. \end{aligned} \quad H(t) = \begin{cases} 0 & t < 0 \\ 1 & t > 0 \end{cases} \quad (7)$$

### STEP RESPONSES FOR VENTILATION TEMPERATURE

The solution for a step in the ventilation boundary temperature involves the following temperature components (using a bold face superscript v for the ventilation step response):

$$U_a^v(t), U_f^v(t), U_r^v(t), U_{rt}^v(t), U_1^v(x, t) \text{ for } 0 \leq x \leq D_1, U_2^v(x, t) \text{ for } 0 \leq x \leq D_2 \quad (8)$$

These functions describe the step response at all points in the thermal model. Some examples of solutions are given in Figure 3.

Figure 3. Temperature distribution through roof ( $-0.07 < x < 0$ ) and floor ( $0 < x < 0.4$ ) for the ventilation step for  $t = 0.1, \dots, 10$  hours. The top curve shows the steady-state temperature.

### SOLUTION TECHNIQUES

A methodology called dynamic thermal networks to solve thermal problems involving transient heat conduction have been presented by Claesson and co-workers in a number of papers. These networks represent the relations between boundary heat fluxes and boundary temperatures. The current heat fluxes are obtained by integrals (or sums) of preceding boundary temperatures multiplied by weighting functions, Claesson (2002A, 2003). The theory is applied to composite walls in Wentzel and Claesson (2003), to a building with walls, roof and foundation in Wentzel and Claesson (2004) and Wentzel (2005). Solution techniques involving Laplace transforms and Fourier series with determination of eigenvalues are used. This whole system with all its complex interactions may be represented by a thermal network for the Laplace transform and for the eigenvalues. From these similar networks the Laplace transform and the equation for eigenvalues are readily obtained. The final Laplace solution is obtained by an integral inversion. The full thermal model for the attic requires some four pages of formulas and relations in Mathcad. The computer time for about five digits accuracy is a few minutes.

### General superposition formula

Let  $\mathbf{P}$  denote any considered point (node, point in floor or roof) for which the temperature is to be determined:

$$\mathbf{P}: a, f, r, rt, x = x_1 \ (0 \leq x \leq D_1), x = x_2 \ (0 \leq x \leq D_2) \quad (9)$$

The temperature at  $\mathbf{P}$  as function of time  $t$  depends on the three boundary temperatures taken for preceding times up to time  $t$ . General superposition gives the following *exact* formula:

$$T_{\mathbf{P}}(t) = \int_0^t [W_{\mathbf{P}}^v(\tau) \cdot T_v(t - \tau) + W_{\mathbf{P}}^e(\tau) \cdot T_e(t - \tau) + W_{\mathbf{P}}^i(\tau) \cdot T_i(t - \tau)] d\tau \quad (10)$$

Here, the weighting functions are given by the time derivative of the three basic step-response solutions at the considered point  $\mathbf{P}$ :

$$W_{\mathbf{P}}^v(\tau) = \frac{d}{d\tau} [U_{\mathbf{P}}^v(\tau)], \quad W_{\mathbf{P}}^e(\tau) = \frac{d}{d\tau} [U_{\mathbf{P}}^e(\tau)], \quad W_{\mathbf{P}}^i(\tau) = \frac{d}{d\tau} [U_{\mathbf{P}}^i(\tau)], \quad (11)$$

The weighting factors are positive (or zero), since the U-functions increase monotonously with time, and the derivatives tend to zero (exponentially) for large times. Equation (10) thus expresses the full analytical solution of the problem. No discretization or numerical limitations are used at this point.

### Discretization

In the discrete numerical model, the boundary temperatures are by assumption piecewise constant during each time interval  $n$ :

$$T_v(t) = T_{v,n}, \quad T_e(t) = T_{e,n}, \quad T_i(t) = T_{i,n} \quad \text{for } (n-1)h < t < n \cdot h \quad (12)$$

Here,  $h$  is the time step, which often is typically  $h = 1$  hour. Formula (10) gives:

$$T_P(nt) = T_{P,n} = \sum_{v=1}^{\infty} \int_{v h - h}^{v h} [W_P^v(\tau) \cdot T_{v,n-v} + W_P^e(\tau) \cdot T_{e,n-v} + W_P^i(\tau) \cdot T_{i,n-v}] d\tau \quad (13)$$

The sum of all weighting factors becomes equal to one. Equation (13) may therefore be written in the following way:

$$\sum_{v=1}^{\infty} [W_{P,v}^v \cdot T_{v,n-v} - T_{P,n} + W_{P,v}^e \cdot T_{e,n-v} - T_{P,n} + W_{P,v}^i \cdot T_{i,n-v} - T_{P,n}] = 0 \quad (14)$$

This relation may be represented graphically as a kind of dynamic thermal network, Figure 4.

Figure 4. Dynamic thermal network to represent the weighting formulas (14).

Data from the reference case (6) gives that sum above may be truncated after 15 time steps of one hour each.

### PARAMETER STUDY. AN EXAMPLE

With the model and solution described above it is easy to investigate the importance of the parameters in the model for any given boundary conditions. As an example has the importance of the exterior insulation thickness been studied using a climate in Lund for one year (1990).

When investigating moisture related issues it is of interest to calculate the risk of high relative humidity on the attic roof surface which is directly dependent on the difference between the outdoor (ventilation) temperature and the roof surface  $Diff = T_r - T_v$ . The risk for mould problems increases with  $Diff$ . Figure 5 shows  $Diff$  for a year in Lund 1990 presented in cumulative histogram form. The x axis is  $Diff$  and the y axis is the number of hours the value is below  $Diff$ . The calculations show that 1cm of exterior insulation does not reduce the number of hours with cooling of the ventilated air. There are about 4500 hours with cooling. With 5 cm insulation, as in Figure 10 however, does the number of hours with cooling of ventilates air go down to about 2500 hours.

Figure 5 Cumulative histogram of *Diff* from hourly simulation of year 1990 in Lund, Sweden. Left: Exterior insulation thickness 0cm. Right: Exterior insulation thickness 5cm.

## CONCLUSION

The paper presents an analytical solution method based on dynamic thermal networks for the heat transfer problem in an attic with a pitched roof. Although there exists a number of numerical approaches to solve this problem (Energy+, IDA-ICE etc), no analytical solution has as far as the authors know been presented before. The solution shows the physical behavior of the different components in a very clear way. It is also easy to investigate the effect of the included parameters. The temperature at any point can be calculated using about 15 preceding boundary temperatures. A few examples of possible parameter studies are presented.

### ABSTRACT

The aim of this paper is to present a tool which will support decision-makers of façade design process while giving decisions on façade parameters to consider their interactions with functional performance issues. The tool is believed to contribute the holistic design of facades which is lacking in existing literature. The functional performance aspects included in the tool are structural, fire, water related, air permeability related, thermal, moisture related, daylighting, and acoustic performances. Façade parameters that are taken as the main decision subjects within the tool are orientation, transparency ratio, façade type, window type, glazing, framing, solar control, wall configuration, finishing, and detailing. First, for each façade parameter, design options are generated to keep the tool relatively simple and comprehensible. Then, matrices having design options in rows and performance aspects in columns are established. To support the decision-making, each intersecting cell in matrices proposes a rating. The proposed rating bases on comparisons and indicates for that façade parameter how superior is that design option when compared to the others in terms of that specific performance aspect. The tool not only proposes strict ratings, but also gives prescriptions that describe how to rate the options in various environmental and/ or spatial conditions. Consequently, the tool is composed of separate rating charts (matrices) designed for each predefined façade parameter. The proposed tool is in the form of spreadsheet designed via Microsoft Office software. The information provided in the tool is based upon an extensive literature review. The tool is believed to provide insight about the entire façade performance while addressing the interactions, conflicting issues among separate performance aspects and their relationships with design decisions. Thus, it will enable the decision-makers to give the decisions in a transparent way by highlighting the compromises in design and will support the communication among stakeholders.

### KEYWORDS

Façade design, façade performance, decision-making, decision support tool, holistic design.

### INTRODUCTION

Façade design is a significant sub-process of building design. This process is driven by a substantial number of factors such as user requirements (and performance requirements accordingly), environmental conditions, building/ space features, project conditions (various constraints, time/ budget limitations, feasibility issues, etc.), legislation, and stakeholders from different disciplines. Moreover, limitless variety of today's material and technology opportunities, changing conditions in time, designers' working trends (sense of aesthetics which is hard to assess) have influences on façade design (Knaack, et al., 2007, Klein, 2013). All these necessitate a holistic approach for façade design not to skip any significant factor and to make an optimization.

Although there are a few researches (Jin, 2013, Ramachandran, 2004, Hendriks & Hens, 2000, Aksamija, 2013, Oliveira & Melhado, 2011, Rivard, et al., 1999) in literature, there is a lack of a holistic point of view in façade design. It is believed that there is a need for an approach through which all factors, variables, conditions, constraints, and interactions can be seen/ addressed together.

A guide focusing the whole, rather than the fragments may have a positive contribution to both the product (façade) and the process (design). Instead of testing and evaluating a considerable number of alternatives via simulation tools or field studies in real conditions, to follow a model having holistic point of view in line with design goals and to reduce the number of design alternatives in early stages of design process to a lesser amount and near-ideal options and thereafter to carry out the evaluation accordingly may have a significant contribution to the facade design process.

Being within different disciplines' area of interest make it essential to design this building system (the façade) in a systematic way. There is not any single resource which guide the stakeholders for all these subjects. The stakeholders need to apply for separate resources during the facade design process.

Nevertheless, it is possible to provide a holistic support in the early stages of facade design process by organizing all the information/ knowledge in the literature from various researches conducted by different disciplines with different points of view and by establishing the relationships in-between to constitute a meaningful whole.

Main objectives of the study are to develop a systematic/ methodology for design process based on functional performance issues, and to propose a user-friendly tool for the usage of stakeholders of façade design process. To achieve these goals, a tool is developed which provides insight/ gives impression about façade performance as a whole. The tool highlights the interacting, conflicting issues of the process in order to see the whole with a holistic point of view.

In this way, both time/ cost savings and quality improvement are expected. Through the use of the proposed design decision support tool, the stakeholders of facade design process may give faster and more proper decisions and make more efficient collaborations.

It will support transparent and integrated façade design process, by doing so, strengthen the dialogue and collaboration among the participants, in turn it will ensure/ improve the product (façade) quality. It will assist design decision-making process and optimization in design, enable the stakeholders gain holistic point of view, and contribute to/ support the design of well-performing facades today and in future.

## **METHODOLOGY**

The method followed in the study is illustrated in Figure 1. In the first part of the study, an extensive literature review regarding façade design and façade performance is conducted. The review of the existing literature covers all the relevant publications including books, e-books, journal articles, conference proceedings, theses, seminar/ course notes, standards, codes, regulations, commercial publications, encyclopaedias, dictionaries, etc. In the second part, during the development of the design decision support tool, the knowledge is organized by resolving, filtering, and relating the literature. In addition to this, expert opinions are gathered for rating the design options and weighting the relationships.

Functional performance aspects that are associated with biological/ physiological and social/ psychological requirements of the user are taken as the focus of the tool. The key performance aspects included in the tool are structural, fire, water related, air permeability related, thermal, moisture related, daylighting, and acoustic performances (Rich & Dean, 1999, Herzog, 2008, Boswell, 2013, Jin, 2013, ITU Seminar, 2013, Oraklıbel, 2014). On the other hand, façade

parameters that are taken as the main decision subjects within the tool are orientation, transparency ratio, façade type, window type, glazing, framing, solar control, wall configuration, finishing, and detailing.

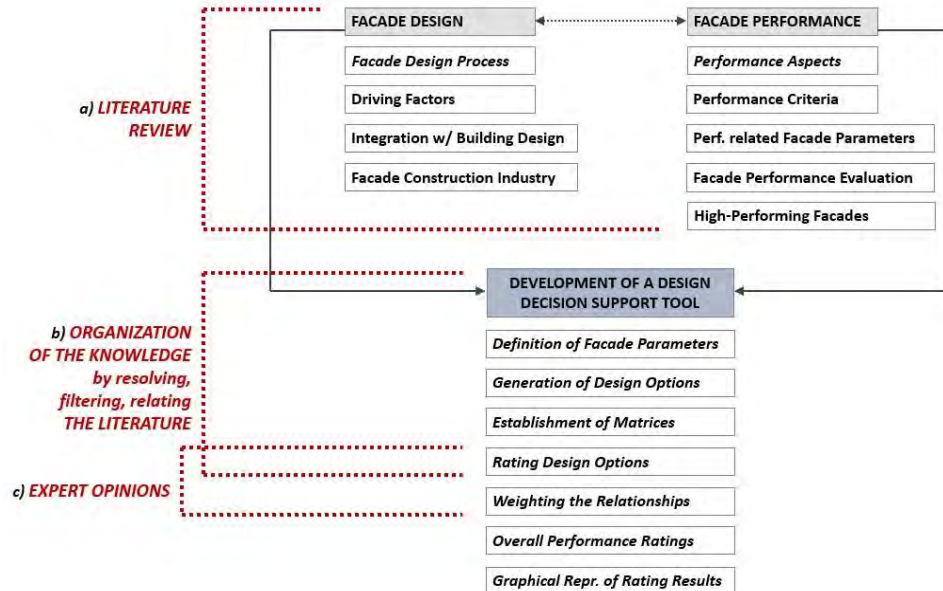

Figure 1. Methodology of the study

The proposed tool is in the form of spreadsheet designed via Microsoft Office software. First, for each façade parameter, design options are generated to keep the tool relatively simple and comprehensible. The design options are generated in accordance with the existing façade industry and knowledge. The options are not for limiting the flexibility in design, they are for guiding the tool users (façade design decision-makers) by indicating the consequences of various design decisions. So, the tool user can make deductions for their specific conditions. Then, matrices having design options in rows and performance aspects in columns are established. To support the decision-making, each intersecting cell in matrices proposes a rating (++ , + , 0 , - , --) or a rating prescription having conditional sentences. So, the tool user is expected to rate each option in terms of each performance in accordance with the prescriptions. The tool not only proposes strict ratings, but also gives prescriptions that describes how to rate the options in various environmental and/ or spatial conditions. These conditions may totally change the rating. Within the context of the study, environmental conditions represent location, climate, and surrounding (e.g. buildings, landscape, noise sources) while spatial conditions are for function of the building/ space, building height, spatial features of the room (e.g. room proportions, surface colours, heating, cooling, ventilation, and lighting systems). Some other significant factors as budget, feasibility, aesthetics, etc. are kept out of the tool and left to the user to make decision regarding these issues according to the project conditions, architectural intentions, etc.

The rating proposed in the tool bases on comparisons and indicates how superior is that design option (for that façade parameter) when compared to the others in terms of that specific performance aspect. If the option has direct advantage for that performance when compared to the other options, it can be given +. Here, the 'direct advantage' means if the option is chosen instead of other ones, the performance of the façade will be affected positively. On the other hand, if it has direct disadvantage for that performance, it can be rated as -. If it has no direct effect, or negligible difference which means there is no superiority among the options, it can be given 0. Besides, degree of superiority/ inferiority among options may increase for some environmental and/ or spatial conditions, then the values can be multiplied by 2 and become ++, --, and 0. Consequently, the tool is composed of separate but interlinked rating charts

designed for each predefined façade parameter. Some given decisions inevitably limit the options to be selected for the other decision subjects. These are prescribed within the charts, as well.

Moreover, an individual performance aspect is affected by more than one design decision. But, each design decision may have different weighted impacts on that performance. So, for each performance aspect, each design decision is weighted according to the strength of relationships (6 for a strong relationship, 3 for a medium-strength relationship, 1 for a weak relationship). The tool gives the ideal design option(s) for each decision subject based on the rates and weights. It is not always possible to choose the ideal option proposed by the tool. It may be due to space organization, land settlement, etc. Under these circumstances, the tool implicitly recommends paying attention to the inferior performances in other design decisions. For the assessment of each single performance of a façade design; firstly, each rate given by the tool users is multiplied by its weight (the strength of the relationship between the decision subject and the performance aspect), secondly, these multiplied scores are accumulated with the assumption that the sum total of the design decisions composes the façade design.

## RESULTS

The results of the study are the separate but interlinked rating charts (matrices) prepared for each predefined key decision subject. The rating charts/ prescriptions which belong to orientation are presented in this paper. Screenshots from rating charts are given in Table 1. The chart on the left (assume it without any rating) is the one that appears when the user clicks on the orientation decision subject on the tool's home page. Then, if the 'rate !' button under the thermal performance is clicked on, the chart on the right side appears. In this page, the user is expected to rate the options according to the given prescriptions. As soon as the options are rated, on the left chart, the empty cells are updated, and the tool highlights the ideal and worst options with a holistic point of view (based on the weights and the user's rates). Ultimately, the user is expected to make a choice by clicking on 'choose !' button. When the option is selected, the scores of that option is taken into account for evaluation.

Table 1. Screenshots from rating charts (tool interface, and sample rating)

EVALUATION								
HOME								
BACK								
Options & How to Rate		PS THERMAL PERFORMANCE to balance solar heat gain with solar shading						
ORIENTATION	North	In N hemisphere, for heating dominated climates, give (+) for S, SE, SW, (0) for E, W, (-) for N, NE, NW, for cooling dominated climates, give (-) for N, NE, NW, - for the rest. In S hemisphere, vice versa, however, in N hemisphere, for cooling dominated climates, in spaces having need to direct sunlight (esp. for health reasons), give (0) for S, SE, SW.						
	South	the above rating is for spaces occupied throughout the all day.						
	East	if it is mostly occupied in the mornings, in N hemisphere, for heating dominated climates, give (+) for E, S, SE, (-) for the rest. for cooling dominated climates, give (-) for N, NW, W, (-) for the rest. In S hemisphere, vice versa.						
	West	if it is mostly occupied in the afternoons, in N hemisphere, for heating dominated climates, give (+) for W, S, SW, (-) for the rest. for cooling dominated climates, give (-) for N, NE, E, (-) for the rest. in S hemisphere, vice versa.						
	North East	plus all the above, change the rating to protect or utilize (for hot & humid climates) from the predominant wind.						
	North West	if the space mostly occupied in certain seasons like Winter or Summer, the rating changes as well. S, SE, SW are again advantageous in Winters, while N, NE, NW can be superior options for spaces mostly occupied in Summers.						
	South East	for spaces rarely occupied, there is no need to rate the options.						
	South West							
	rate after checking these issues...	location (Northern or Southern hemisphere) and predominant wind direction (& intensity)	climate (heating or cooling dominated, or mixed based on heating degree days)	function of the space (use period (daily & seasonal))				
	SELECTED OPTION	CHOOSE !						

The rating prescriptions for the orientation is given in Table 2. All the prescriptions in the chart are grounded on the information/ knowledge deduced from the literature. The options for the orientation are North (N), South (S), East (E), West (W), Northeast (NE), Northwest (NW), Southeast (SE), and Southwest (SW).

Table 2. Rating prescriptions for the orientation

Options for the Design Decision & How to Rate Them		P1	P2	P3	P4	P5		P6	P7		P8
DESIGN DECISION	Options	STRUCTURAL PERFORMANCE	FIRE PERFORMANCE	WATER related PERFORMANCE	AIR PERMEABILITY related PERFORMANCE	THERMAL PERFORMANCE		MOISTURE related PERFORMANCE	DAYLIGHTING PERFORMANCE		ACOUSTIC PERFORMANCE
ORIENTATION	North	give (-) for the options exposed to predominant wind directions (due to pressure & suction forces) , (+) for the perpendicular directions, and (0) for the rest.	give (-) for the options exposed to the predominant wind directions, (+) for the most wind protected ones, and (0) for the rest.	give (-) for the options exposed to predominant wind directions, (+) for the most wind protected ones, and (0) for the rest.	give (-) for the options exposed to predominant wind directions, (+) for the most wind protected ones, and (0) for the rest.	in N hemisphere, for heating dominated climates, give (+) for S, SE, SW, (0) for E, W, (-) for N, NE, NW, for cooling dominated climates, give (+) for N, NE, NW, - for the rest. in S hemisphere, vice versa. however, in N hemisphere, for cooling dominated climates, in spaces having need to direct sunlight (esp. for health reasons), give (0) for S, SE, SW.		give (-) for the options exposed to predominant wind directions, (+) for the most wind protected ones (except N orientations in N hemisphere and S orientations in S hemisphere due to low solar radiation that reduces the drying potential), and (0) for the rest.	according to the function of the space, define which of the following is desirable: diffuse & homogeneous skylight (a) or direct sunlight (b). for a, in N hemisphere, give (+) for N, NE, NW, (-) for the rest (high glare potential).in S hemisphere, do the rating reversely.		give (-) for the options in the direction of noise sources, (+) for the most noise protected directions, and (0) for the rest.
	South					the above rating is for spaces occupied throughout the all day.			if it has mainly winter and cloudy conditions during the year, then for some space functions, sky illumination may not be sufficient in N orientations in N hemisphere. check the latitude & climate and make the relevant adjustments (e.g. give (0) for N, and (+) for NE, NW), for b, give (+) for S since it provides direct sunlight and relatively easier to control. give (0) for E, W, SE, SW for providing low-angle direct sunlight which is hard to control in terms of glare. give (-) for the rest.		if the space is highly noise-sensitive, then multiply the rating values by (2).
	East	if it is high-rise building and wind intensity is high, multiply the rating values by (2).	if building function has high importance in terms of fire protection, then multiply the rating values by (2).	if it is high-rise building and wind intensity is high, multiply the rating values by (2).	if it is high-rise building and wind intensity is high, multiply the rating values by (2).	if it is mostly occupied in the mornings, in N hemisphere, for heating dominated climates, give (+) for E, S, SE, (-) for the rest. for cooling dominated climates, give (+) for N, NW, W, (-) for the rest. in S hemisphere, vice versa.					
	West					if it is mostly occupied in the afternoons, in N hemisphere, for heating dominated climates, give (+) for W, S, SW, (-) for the rest. for cooling dominated climates, give (+) for N, NE, E, (-) for the rest. in S hemisphere, vice versa.		if it is high-rise building and wind intensity is high, multiply the rating values by (2).			if the space is rarely used, there is no need for rating.
	North East	if there is no predominance among the winds of different orientations, then there is no need for rating.	if there is no predominance among the winds of different orientations, then there is no need for rating.	if there is no predominance among the winds of different orientations, then there is no need for rating.	if there is no predominance among the winds of different orientations, then there is no need for rating.	if stack effect dominates the air infiltration (in cold climates), there is no need to rate the options according to wind directions.		if there is no predominance among the winds of different orientations, then there is no need for rating.			
	North West					plus all the above, change the rating to protect or utilize (for hot & humid climates) from the predominant wind.		plus all above conditions, surrounding obstacles (buildings, trees, etc.) or view change the rating. highly reflective surrounding surfaces (including the ground) may contribute to the illumination levels or a pleasing view may be a desire. adjust the above ratings accordingly.			
	South East					if the space mostly occupied in certain seasons like Winter or Summer, the rating changes as well. S, SE, SW are again advantageous in Winters, while N, NE, NW can be superior options for spaces mostly occupied in Summers.					
	South West					for spaces rarely occupied, there is no need to rate the options.			for spaces rarely occupied, there is no need to rate.		
rate after checking these issues...		predominant wind direction (& intensity) /building height (as high or low-rise)	predominant wind direction (& intensity) /building function	predominant wind direction (& intensity) / building height (as high or low-rise)	predominant wind direction (& speed) / building height (as high or low-rise) climate	location (Northern or Southern hemisphere) and predominant wind direction (& intensity)	climate (heating or cooling dominated, or mixed based on heating degree days)	function of the space (use period daily & seasonal)	predominant wind direction (& intensity) / building height (as high or low-rise)	location (Northern or Southern hemisphere, latitude) / climate	surrounding noise sources and function of the space (use period, noise sensitivity)

The scores obtained from separate charts are accumulated (the sum of + and - is 0, one advantage plus one disadvantage make the design neutral) for the overall performance evaluation of façade design. Then the results are illustrated by a spiderweb chart (the format is given in Figure 2). The final spiderweb graphic, which includes separate sections for each performance aspect, gives the opportunity to compare the façade design alternative with the tool's ideal. The tool does not give real performance values, instead it gives the opportunity to relatively compare alternative designs in terms of performance aspects and to see the overall performance footprint.

## DISCUSSIONS AND CONCLUSION

The tool is believed to provide insight about the entire façade performance while addressing the interactions, conflicting issues among separate performance aspects and their relationships with design decisions. Thus, it will lead to a holistic façade design, better trade-offs, and transparency in decision-making, especially in early stages of façade design process. Design is a process of limiting possible alternatives and here the tool may function as a supportive

guidance. By having the potential to prevent negative iterations in the design process, it will be time-saving, as well. Although the decisions need to be finalized by integrating some other issues like costs, and aesthetic features of the design alternatives, by means of the tool, options can be compared in terms of their functional performances. Besides, the tool provides the notion of how (by changing which design decision(s)) to improve the performance of the final design.

Figure 2. A representative spiderweb chart

Project conditions may vary, so the importance factors of the performance aspects. In that case, design decisions can be given accordingly which makes the tool flexible to changing priorities/ conditions. In future studies, design options within the scope of the tool can be expanded and rated by following the similar logic. Furthermore, the tool can be customized for specific climatic conditions, or building/ façade types. It may evolve in future, as new knowledge is incorporated into the tool.

## Considerations on the Thermal Modelling of Insulated Metal Panel Systems

### ABSTRACT

The very strict regulations imposed by the European directives regarding low energy consumptions of buildings imposes the availability of thermal and energy efficient solutions for the building envelope. One common solution is given by insulated metal panel systems, which are typically used for industrial buildings but lately also used for other types of buildings (e.g. residential buildings, hotels, hospitals). These types of solutions must be properly addressed from the thermal modelling and simulation point of view considering a different thermal behaviour due to its detail components. For insulated metal panel systems the typical calculations are done by considering only the current field area without the impact of the thermal bridges. This means that the value used in calculations is just a 1D, and not a 2D or a 3D simulation which are closer to the real heat transfer phenomena for this types of constructive details. Thus, the paper addresses a study regarding the manner by which metallic building components can be thermally evaluated and optimized in order to improve their thermal performance and reach the imposed thermal transmittances-U values imposed for the market of high performant energy efficient buildings. The paper brings a complex approach in evaluating the thermal performance of insulated metal panel systems.

### KEYWORDS

Metal panels, thermal bridges, heat transfer, modelling, simulation

### INTRODUCTION

On an international level the development of high performance buildings (i.e. nearly Zero Energy Buildings – nZEB, passive buildings) is one of the main focuses aimed on achieving important decreases of the energy consumptions and greenhouse gas emissions. On a European level a decrease in the energy consumptions level of 20% is expected by 2020 (2020 Energy Strategy) and of 27% by 2030 (2030 Energy Strategy). Thus, the construction of new buildings offers the best opportunity to implement thermally optimised solution for the building envelope components, solutions that are able to meet the European targets regarding energy consumptions.

The building envelope plays a very important role in establishing both the energy demand for heating or cooling the building and also the interior comfort level of that building. The construction market offers several solutions described as optimal solutions for meeting the nZEB target imposed by the European directive (Directive 2010/31/UE). Among traditional solutions, the insulated metal panel systems (i.e. sandwich panels) typically used for industrial buildings are becoming popular among builders as an alternative solution for other types of buildings (e.g. office buildings, hospitals, residential buildings). Although that the metal panel has an interior layer of thermal insulation, this is covered on both sides by a corrugated metal sheet, thus decreasing the thermal performance of the ensemble. Also, several thermal bridges occur in the joints area, thermal bridges that must be addressed with at least a 2D calculation approach.

In many situations the calculations are done by a 1D approach, without considering the negative effect of the thermal bridges. Thus, an inaccurate thermal assessment can lead to code compliance issues and a poor thermal performance in the operating phase of the building. The study aims to analyse the thermal performance of insulated metal panel systems by approaching 3D calculations with the help of CIMPSPAT program. The adjusted thermal resistance  $R'$  (i.e. thermal resistance that considers the effect of the thermal bridges) and the adjusted thermal transmittance  $U'$  are calculated and compared with the standard values for traditional and values for nZEB.

## METHODS

A heat transfer computing software called CIMPSPAT is used for the numerical modelling and simulation of the 3D heat transfer phenomena that takes place in insulated metal panel systems. The CIMPSPAT computing software is similar to other tools like THERM, Physibel, Antherm and others. Similar to mentioned tools, CIMPSPAT was developed in the last 35 years by our research staff. The finite-differences method is used for solving the third order heat transfer differential equations. The boundary conditions for the simulated cases are set in accordance to national and European standards. The program does 3D calculations by employing the heat conduction equation in a stationary thermal regime:

$$\frac{\partial}{\partial x} \left( \lambda(x, y, z) \cdot \frac{\partial \theta(x, y, z)}{\partial x} \right) + \frac{\partial}{\partial y} \left( \lambda(x, y, z) \cdot \frac{\partial \theta(x, y, z)}{\partial y} \right) + \frac{\partial}{\partial z} \left( \lambda(x, y, z) \cdot \frac{\partial \theta(x, y, z)}{\partial z} \right) = 0 \quad (1)$$

where:  $\theta$  is the temperature variable in time, in the (x,y,z) node,  $\lambda$  is the thermal conductivity of the body [W/(m·K)]

The geometry of the panel was discretized using a discretisation network in accordance with the stipulations of the standard EN ISO 10211. The digitization network is done automatically by the program, until the conditions for the heat flow between the inner and outer surfaces of the wall give a difference under 0.001W and in each node of the spatial mesh the obtained differences are under 0.000001 W (EN ISO 10211).

The input of data is done with the help of a graphical module. The required data is the spatial geometry of the component, the physical characteristics of each material that is forming the building component, the boundary conditions, the ambient temperatures, the exterior temperature, and the interior and exterior air humidity. The library of the program contains climatic data in accordance with the SR EN ISO 13790 standard and other specific standards.

The analysed components are specific details for walls made with insulated metal panel systems existing in the construction market. The component is described by three layers: i.e. an exterior and an interior profiled sheeting and an inner layer of thermal insulation having a thermal conductivity  $\lambda=0.04$  [W/(m·K)].

The simulated case scenarios are described as it follows: in current field area without the purlin (1) and in the area with the purlin (2). Thus, results are given considering both areas of a metallic component. Two hypotheses were simulated for each studied case:

- hypothesis (a): an air layer exists between the two thermal insulation layers that are in contact with the interior and exterior sheeting;
- hypothesis (b): a thermal insulation layer is placed between the two thermal insulation layers in contact with the interior and exterior sheeting.

For case scenario I is presented a wall with a thickness of 150 mm in two variants, the first in the current field area (a) and the second in the purlin area (see figure 1), the Z purlin having a length equal to 150 mm. For case scenario II is presented a wall with a thickness of 250 mm with an interior layer of thermal insulation between the existing thermal insulations (b), in the current field area (i.e. 1.II.b) and in the Z purlin area, purlin with a length of 200 mm (i.e. 2.II.b). For case scenario III is presented a wall with a thickness of 300 mm with an interior layer of thermal insulation between the existing thermal insulations (b), in the current field area (i.e. 1.III.b) and in the Z purlin area, purlin with a length of 250 mm (i.e. 2.III.b). The Z, C and U purlins have a thickness equal to 1.5 mm, while the profiled sheeting has a thickness equal to 0.5 mm. The mentioned case scenarios are briefly described in table 1. Also, the geometrical model of the constructive details is presented in figure 1.

Table 1. Studied case scenarios

	Case Scenario

b.	1.I.b	1.II.b	1.III.b	2.I.b	2.II.b	2.III.b

Figure 1. Extract from the analysed case scenarios

## RESULTS

As mentioned before the European Directive 31/UE/2010 defines new types of energy efficient buildings starting by 31 December 2021. The nZEB require significantly improve thermal performances that will lead to higher thermal resistances (i.e. lower thermal transmittances) in accordance to what a building envelope can be described as having nearly zero energy consumptions. Although that the term of “nearly zero” is understood as more related to building systems than the building envelope, the reality is that the envelope still plays a key role in reaching that zero level.

The Romanian Governmental Order (GO 2641/2017) that came into force in April 2017 imposes more strict requirements for reaching the nZEB levels. Minimum adjusted required values for thermal resistances of building envelope components are given for both of residential and other types of buildings. The adjusted thermal resistances values refer to the ones obtained by applying the thermal bridges effect described by the linear and punctual thermal transmittance coefficients. In the case of an exterior wall for residential building the minimum adjusted required values is  $R'=1.80 \text{ [m}^2\text{K/W]}$ , that being an adjusted thermal

transmittance  $U' \leq 0.56$  [W/(m<sup>2</sup>K)]. For other types of buildings the values for exterior walls are not higher but even smaller than the one mentioned for residential buildings, e.g. for category I of building going from  $R'=1.10$  to  $1.8$  [m<sup>2</sup>K/W] while for category II of buildings going from  $R'=1.0$  to  $1.7$  [m<sup>2</sup>K/W], category being defined based on the main usage of the building. Unfortunately, the minimum required values for both residential or other types of buildings, do not meet the values defined for a nZEB that should be around  $R' \geq 6.67$  [m<sup>2</sup>K/W], which means an  $U' \leq 0.15$  [W/(m<sup>2</sup>K)].

Thus, the values obtained through 3D calculations were compared to the above mentioned values in order to evaluate if the analysed case scenarios comply with them. It is good to mention that in current design practice thermal performance of metal insulated panels is evaluated mainly in the current field area and not in the area purlins area.

## DISCUSSIONS

Table 2 gives an accurate image of the thermal behaviour of the studied cases. As it can be observed for all examined cases the adjusted thermal transmittances  $U'$  have lower values

compared to national norms (GO 2641/2017) but much higher values compared to the ones described by the nZEB targets. When 1D calculations are done for the presented details, the results obtained, without considering the negative effect of the thermal bridges, is somewhere equal to a thermal resistance of 4 [ $\text{m}^2\text{K/W}$ ] for case scenarios I, value higher than all results (see table 2) obtained by implementing complex calculations (i.e. 2D or 3D). A 1D calculation approach does not consider the negative effect of the thermal bridges, thus giving a thermal performance even two times better than the actual (i.e. real) performance of a component. Therefore, such complex details should always be analysed by a 3D approach, using a spatial discretization network associated with the analysed case. Thus, the mesh will describe the exact shape of the corrugated sheet (i.e. the spatial shape), and also the presence of the steel purlins and of the fixing elements.

An example of the geometrical model and the spatial temperature field for an exterior wall in connection with an intermediate metallic thermal insulated flooring, is presented in figure 2. Such complex details that beside the material layers have several metallic elements (i.e. purlins) in its structure, placed in various positions (e.g. horizontal or vertical) and orientations, impose a 3D calculation procedure that can evaluate the spatial volume of the analysed detail. The metallic purlins give a spatial thermal effect of the heat flows that are passing through the building component. Doing 2D calculations for several defined areas of the geometrical model and overlapping the plane effects will not lead to accurate results for these type of complex details. The results will be overestimated compared to the actual thermal behaviour of the building envelope.

The simulated model and the temperature field for case 2.I.b and case 2.III.b are presented in figure 3. All simulated models started from the geometrical model presented in figure 1, that was described and modelled based on the real dimensions for each constructive detail. Figure 3 presents (a) the generic modelling in the purlin area.

Figure 3. The geometrical model (a) and the spatial temperature field (b) - with purlin

## CONCLUSIONS

Meeting the required energy efficiency targets imposed by the European Union is a very hard task considering that even nowadays, some of the solutions offered on the construction market are not able to fulfil the thermal performance values imposed by design norms. When

calculating complex details (e.g. insulated metal panels), the approach is usually done 1D instead of a 2D or more accurate a 3D calculation procedure. Therefore, the final thermal and energy performance of a building is quite different than the performance obtained during the operation phase of the building, case usually met in current practice at metallic structures. This has significant economical implication for the owners or operators of that building, from the energy consumption point of view. Even for the case of thermally optimized details (i.e. case scenario for all studied dimensions)) the thermal performance still does not comply with required values for nZEB. That means that several solutions could be employed to improve their thermal performance: thicker thermal insulation layer, an extra thermal insulation system on the exterior side of the panel, or better thermal performing materials (e.g. nanoinsulating materials) (Lakatos, 2014, 2017) and fasteners made of non-super conductive materials.

To conclude, beside the reduction of the energy consumption also a reduction of the greenhouse gas emission must be obtained, which means a low CO<sub>2</sub> emission index for the analysed building. With building envelope components with a thermal performance far worse than the modelled scenario in design phase, will set a trend opposite to what is needed, not only on a European but also on a worldwide level. The “A” energy class buildings or nZEB obtained on “paper” must behave likewise in operating phase. A 3D complex approach of the calculations for the insulated metal panel systems is able to offer accurate results for what means a real operation of a building.

### ABSTRACT

Phase change materials (PCMs) glazing systems might be able to improve the building energy performance because of controlling solar heat gains and peak heating and cooling loads. EnergyPlus, a state-of-the-art energy simulation tool, allows simulating the heat transfer through opaque elements that incorporate PCMs. However, EnergyPlus does not allow this for transparent elements with PCMs. As consequence, the main objective of this research is to develop a numerical thermal model of double glazing windows with PCM in the cavity to be coupled with EnergyPlus in the future. To develop the numerical heat transfer model, the sensible and latent heat of the PCM is numerically modelled in MATLAB. This model is used to evaluate the impact of PCM on the inner surface temperature of the window and the Predicted Mean Vote (PMV) in Santiago of Chile. The PCM RT25HC of Rubitherm® shows the better performance because it keeps the internal surface temperature of the window near of the comfort range for more time and the Predicted Mean Vote (PMV) below 1.0.

### KEYWORDS

PCM glazing, thermal model, office buildings, PMV.

### INTRODUCTION

Central Chile shows a semiarid climate (Bsk according Köppen-Geiger classification) which is characterized by high solar radiation and outdoor temperature during 6 to 8 months. On the other hand, most of office buildings are fully glazed façade office buildings that have very high cooling energy consumption due to high solar heat gains even tough in winter (Bustamante, Vera, Prieto, & Vásquez, 2014).

Phase change materials (PCMs) are able to reduce building cooling loads when incorporated to opaque building envelopes (Ilaria, Lorenza, Goia, & Serra, 2018). However, open floor buildings have low percentage of opaque surfaces. Therefore, there is the opportunity to use windows with PCM to control solar heat gains, daylighting transmission and cooling loads (Giovannini, Goia, Verso, & Serra, 2017; Silva, Vicente, & Rodrigues, 2016). EnergyPlus, a state-of-the-art energy simulation tool, does not include the heat transfer modelling through transparent elements that incorporate PCMs. Otherwise, the heat transfer through opaque elements is well supported by EnergyPlus (Tabares-Velasco, Christensen, & Bianchi, 2012).

Different heat transfer models of the state-of-the-art has the potential to be coupled to an energy modelling software. In particular, Goia et al. (2012) developed a 1D model for heat transfer considering shortwave and longwave radiation heat exchange, conduction and convection. On

the other hand, Liu et al. (2016) developed a model considering absorption of the different layers, conduction, convection and radiation of shortwave and longwave transfer. They validated the model with measurements of temperatures.

As consequence, the main objective of this paper is to develop a numerical thermal model of double glazing windows with PCM, which is incorporated in the window's cavity. This numerical model is based on: the main heat transfer equations of Goia et al. (2012) and their nodal distribution to use Crank-Nicolson finite differences method; border conditions according to Liu et al. (2016); PCM's solar properties of Goia et al. (2015); and Tabares-Velasco et al. (2012), where is explained the specific heat calculation of opaque walls based on the relationship between enthalpy and temperature of PCM. To develop the numerical heat transfer model, window properties and the sensible and latent heat of the PCM are numerically modelled in MATLAB. The model is used to determine the best PCM to improve the window's thermal behaviour and thermal comfort of an office space located in Santiago of Chile.

## METHODOLOGY

### Overall

The process to get the best PCM to improve thermal comfort in an office building in Santiago is carried out in three steps: (i) selection of PCM to be evaluated, (ii) calculation of the mean radiant temperature of the office space using PCM and without PCM by means of a numerical thermal model of heat transfer introduced in this paper, and, (iii) evaluation of the thermal comfort using Predicted Mean Vote (PMV). In the following sections, the building model, climate of Santiago and the heat transfer model are presented.

### Building model

The space to be studied corresponds to an office of 6.0 m x 8.0 m x 3.0 m, as shown in Figure 1. A window of 3.0 x 2.0 is oriented north or west. The walls, ceiling and floor are considered adiabatic. Thus, heat transfer only occurs through the glazed façade. The HVAC system consists of an ideal system with heating and cooling thermostat setpoints of 20°C and 25°C, respectively. The internal heat gains are not considered in this case because this study is focused on the heat transfer through the window.

Figure 1. Office space building.

### Climate

In Santiago, the highest temperature is 33.2°C, which occurs in December, and the lowest temperature is in August (-6°C). The mean outdoor temperature is 14.4°C. Figure 2a shows the annual air temperature in Santiago. Analysis of solar radiation in Santiago revealed that direct and diffuse solar irradiation are 1632.09 kWh/m<sup>2</sup> and 649.48 kWh/m<sup>2</sup>, respectively. Figures 2b and 2c shows the diffuse and direct solar radiation respectively.

### Selection of PCM

PCMs selected are paraffin of the RT Line of Rubitherm company. The melting temperature varies between 12°C and 35°C based on the Internal Report of SOLTREN project (Shipkovs et al., 2018). The detailed information about each PCM is presented in Table 1.

Figure 2. (a) Annual temperature in Santiago. (b) Annual diffuse solar radiation in Santiago. (c) Annual direct solar radiation in Santiago.

Table 1. PCM from Rubitherm® to be studied

PCM	Melting temperature [°C]	Heat capacity storage [kJ kg <sup>-1</sup> ]
RT12	12	155
RT25	25	170
RT25HC	25	230
RT28HC	28	250
RT31	31	165
RT35	35	160

Figure 3. Discretization of thermal model.

### Numerical heat transfer model

The heat transfer model has been developed based on model of Goia et al. (2012), Liu et al. (2016), Goia et al. (2015) and Tabares-Velasco et al. (2012). The model consists of a 1D nodal heat transfer of shortwave and longwave radiation, conduction and convection. In this model, 2 nodes are in each glass and 4 nodes in the gap (air or PCM). The discretization scheme is presented in Figure 3.

The model considers the following assumptions: (1) Convection is considered in the air gap cavity; (2) convection is neglected when the window cavity is filled with PCM; and (3) the absorption through the different layers is considered. Ec. 1 represents the heat transfer through the PCM:

$$\rho C_p \frac{\partial T}{\partial t} = k \frac{\partial^2 T}{\partial x^2} + \phi \quad (1)$$

where,  $t$  is the time (s),  $T$  is the temperature (K),  $\rho$  is the density (kg/m<sup>3</sup>) and  $C_p$  is the specific heat (J/(kg·K)),  $k$  is the thermal conductivity, and  $\phi$  is the radiation source term. To solve the equation, Crack-Nicolson finite differences method has been used. The following equations represents the discretization:

$$\frac{\partial T}{\partial t} = \frac{T_i^{n+1} - T_i^n}{\Delta t} \quad (2)$$

$$\frac{\partial^2 T}{\partial x^2} = \frac{T_{i-1}^{n+1} - 2T_i^{n+1} + T_{i+1}^{n+1}}{\Delta x^2} \quad (3)$$

where,  $\Delta t$  is the time step, 1 minute in this paper,  $\Delta x$  is the spatial step (m),  $T_i^n$  is the temperature in the node  $i$  and time  $n$ . To this discretization is added the generated radiation. Finally, following is presented the matrix form of the equation to be solved.

$$(I - rA)T^{n+1} = (I + rA)T^n + r(b^n + b^{n+1}) + \phi' \quad (4)$$

Where,  $I$  is the identity matrix,  $A$  is a matrix of Eq. (5) and  $b$  are the remains of the boundary condition also presented in Eq. (5).

$$A = \begin{pmatrix} -2 & 1 & 0 & 0 & 0 & 0 & 0 \\ 1 & -2 & 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & -2 & 1 & 0 & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & 1 & -2 & 1 \\ 0 & 0 & 0 & 0 & 0 & 1 & -2 \end{pmatrix}, \quad b = \begin{pmatrix} q_1 \\ 0 \\ \vdots \\ 0 \\ q_2 \end{pmatrix} \quad (5)$$

The numerical thermal model of the heat transfer of the window was implemented in MATLAB. Also, a model of the office space in EnergyPlus was used for calculating the inputs for the MATLAB model. The inputs are the interior mean air temperature, exterior air temperature, the interior and exterior surfaces temperatures of the window, solar radiation and convection parameters.

### Thermal comfort evaluation

Thermal comfort is evaluated in terms of the Predicted Mean Vote (PMV) (ISO-7730:2005), a mathematical model of a thermal scale that runs from Cold (-3) to Hot (+3) which describe the thermal sensation of occupants.

## RESULTS

Figures 3 shows the interior surface temperature of the window oriented north and west in a representative summer and winter week, respectively, for all the PCMs evaluated as well as for the window cavity filled with air. Firstly, these results show all peaks of internal window surface temperatures filled with PCM are delayed in comparison with the window filled with air. This effect is due to the difference between the specific heat of the air and PCM. RT12 paraffin is always in liquid state because the temperature in the window is at least 20°C approximately. When RT25, RT25HC and RT28 paraffin are used in both, north or west façade, they change phase every day, keeping the internal surface temperature constant near to the melting temperature during all working hours. During winter, these three PCMs in north façade are able to keep the internal temperature near to the melting temperature. However, only RT25 and RT25HC are able to change phase in west façade case. The difference of heat storage between RT25 and RT25HC has no relevant effect in this case. Finally, RT31 paraffin changes phase only in summer for both window orientations, and RT35 paraffin never changes phase.

Also, the PCM has a night effect. During summer in the west façade case, the phase change is able to keep the internal surface temperature by two days. To ensure the correct behavior of the PCM glazing, it is needed that the phase change occurs every day. In the morning, the PCM must change to liquid state, and at night must change to solid state. In this case, on day 2, the

heat storage is over at the end of the working hours, then, the internal temperature increases, and the thermal comfort of occupants is affected. Due to this, in summer, RT31 and RT35 paraffin have the ability to change phase every day, and in winter, RT25 and RT25HC paraffin show this ability.

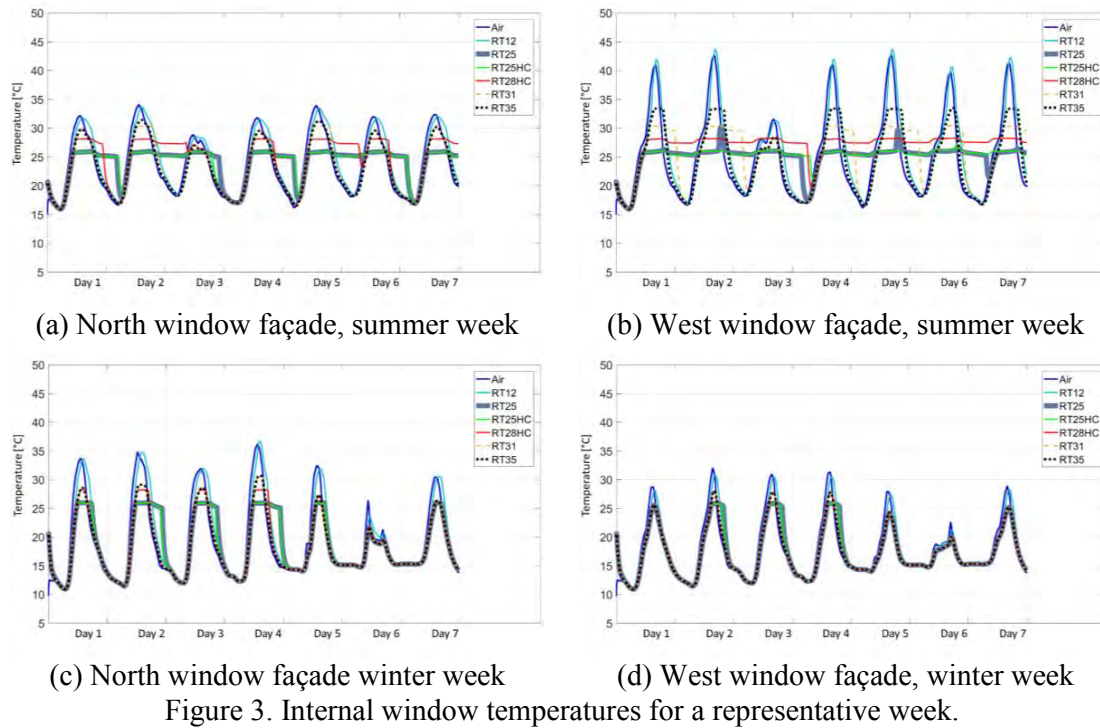

Figure 3. Internal window temperatures for a representative week.

Table 2. Mean PMV results for each case

Cavity filling	Summer		Winter	
	North	West	North	West
Air	1.0	1.5	1.1	0.9
RT12	0.9	1.6	1.1	0.9
RT25	0.7	0.9	0.9	0.8
RT25HC	0.7	0.9	0.9	0.8
RT28HC	0.8	1.0	0.9	0.8
RT31	0.8	1.0	1.0	0.8
RT35	0.9	1.1	1.0	0.8

Table 2 shows the mean PMV for the temperature peaks of each day for the representative week of winter and summer. It shows that the PMV for the window filled with air is above or very close to 1.0, which means the indoor environment is slightly hot. On the other hand, PMV value less than 1.0 indicates a comfortable environment. In the north façade for summer, all the PCMs evaluated decrease the PMV below 1.0, but in the west façade, only RT25 and RT25HC decrease the PMV below 1.0. In winter, all PCMs evaluated show PMV values near to 1.0.

## CONCLUSIONS

This study developed a heat transfer model of a double-glazed window filled with PCM. The PCMs RT25 and RT25HC have better behavior than the other PCMs because they reduce the inner surface temperature of the windows between 0°C and 10°C. As consequences, RT25 and RT25HC allows achieving a comfortable office indoor environment because PMV values are below 1.0. Also, it was found that RT25 and RT25HC does not change phase during summer

for 2 days or more, thus the benefits of PCMs are not obtained during these days. Further studies are needed in order to evaluate other climates, whereas future work consists on integrating this model to EnergyPlus to evaluate the impact of windows with PCM on the building energy performance.

### ABSTRACT

The target of the nearly zero-energy building (nZEB), stated by the European Union, represents one of the most strenuous challenges to reduce energy consumptions and greenhouse gas emissions in the building sector. In Italy, the nZEB concept refers to a set of energy performance requirements, fixed at national level and establishing a maximum allowable mean thermal transmittance value of the building envelope, as a function of the heating degree-days and of the shape factor. The building envelope is becoming more and more thermally insulated; this determines the reduction of the energy need for heating, but on the other hand it can cause the indoor overheating and the resulting increase of the energy need for cooling. In the design of highly energy efficient buildings, the different energy needs should be kept in balance as to increase the overall energy performance.

The article aims to investigate the conditions and extent for which the envelope insulation is beneficial for containing overall energy needs. A sensitivity analysis that involves different insulation levels of the building envelope is performed on some apartments of a typical residential building, located in three different Italian climatic zones. The energy performance calculations are carried out by means of a detailed dynamic simulation tool (*EnergyPlus*). The results point out that, whereas the effect of increasing the thermal insulation causes a stable reduction of the energy need for heating, the energy need for cooling is very sensitive to the apartment storey; specifically, it increases in ground-floor apartments, and decreases for top-floor building units. Its reduction becomes progressively more consistent at the decrease of the heating degree-days. Considering the annual imbalances between the energy needs for cooling and heating due to the hyper-insulated envelope, reference values of thermal transmittance can be derived as to maximise the overall energy performance of the building.

### KEYWORDS

Nearly zero-energy building; thermal insulation; building energy performance; building envelope; dynamic simulation.

### INTRODUCTION

Directive 2010/31/EU (European Union, 2010) promotes the energy performance improvement of buildings and enforces the Member States to draw up national plans for increasing the number of nearly zero-energy buildings (nZEBs). In Italy, the detailed application of the definition of nZEB has been specified by the Ministerial Decree (M.D.) 26/06/2015 (Italian Republic, 2015): a set of provisions concerning the building envelope, the technical building systems and the use of renewable energy sources must be complied with to achieve the nZEB target. In particular, the national strategy focuses on the building envelope (Zinzi et al., 2017), enforcing restrictive mean thermal transmittance values. In addition, the adoption of adequate insulation thickness as to meet winter energy requirements could lead to indoor overheating and, consequently, to an increase of the energy need for space cooling. Guaranteeing the best

trade-off between energy performance for heating and cooling is of crucial importance to minimize the overall energy needs.

Several studies investigated the role of the building envelope in achieving the nZEB target and demonstrate the discrepancy between the envelope requirements and the building energy behaviour in summer. Ballarini and Corrado (2012) proposed a methodology to investigate the effect of thermal insulation in summer. They underlined that transparent envelope and shading devices have a greater influence on summer energy needs than the opaque envelope. Murano et al. (2017) demonstrate the imbalance of nZEB energy need for heating and cooling by evaluating the effects of the reduction of the  $U$ -values of the envelope components and of the improvement of solar shadings on the energy needs of three reference buildings. Applying the two measures simultaneously, they proved that the influence of the thermal insulation on the energy needs for heating is greater than the effect of solar shading on the energy needs for cooling. Chvatal and Corvacho (2009) and Chvatal et al. (2005) investigated the summer overheating in buildings as a consequence of thermal insulation and thermal inertia of the building envelope; when solar and internal gains are not adequately controlled, there is a tendency towards more discomfort as the envelope insulation increases. Sameni et al. (2015) highlighted the risk of overheating in a hyper-insulated social housing, identifying the most critical flats on the basis of both occupants' behaviour and geometrical characteristics.

Within this framework, the choice of an optimal insulation level would prevent overheating and ensure the lowest overall energy consumption. The present research focuses on a typical Italian residential building and carries out a sensitivity analysis including different insulation levels and climatic zones. The imbalance of the energy needs and its effect on the overall primary energy for heating and cooling are discussed for four representative apartments, highlighting the different behaviour for storey location and climatic condition.

## METHODS

### Theory

The dynamic numerical simulation of the building was performed by means of *Energy Plus*. Each apartment has been modelled as a single thermal zone. The code solves a convective heat balance equation on the internal air node of the building thermal zone. As the analysis of technical building systems is out of the scope of the work, an infinite heating and cooling capacity was adopted to determine the net energy needs for space heating and space cooling.

The overall energy performance ( $EP_{gl}$ ), expressed as the ratio of the annual non-renewable primary energy for space heating and space cooling to the net conditioned floor area, was determined as the weighted sum of the thermal energy needs for heating and for cooling:

$$EP_{gl} = \frac{EP_{H,nd} \cdot f_{p,nren,gas}}{\eta_{H,u} \cdot \eta_{H,g}} + \frac{EP_{C,nd} \cdot f_{p,nren,el}}{\eta_{C,u} \cdot \eta_{C,g}} \quad (1)$$

where  $EP_{H/C,nd}$  is the annual energy need for space heating/cooling,  $f_{p,nren,gas/el}$  is the non-renewable primary energy conversion factor for natural gas (1.05) and electricity (1.95) respectively,  $\eta_{H/C,u}$  is the mean seasonal efficiency of the heating/cooling utilisation subsystems (i.e. heat emission, control and distribution, equal to 0.81) and  $\eta_{H/C,g}$  is the mean seasonal efficiency of the heating (0.95) and the cooling (2.50) generation subsystem, respectively. The reference mean seasonal efficiency values of the thermal subsystems were assumed in compliance with M.D., and the most used energy carriers in Italy were adopted. Gas condensing boiler and chiller were used as reference generators for heating and cooling.

### Case study

The case study is a 4-storey multi-family house, studied in a previous work (Murano et al.,

2016). It is not a real building but an “archetype”, which is a “virtual” building characterised by a set of properties detected through statistical analysis of a large building sample. It is supposed to be located in Palermo (Southern Italy), Rome (Central Italy), and Turin (Northern Italy). The main climatic data (UNI, 2016) are listed in Table 1. The building consists of 12 units; its main facades are North-South oriented. Four representative apartments were chosen as to cover a wide range of the shape factor values (i.e. ratio of the envelope surface to the conditioned volume) and kinds of adjacent spaces (e.g. ground, conditioned spaces). The main geometric data are reported in Table 2. The sensitivity analysis took into account six levels of thermal insulation, from highly (level no. 1) to scarcely insulated (level no. 6). Each level is a combination of the  $U$ -values of the opaque and transparent envelope components (Table 3); the same  $U$ -value is assumed for each opaque component (walls, roof and ground floor) and the insulating material is placed on the exterior side. The areal thermal mass is about  $270 \text{ kg}\cdot\text{m}^{-2}$  for the external walls and the ground floor, and  $400 \text{ kg}\cdot\text{m}^{-2}$  for the roof. For each insulation level, the  $U$ -value of windows varies accordingly, while the total solar energy transmittance of glazing at normal incidence is kept constant ( $g_{gl,n}=\text{SHGC}_n=0.67$ ). A solar shading ( $\tau=0.15$ ,  $\rho=0.70$ ) is supposed to be placed on the external side of all windows. The external opaque surfaces are intermediate coloured (solar absorption coefficient equal to 0.6).

Table 1. Main climatic data of the analysed locations.

Cities	Heating period		Cooling period		$H_{\text{sol,gl,hor,C}}$

$U$  = thermal transmittance [ $\text{W}\cdot\text{m}^{-2}\text{K}^{-1}$ ],  $\kappa_i$  = internal areal effective heat capacity [ $\text{kJ}\cdot\text{m}^{-2}\text{K}^{-1}$ ],

$Y_{\text{ic}}$  = periodic thermal transmittance [ $\text{W}\cdot\text{m}^{-2}\text{K}^{-1}$ ]

The weather data were derived from the CTI database (CTI, 2017). Hourly profiles of the

internal heat sources and the ventilation flow rate were determined according to UNI/TS 11300-1 (UNI, 2014). As specified by the Italian regulations, a continuous thermal system operation is considered during the heating and cooling seasons. The set-point temperature was fixed at 20 °C and 26 °C for heating and cooling, respectively. The solar shading devices are considered in function when the hourly value of solar irradiance exceeds 300 W·m<sup>-2</sup>.

## RESULTS AND DISCUSSION

The results of the sensitivity analysis are reported in Figures 1-2. For each location, Figure 1-a) shows annual cooling energy need vs. annual heating energy need of the whole building for different insulation levels. Figure 1-b) shows cooling peak power vs. heating peak power for the same insulation levels. Figure 2 shows the same outcomes both for the whole building and for each building unit. In addition, Figures 2-a), 2-c) and 2-e), for different location, also show the annual overall primary energy vs. the annual energy needs for heating and cooling. The dotted grey lines represent the *iso-EP<sub>gl</sub>* lines, calculated as described in “Methods” section.

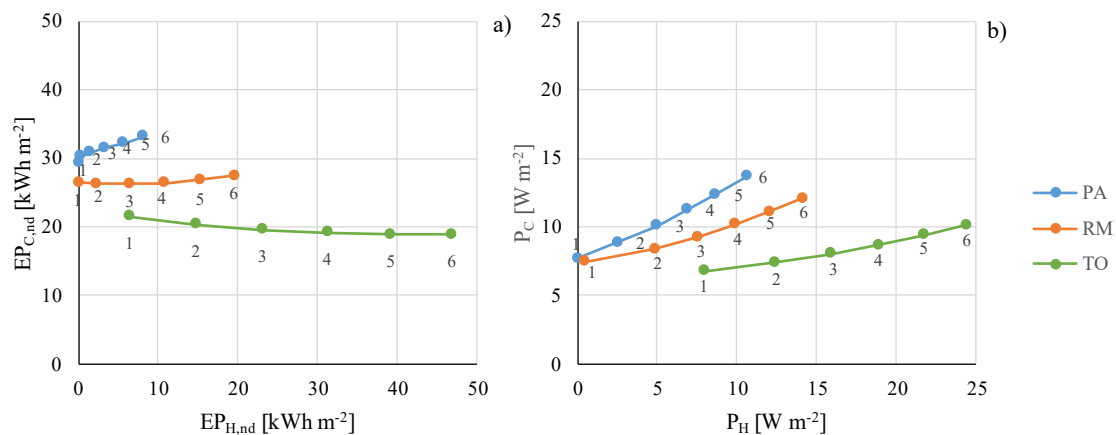

Figure 1. Net energy need ( $EP_{nd}$ ) and peak power ( $P$ ) for heating (H) vs. cooling (C) for the whole building and for six insulation levels.

Analysing the whole building (Figure 1), the sensitivity of the heating energy need to the insulation level is higher in the zones with higher HDD, like Turin, and generally it is more sensitive than the cooling energy need. Anyway, in Turin a reduction of heating energy need by progressively reducing the  $U$ -values corresponds to an increase of need for cooling.

Differences in the energy behaviour between the apartments are noticeable, above all in Rome and Palermo (Figure 2). In Palermo, where the CDD are higher, the influence of thermal insulation is more evident in summer than in winter and an opposite effect is revealed between the units at ground floor and those at the highest floor. Specifically, by reducing the thermal transmittance of the envelope, at ground floor the reduction of heating corresponds to an increase of the energy need for cooling, while at the highest floor the reduction of cooling is higher than the reduction of the energy need for heating.

The difference between apartments is less evident moving from Palermo to Turin, even if the hyper-insulation of the ground floor units always determines a higher energy need for cooling regardless of the climatic zone. For instance, considering a medium insulation level (level no. 4) in Turin, the difference between the cooling energy needs of the ground floor and the third floor units is greater by 68% than the difference between the respective heating needs. In Palermo, switching from insulation level no. 6 to no. 1, the cooling need is reduced by 31% for BU3B and increases by 32% for BU0C. This is due to a greater value of the solar-air temperature on the upper units, where a high level of insulation has a favourable effect. On the

other hand, the hyper-insulation of the ground floor does not allow the discharge of the accumulated heat, thus leading to an increase of the cooling need. For intermediate floors above all in Palermo, the sensitivity to the insulation level is negligible, due to a very low shape factor.

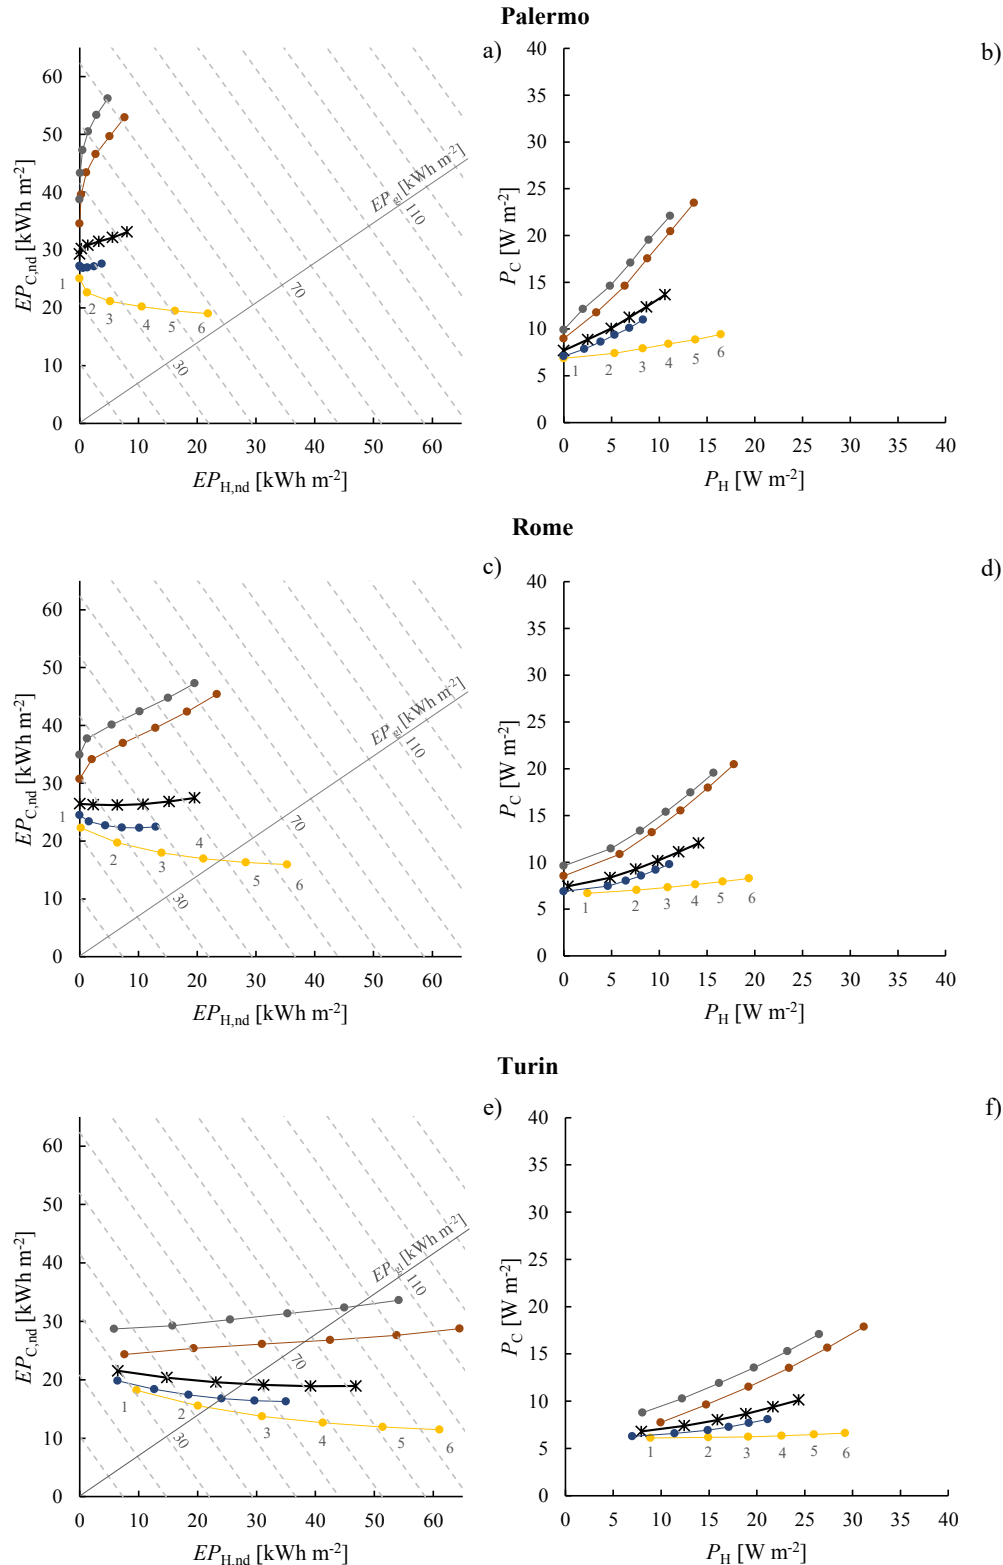

Figure 2. Net energy need ( $EP_{nd}$ ) for heating vs. cooling, and overall primary energy for the whole building and for different building units, for six insulation levels.

The high differences of the energy needs between units at different storeys are also evident in the overall primary energy ( $EP_{gl}$ ), so that the same  $EP_{gl}$  can be achieved by insulating the units differently. For instance in Palermo, BU3B and BU0C have the same  $EP_{gl}$  with  $U = 0.1 \text{ W}\cdot\text{m}^{-2}\text{K}^{-1}$  in the former case and  $U = 0.4\div 0.5 \text{ W}\cdot\text{m}^{-2}\text{K}^{-1}$  in the latter case.

Due to the imbalances between annual energy needs for heating and cooling and in the ground floor units, it would be possible to identify limit  $U$ -values below which  $EP_{gl}$  tends to increase. An example is BU0C in Palermo; by switching from level no.2 to level no.1, the same  $EP_{gl}$  is obtained ( $24 \text{ kWh}\cdot\text{m}^{-2}$ ). Level no.2 would consist in a limit  $U$ -value for this unit.

The thermal transmittance decrease generally causes the reduction both of heating and cooling peak powers. A higher power for heating than for cooling occurs in Turin rather than in Palermo, where in addition the cooling peak power is more sensitive to the insulation level.

## CONCLUSIONS

To improve the energy design of buildings, the findings of the work pointed out that, where possible, it would be desirable to differentiate the envelope requirements for each building unit in function of the geometrical properties, storey location and exposure. In such a way, the imbalances between energy needs for heating and cooling on the building energy performance due to the hyper-insulation of the envelope can be controlled and the overall  $EP$  minimised.

The analysis will be widened by investigating more use categories, glazing properties and shading positions, and assessing the primary energy through detailed models of the technical building systems, as to take into account the temporal variability of system efficiencies.

### **ABSTRACT**

Thermal properties of the opaque building envelope components are crucial for limiting the energy needs of a building. In particular, dynamic thermal properties of envelope components can significantly contribute to the minimization of heat transfer through the envelope and to the appropriate utilization of the internal and solar gains. This is particularly important in the cooling operation, especially in hot climates. Previous experimental and numerical studies on the determination of dynamic thermal parameters of opaque building components neglected the influence of moisture conditions prevailing within the ambient climate. This paper utilizes a calibrated and validated dynamic heat and mass transfer model to analyse the impact of ambient moisture conditions on the determination of dynamic thermal parameters. Time shift and decrement factor are determined for different wall structures (internally insulated or externally insulated) with regard to different outdoor climatic conditions (dry and humid climate). The impact of moisture conditions on the results is analysed and assessed. The results of this study clearly show that the effect of ambient moisture conditions on time shift and decrement factor can be significant and that an application of purely thermal models will lead to inaccurate predictions of the dynamic thermal behaviour of building components.

### **KEYWORDS**

Building envelope, moisture dependent response, heat flux time shift, decrement factor

### **1) INTRODUCTION**

The thermal quality of opaque building envelope is a key factor in buildings whole energy performance. In order to reduce the energy consumption in the building sector and to preserve comfortable indoor conditions, heat losses and gains have to be controlled in both, new and rehabilitated buildings, which are particularly incline to overheating problems. Especially for climates with important annual cooling season, Dynamic Thermal Properties (DTP) are determined to assess the thermal performance of a building envelope and its ability to damp and delay externally impinging heat waves with respect to the building's interior. In this context, the DTP are also important indicators to prescribe efficient solutions for building envelopes.

Some researchers have already shown that, besides thermal conditions, further boundary conditions have an effect on the DTP of building components. For example Kontoleon and Bikas (2007) showed that solar absorptivity is affecting time shift and decrement factor. Moreover, a study conducted by Bishara (2017) showed that internally applied convective heat transfer conditions have a non-negligible impact on the DTP of a wooden wall structure. With regard to material moisture content, Kontoleon and Giarma (2016) showed that a certain impact of a single layer wall's moisture content on its thermal inertia parameters exists. However, the effect of hygrothermal boundary conditions on the DTP of an opaque envelope component has not been extensively investigated yet. In particular, it is not known to which extend relative humidity (RH) conditions are affecting the DTP of multi-layered envelope components.

This paper aims at a preliminary analysis of the influence of hygrothermal boundary conditions on the dynamic thermal behaviour of both, insulated and non-insulated, multi-layer walls, considering different materials and layer order.

## 2) METHODS

### 2.1) Wall structures and climatic boundary conditions

The wall structures studied in this work (see Figure 1) are similar to those analyzed with respect to thermal insulation performance by Ozel (Ozel, 2011) and Al-Sanea et.al (Sanea et.al, 2011). Case (a) is a concrete wall, 25 cm thick with external (2 cm) and internal (1.5 cm) plaster layer. In case (b), an external EPS insulation layer of 10 cm thickness is applied to the same concrete wall. Case (c) considers the same EPS insulation layer as well as an OSB layer of 1 cm thickness, installed at the internal side of the concrete wall. In a further step, two further insulation materials, namely wood fiber (WF) and mineral wool (MW) are applied, instead of the previously considered EPS layer (externally and internally, respectively).

Figure 1. Investigated wall structures a) concrete wall with plaster, b) concrete wall with external EPS insulation layer, c) concrete wall with internal EPS insulation layer.

The external boundary conditions considered in this study are intended to depict summer conditions within a warm-humid (e.g. Nice, France) and a warm-dry (e.g. Madrid, Spain) European climate. The influence of radiation was neglected at this point. Internally, constant hygrothermal boundary conditions are applied (25°C, 45%RH). Both climates, climate1 (warm-humid), and climate2 (warm-dry), are shown in Figure 2a.

Figure 2. a) External climatic boundary conditions, b) Principal of dynamic heat wave propagation through an opaque building envelope component.

### 2.2) Calculation of decrement factor and time shift

The dynamic thermal behaviour of an opaque building envelope is induced by an external temperature solicitation with a period  $P$  of 24 h. This heat wave can be approximated with a harmonic function (in black in Figure 2b), which ranges from a temperature minimum ( $\theta_{e,min}$ ) to a maximum ( $\theta_{e,max}$ ) that define the solicitation amplitude ( $A_{out}$ ). Due to storage effects that dependent upon the thermal mass of the building component, the internal response to an external temperature signal is damped and delayed. The resulting heat flux profile exhibits maximums

( $q_{i,max}$ ) and minimums ( $q_{i,min}$ ) with a decreasing amplitude moving to the internal surface heat flux amplitude ( $A_{in}$ ). Moreover, the temporal occurrence of minimum and maximum is shifted with respect to the external original signal. This temporal shift between external and internal peak values occurrence time is the time shift ( $\Delta t_{ie}$ ).

For the analysis of DTPs, the values of internal heat flux and external temperature are needed. They are used to determine decrement factor and time shift according to EN ISO 13786 (European Committee for Standardization, 2007), for each analysed day.

The decrement factor  $f$  is calculated by correlating periodic thermal transmittance and steady state thermal conductance:

$$f = \frac{|\hat{q}_i|}{|\hat{\theta}_e| \cdot C_s} = \frac{Y_{ie}}{C_s} \quad \text{with} \quad C_s = \frac{\phi}{(T_1 - T_2) \cdot A} \quad (1, 2)$$

The time shift  $\Delta t_{ie}$  is calculated as the difference of phase displacements of the first harmonics, which are  $\varphi$  for the external surface temperature and  $\psi$  for the internal heat flux respectively:

$$\varphi_e = \bar{\theta}_e + \theta_{e,1} \cdot \cos(\omega \cdot t + \varphi) \quad \text{and} \quad \psi_i = \bar{\phi}_i + \phi_{i,1} \cdot \cos(\omega \cdot t + \psi) \quad (3, 4)$$

$$\Delta t_{ie} = \frac{(\psi - \varphi)}{(2\pi)} \cdot 24 \quad (5)$$

### 2.3) Numerical simulation model

For each wall structure presented in 2.1., a two-dimensional numerical thermal simulation as well as a simulation considering heat, air, and mass (HAM) transport processes are conducted. The numerical models (thermal and HAM) are implemented within the software tool Delphin which provides a validated tool set for the representation of hygrothermal transport processes (Nicolai, 2011). This software has been applied in previous studies for analyzing decrement factor and time shift of different wall structures and under various hygrothermal boundary conditions, whereas a very good correlation with laboratory measurement results could be achieved (Bishara, 2017). For climate1, initial conditions are set to 25°C and 80% RH. In case of climate2, initial conditions are 22.5°C and 80% RH. Since the initial moisture content may also affect the calculation results, the same value was chosen for both climates in order to ensure comparable calculation conditions. The material data are taken from the extensive Delphin material database. Output values of temperature and heat flux are generated each minute of calculation, for a simulation period of 10 days. In total, a set of 28 simulation cases is analysed.

## 3) RESULTS AND DISCUSSION

Decrement factors are calculated, considering the steady thermal conductances, which are provided in Table 1. Time shifts and decrement factors are calculated for each day of the analysis and the results are evaluated for the 10<sup>th</sup> day, when steady periodic conditions have been reached for each of the analysed cases.

Table 1. Steady state thermal conductances.

	concrete	EPS ext.	EPS int.	WF ext.	WF int.	MW ext.	MW int.
$C_s$ [W/m <sup>2</sup> K]	5.46	0.339	0.333	0.391	0.384	0.374	0.367

The decrement factor results for climate1 are shown in Figure 4a. Each of the three wall structures show deviations between thermal and hygrothermal simulation results. In case of the concrete wall, the thermal simulation leads to a decrement factor overestimation of 2.5%. In case of the EPS insulated walls, the thermal values are underestimated (external 7.1%, internal

1.8%). With regard to time shift, differences between thermal and hygrothermal results are visible, as well. They are lowest for the concrete wall without insulation (thermal overestimation of 0.5%), and highest for the case of external insulation (thermal underestimation of 1.6%).

Figure 4. Results for climate 1: a) decrement factor, b) time shift

The moisture gradient, which induces through over the wall components due to the different ambient humidity conditions, affects the energy transport. Therefore, the concrete wall's internal surface heat flux is reduced, whereas the insulated wall variants show increased heat flux values. It is well known that porous materials show a relation between material moisture content and thermal conductivity, which is rising with increasing moisture content. Initial material moisture contents for both simulations, thermal and hygrothermal, is set to 80% RH. The Delphin software automatically scales the initial thermal conductivity of all materials to the given humidity reference value. Consequently, the initial thermal conductivities applied to the thermal numerical model remain at a high level, whereas they decrease during the HAM simulations due to the lower ambient humidity values. As a result, time shift values of the hygrothermal simulation are higher than those of the thermal analysis.

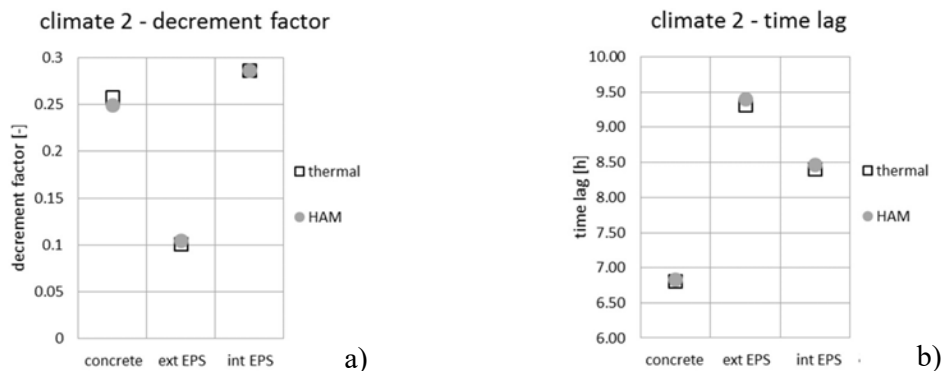

Figure 5. Results climate2: a) decrement factor, b) time shift

With regard to climate2 external conditions, the difference between thermally and hygrothermally determined decrement factor is about 3.3% for the concrete wall. Moreover, the thermal and hygrothermal time shift values are in accordance with each other.

For both insulation variants, the deviations are minimized compared to the climate1 results. The decrement factor deviation for an external insulation variant is about 3 %, and for an internal insulation variant 0.2%. The deviation is small too, in case of time shift (<1 %).

With climate2, the partial pressure difference between indoors and outdoors is less than with climate1 ambient conditions. Therefore, the differences between thermal and hygrothermal calculation of decrement factor and time shift are also smaller.

Figure 6 shows the thermally and hygrothermally determined decrement factors and time shifts for the different insulation materials and in dependence of different insulation layer positions. It can be seen from Figure 6a, that for all considered insulation materials under climate1 conditions, external insulation is promoting lower decrement factors, and thus a better heat insulation capability, than internal insulation. At the same time, installing EPS insulation leads to the smallest difference between thermal and HAM simulation results. Differences in case of wood fiber are 48.8% for external and 39.3% for internal installation. Deviation is highest for externally installed mineral wool, reaching 63.9%, and lowest for internal installation (32.0%). Also with regard to time shift, external insulation promotes better results than internal insulation (see Figure 6b). Again, deviations between thermal and hygrothermal values are lowest for EPS. They are higher in case of wood fiber (external 8.1%, internal 8.3%) and highest in case of mineral wool (external 12.7%, internal 13.3%).

Differences between thermal and hygrothermal values are relatively low for a wall being insulated with EPS. The major differences between thermal and hygrothermal results in case of a wall being insulated with wood fiber or mineral wool are due to a higher material porosity of these insulating materials, compared to EPS. Thus, moisture diffusion is higher and leads to higher moisture contents and thus to increased thermal conductivity and thermal diffusivity values. Consequently, energy transport is enhanced, which raises decrement factor and minimizes time shift.

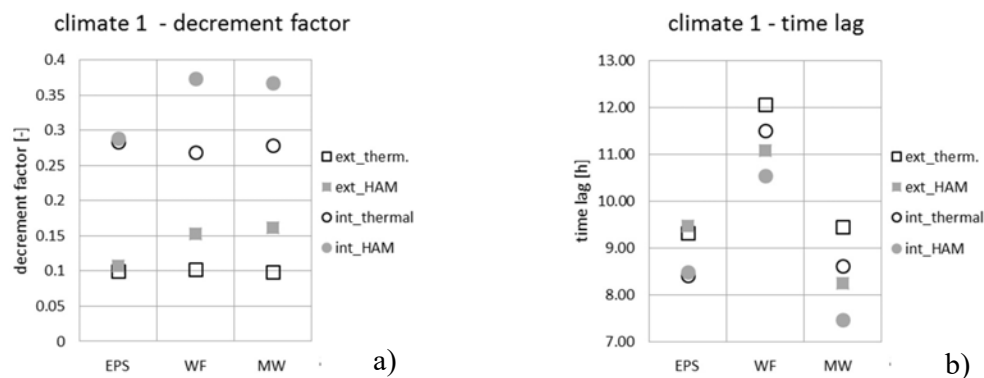

Figure 6. Climate 1 – Results for different insulation materials and layer position.

External insulation achieves preferable results under climate2 conditions too, as can be seen from Figures 7a and 7b. Differences between thermal and hygrothermal simulation are lowest for the wall structure with EPS insulation. In case of wood fiber insulation, the difference between thermally and hygrothermally determined decrement factor is 35.7% in case of external insulation, and 36.9% in case of internal insulation. For the external application of mineral wool, the decrement factor difference is even higher, being 67.9%, whereas internally applied mineral wool leads to a difference of 17.2%.

The time shift analysis under climate2 external conditions also reveal differences between thermal and hygrothermal values. They are low for the concrete wall and higher in case of wood

fiber insulation (external 7.6%, internal 8.0%). In case of the mineral wool insulation, deviations are highest (external 11.4%, internal 9.5%).

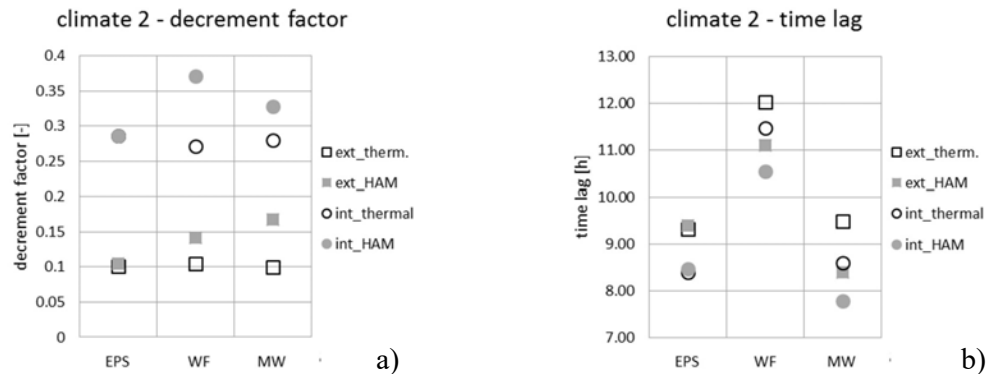

Figure 7. Climate 2 – Results for different insulation materials and arrangement.

#### 4) CONCLUSIONS

In the present work, the influence of ambient moisture conditions on the determination of decrement factor (DF) and time shift (TS) was analyzed. In this context, various multi-layered wall structures were investigated by means of thermal and hygrothermal numerical simulations. The results clearly showed that ambient relative humidity affects dynamic thermal characteristics of the analyzed wall structures. Especially when porous materials are considered, a purely thermal determination of DF and TS leads to erroneous results. The errors in these cases were up to 68% in terms of DF, and up to 13% in case of TS. As a result, this can have a negative effect on the predicted cooling demand of a building. Future research will focus on an analysis of real ambient moisture conditions and their impact on dynamic thermal characteristics of various wall structures. In this context, also the initial material moisture content will be varied in order to determine its impact on the hygrothermal solutions. Moreover, different insulation thicknesses and the impact of external radiation will be regarded.

## **Conceptual framework for improved management of risks and uncertainties associated with the performance of the building enclosure**

Ivar Björnsson<sup>1,\*</sup> and Miklós Molnár<sup>2</sup>

<sup>1</sup>Division of Structural Engineering, Lund University, Sweden

*\*Corresponding email: ivar.bjornsson@kstr.lth.se*

### **ABSTRACT**

The building enclosure has a substantial impact on the overall performance of a building, especially in relation to moisture safety, energy use, environmental footprint and economy. Although the introduction of novel building technology can increase the risk of failures in terms of reduced building performance, failures can also result from the recurrence of past mistakes while using well established building technologies. This indicates that the dissemination of existing knowledge, often documented in project reports, handbooks or experience databases, is not always carried out in an efficient way. One way of addressing the issue is by increasing awareness concerning potential risks and uncertainties in the building process. The current paper presents a conceptual framework which has the broader aim of promoting risk awareness, improving the treatment of uncertainties and ultimately facilitating risk informed decision making during the modern design and construction process. The framework incorporates risk treatment with BIM based design and construction and could be supported by existing failure/damage and/or experience databases or knowledge systems.

### **KEYWORDS**

Building performance, risk management, BIM, conceptual framework.

### **INTRODUCTION**

There is currently an imbalance with respect to the treatment of risks and uncertainties in the design and construction of our built environment. While safety formats that aim at ensuring, and assuring, adequate safety against structural failures and malfunction are in place (e.g. CEN 2002), the treatment of risks and uncertainties related to the performance of the building envelope, indoor climate energy use, etc., lags behind. One important factor is that there are less severe consequences associated with building performance failures compared with structural failures. On the other hand, building performance risks are more long term and have a clear negative impact on durability, environment and the end users' economy. In addition, the predicted performance of a building, determined during design or through simulation, may in some cases deviate significantly from the actual observed behaviour of the building; e.g. the deviation of observed and predicted performance of so called green rated buildings (Lee & Hensen, 2015). These deviations highlight the underlying uncertainties which will require consideration in order to more appropriately treat building performance risks.

Building information modelling (BIM) is widely used by the architectural, engineering and construction (AEC) industry. There are a number of ongoing efforts to extend the traditional use of BIM to cover other aspects of building design and construction including engineering risk management (Zou et al., 2017) and building performance (El-Diraby et al., 2017). BIM is considered as having the potential to generate more design alternatives, enabling an optimization of, e.g., a building's energy performance (Habibi, 2017; Li et al., 2017). Another

area of focus for research and development efforts is quantification of the sustainability or robustness of building design (Jelle et al 2013).

Efforts have been made to integrate a risk aware approach into the analysis of building life cycle aspects using BIM (Pruvost and Scherer, 2017). Design alternatives can be re-analyzed in the light of identified uncertainties and simulation results. Analysis of risks is often carried out by development of ontologies and the use of semantic web technology for representation of the risks (Ding et al., 2016). Main difficulties associated with an ontology and semantic representation approach are, however, that the complexity of the semantic representation of risk knowledge. There is a need for collaboration between the experts creating the BIM models and those working with risk interpretation; these types of approaches are often time-demanding.

This paper presents a conceptual framework for the treatment of building performance risks, with focus on the durability of the building envelope, using BIM. The framework has been developed taking into consideration the following aspects:

- Existing knowledge base concerning risks of conventional building solutions is vast.
- The dissemination of this knowledge to avoid failures may be poor or lacking.
- Risk awareness among AEC professionals may not be adequate in all cases.
- Uncertainties concerning building performance may be difficult to treat numerically.

To help address these issues, the framework aims to promote critical reflection rather than delivering detailed answers or metrics; provide support through all phases of the design and construction process, and; improve transparency and traceability of the risk management process in practice. In the current paper, theoretical aspects are highlighted while some discussions concerning the practical implementation of BIM risk management are provided.

## **INTEGRATING BIM & RISK MANAGEMENT**

There is significant interest by researchers to integrate risk management in AEC through BIM and BIM-related technologies. A survey by Zou et al. (2017) reviewed a number of these efforts and identified some common approaches including the use of BIM to implicitly improve risk management, automatic rule checking as well as reactive and proactive IT-based systems to manage safety risks. In terms of application, a vast majority of the existing approaches focus on construction personnel safety risks (e.g. Ding et al., 2016). There are some exceptions, however, including Pruvost and Scherer (2017) who investigated risks in the building life cycle through an explicit consideration of uncertainties in energy simulations; i.e. quantified uncertainty modelling. A difficulty with applying this type of approach in practical cases is that it requires a stochastic model representation; i.e., a statistical description of the model parameters. Realizing such representations for all relevant risk scenarios may be difficult in practice due to a lack of reliable data and the nature of the uncertainties involved (e.g. the prediction of human behaviour in dwellings). Furthermore, the evaluation of the resulting quantified risk metric will require an objective risk based acceptance criteria and it is unclear how one can be obtained which is generally applicable for all building performance risks.

Although there is a great deal interest towards using BIM or BIM-related technologies to facilitate risk management, there are limitations of existing approaches to consider building performance risks. To start, unlike construction safety risks, which are the focus of many existing efforts, there is a discontinuity in the process of managing building performance

risks. The former is often conducted by a dedicated team of practitioners while the latter is affected in varying degrees by the different process actors (architects, structural designers, HVAC engineers, etc) and can also be influenced by the end-users. There is nothing to ensure an effective knowledge transfer between process actors in terms of addressing these risks. In addition, design and construction decisions that affect building performance risks are not necessarily made in light of these risks. This may be due to a lack of knowledge or simply that they are overlooked or neglected as a result of focus on other integral aspects of the construction process; e.g. time pressure or economic constraints.

## CONCEPTUAL FRAMEWORK

In reviewing building failures it is common that the unfavourable influences leading to failure were avoidable. Failures – generally defined as any unwanted deviation from design expectations – can often result from such influences being subjectively unknown, inadequately treated or overlooked during the design or construction process (Schneider, 1997; Breyse, 2012). This highlights a need for more effective knowledge transfer and management within the AEC community. In light of this, a conceptual framework for improving the management of building performance risks is considered which integrates risk relevant information from existing sources with BIM tools. The primary aim is to increase the awareness of risks by the process actors (architects, engineers, constructors) throughout the building process, especially during the early design stages, and facilitate the treatment of potential building performance risks during the entire design process. It is proposed that the framework should facilitate risk informed decision making through a cognitive loop as shown in Figure 1. Focus is on building performance risks resulting from poor or uninformed decisions made during the design and construction; a treatment of risks related to e.g. human behaviour in dwellings requires special attention.

The proposed framework intends on making information concerning technical solutions with long term risks available in BIM-software in order to provide decision support for improved risk management. The following objectives are highlighted:

- Improve risk awareness and promote critical reflection.
- Provide access to existing risk relevant knowledge *throughout all project phases*.
- Improve transparency and traceability.
- Improve risk communication & knowledge transfer *throughout all project phases*.

It is envisioned that the framework shall be integrated with existing BIM platforms as an add-on or independent application. Design decisions concerning building solutions (facade materials, drainage, etc) shall consider potential building performance risks and this requires feedback to the process actors. A risk filter is thus required which can review construction objects within the BIM software and provide output, while citing source materials that describe potential risks, present possible causes and consequences, and describe suitable mitigation and avoidance measures. To enable this filtration, an IT database could be constructed which utilizes existing experience and knowledge concerning performance failures; i.e. a database containing relevant risk information. In contrast with earlier attempts (Ding et al., 2016) risk information shall be made available to construction objects structured according to existing, commercially available, building classification system(s) such as BSAB (<https://bsab.byggjtjanst.se/>) or Uniclass (<https://toolkit.thenbs.com/articles/classification>).

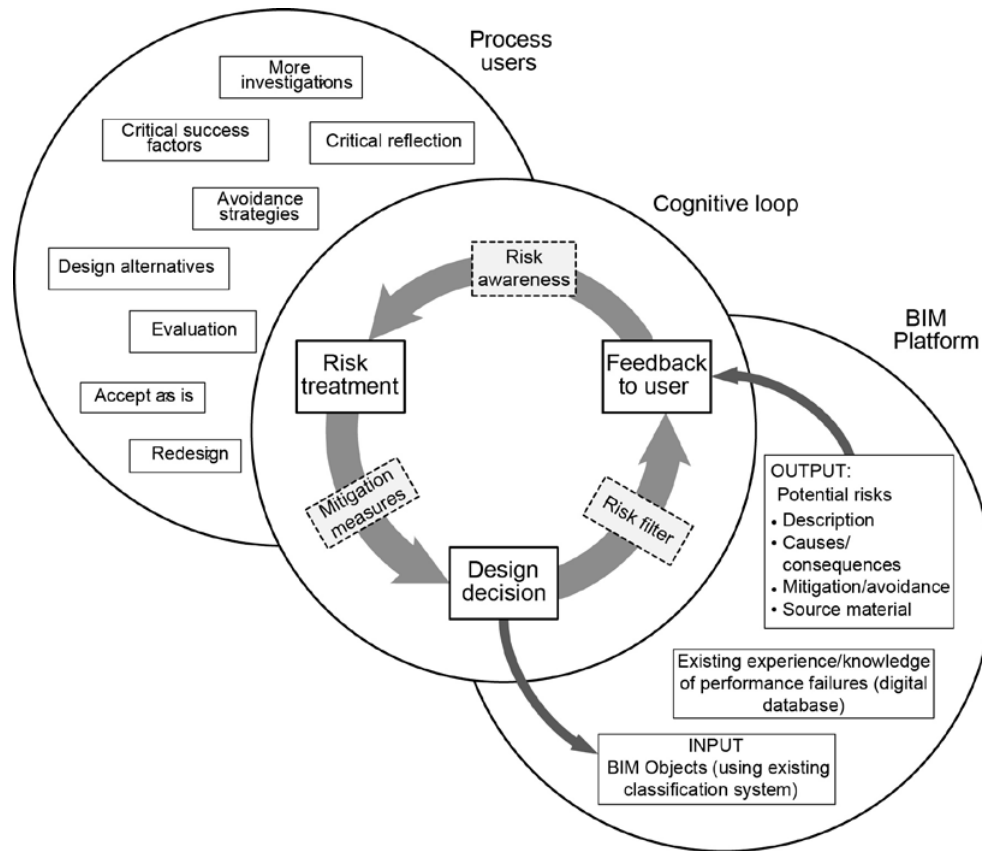

Figure 1. Illustration of Conceptual Framework showing a cognitive loop connecting the BIM platform with process users for integrated risk informed decision making

Commonly, risk relevant information is contained within textbooks or published papers (e.g. Douglas and Ransom, 2013; Molnár et al, 2016) although online or electronic databases may also be available (e.g. Imhof 2004). The relevance and reliability of information to be used as a basis for risk informed decision making has to be secured. In some cases, this type of data may be managed by dedicated agencies with integrated quality control processes. One example from the Nordic region includes BYG-ERFA in Denmark ([www.byg-erfa.dk](http://www.byg-erfa.dk)), which is an independent organization collecting and disseminating quality controlled knowledge concerning building technology failures through traditional information channels such as print and pdf.

Feedback to the user shall be presented in terms of identified risk scenarios providing information concerning the following aspects:

- Description of potential risk (e.g. damage type)
- Potential causes and factors influencing initiation
- Possible consequences of the identified risk
- Possibilities for risk avoidance and mitigation strategies
- Link to source material and reliability of information

The proposed risk analysis steps might also serve as a structure enabling integration of the risk information into a digital knowledge database.

**ILLUSTRATIVE EXAMPLE**

In what follows, an illustrative example is provided which highlights the type of risk information that could be useful for improving the treatment of risks in the design of masonry veneers, see Table 1. The specific risk concerns frost damage of the bricks, that might occur due to the combined effects of high exposure to wind driven rain, frequent freeze-thaw cycles and poor frost resistance of the bricks.

Table 1. Risk relevant information for case: Frost Damage in Masonry Facades

Description	Clay brick veneer with frost damage. Brick exhibiting exfoliation & spalling.
Potential causes	High exposure to wind driven rain in combination with frost-thaw cycles. Poor frost resistance of the clay bricks.
Mitigation/ avoidance	Moulded bricks more frost resistant than extruded bricks; extrusion causes lamination parallel to external surface constituting zones of weakness. Deep-fired bricks more frost resistant than low-fired bricks Recommended to choose brick type considering intended conditions of usage.
Potential consequences	Degradation on large scale. Impaired aesthetics. Demolition of veneer followed by replacement with more suitable bricks or another type of facade.
Additional relevant information	The upper parts of facades are more exposed than lower parts. Current European standards concerning frost resistance of clay brick EN 771-1 requires that veneers exposed to driving rain are built with bricks with high frost resistance (class F2); conforming to the provisions of this standard do however not guaranty complete security against frost damage.
Source material	<i>Damage atlas. Expert system for the evaluation of the deterioration of ancient brick masonry structures.</i> ISBN 3-8167-4702-7. <i>Avoid mistakes in masonry and render</i> (Molnár et al 2016).
Reliability of source data: High	

Typically, the architect will decide the brick type to be used in a brick veneer. Thus, the risk management system can issue a warning to the architect concerning the potential risk for frost damage. The architect is provided an opportunity to investigate whether the selected brick type, under the given exposure conditions, is prone to frost damage and determine whether the original design decision should be altered. A similar assessment can be carried out by the contractor or a building physics expert, if involved in the project.

**CONCLUSIONS & DISCUSSIONS**

The current paper presents a conceptual framework for the treatment of risks related to poor building performance considering modern building applications and specifically integration with digital tools such as BIM. The framework aims to improve the treatment of these types of risks to reduce potential impacts to facility owners and end users in general and the environment in special.

Although the framework from this paper addresses issues of improved risk management in building design on a theoretical level, an implementation plan is underway which has identified important issues concerning practical applications. These issues include the establishment and management of the risk relevant knowledge base, the classification of BIM objects to enable risk filtration, as well as the evaluation of the approach in practical cases. One important aspect of implementing the framework in practice is quality control. This is

significant both in relation to the information which will provide the basis for risk management as well as the process of risk treatment in itself. The former could be achieved by having in place a technical review of risk information by experts within relevant fields of engineering. The latter should provide some mitigation concerning the risk of gross human error in whatever form. Further development of the framework shall assess the effectiveness of the framework in practical application and this process should highlight inherent factors for improved quality control in relation to risk management in the building process.

One anticipated difficulty associated with the implementation of the framework is related to cases of innovative, complex or uncertain (ICU) solutions; as strong focus on risk issues might have an inhibiting effect on introduction of ICU solutions. Thus, some opposition is expected from material suppliers, constructors, etc., if these parties/actors feel that the framework will hinder effectivization of the construction process. The issue of how risks associated with ICU solutions can be introduced with acceptable risk levels and under full transparency for all stakeholders must be considered explicitly. As a direct consequence, possibilities should be created for continuous updating of the risk relevant knowledge base while a risk neutral perspective may be initially taken with regards to ICU solutions until more data and experience are available.

### ABSTRACT

This study aims to analyse the effect of economic indicators on cost-optimal levels of residential building retrofits in Mediterranean region of Turkey. Sensitivity analyses were applied on the cost-optimality calculation results for the residential reference building. The sensitivity analyses address discount rate and potential investment cost decreases. Results reveal that 6% variation in the discount rate corresponds to more than 30 kWh/m<sup>2</sup>y difference in the primary energy consumption of the cost-optimal solutions. Potential investment cost decreases for certain retrofit measures are also effective on identified cost-optimal levels and subsidy opportunities appear as an effective tool to achieve higher energy efficiency in existing buildings and to stimulate building energy retrofits.

### KEYWORDS

Residential building retrofits, Building energy efficiency, Cost-optimal analysis, Economic indicators, Subsidy opportunities.

### INTRODUCTION

Cost-optimality concept, introduced by the European Commission (EC), is one of the key determinants driving policy and targets related to energy efficiency of European building stock (2016). By means of this concept, the Commission expects gradual progress in building energy performance requirements towards nearly-zero energy building (NZEB) target (2013).

The cost-optimality concept mainly assesses energy consumption levels of buildings by associating them with the corresponding costs occurred as a consequence of energy consumption and other expenses linked with components and systems influencing the energy performance of buildings. Having regard to Directive 2010/31/EU (EPBD Recast), EC introduced a methodology framework representing this assessment procedure in 2012 (The European Parliament and the Council of the European Union, 2010; The European Parliament and the Council of the European Union, 2012). This methodology framework requires to couple energy performance and cost calculations to identify the cost-optimal level for Reference Buildings (RBs) representing the building stock. Sensitivity analysis is an important stage of this methodology since it has the potential to reveal outcomes contributing further policy and targets. It displays the alteration in cost-optimal solutions under different economic situations and options.

The specific focus of this study is on the sensitivity analyses directed to the effect of economic indicators and possible investment cost decreases on cost-optimal energy performance level of building retrofits. Towards this aim, retrofit alternatives for a high-rise residential reference building in Mediterranean region of Turkey was analysed. Since the main focus is on the sensitivity analyses, previous stages of cost-optimality calculations are

explained briefly in order to keep entirety. A detailed information about the analysed reference building and initial stages of cost-optimal calculation procedure for this building can be found in research of Ganiç Sağlam et al. (2017).

The procedure presented in this study responds challenges faced in consequence of unsteady economic indicators that extend the range of aspects required to be considered in determination of future energy efficiency targets. It also considers energy retrofit of identical high-rise residential buildings constructed without considering the character of Mediterranean climate they face with. The adapted cost-optimality calculation procedure is presented below together with the sample implementation and policy implication.

## METHOD

This study mainly follows the perspective of cost-optimal methodology framework and implements it for residential reference building retrofit actions.

### The Reference Building

The analysed reference building (RB) represents high-rise apartments constructed between 1985 and 1999 in Turkey. As shown in Figure 1, it has an unconditioned basement and 12 superior floors. Overall heat transfer coefficients of building envelope components are  $1.04 \text{ W/m}^2\text{K}$  and  $1.09 \text{ W/m}^2\text{K}$  for external wall types,  $1.25 \text{ W/m}^2\text{K}$  for basement ceiling and  $0.71 \text{ W/m}^2\text{K}$  for attic slab. The windows consist of double glazing with polyvinyl chloride frame. Overall heat transfer coefficient of the window glazing ( $U_{\text{window}}$ ) is  $2.9 \text{ W/m}^2\text{K}$ , visible transmittance ( $T_{\text{vis}}$ ) is 0.80 and solar heat gain coefficient (SHGC) is 0.75. Internal heat gains including occupancy, activity level and appliances were set to represent recent Turkish family structure surveys and accordingly, it is assumed as each apartment flat accommodates a family consisting parents and two children.

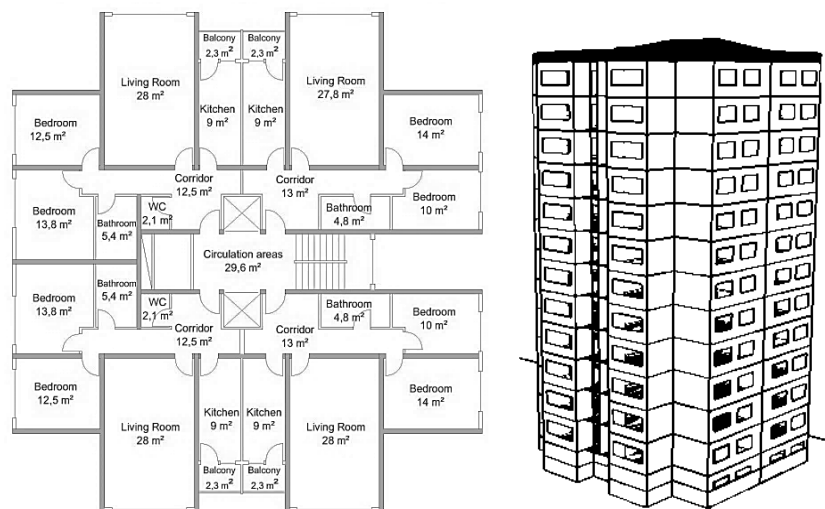

Figure 1. Typical floor plan and the geometry of the reference building.

The RB has a central natural gas boiler and radiators. The nominal thermal efficiency of the boiler is 80%. The cooling energy demand is met by individual split air conditioners using electricity. Seasonal energy efficiency ratio of the split air conditioners are 5.8. Domestic hot water (DHW) system of each flat is individual electric water heater with 80% efficiency. The heating and cooling systems were assumed as being operated continuously with  $20^\circ\text{C}$  and  $26^\circ\text{C}$  set points respectively. Air change rate is assumed as  $0.5 \text{ h}^{-1}$  (Yilmaz et. al, 2015).

Lighting system provides 200 lux illuminance level for kitchen, 300 lux for children bedroom and 100lux for living room, bedroom, corridor and bathroom with compact fluorescent lamps.

### Energy efficiency measures

Various energy efficiency measures referring to building envelope and building energy systems were applied on the RB. The retrofit measures shown in Table 1 were applied to the RB both as individual retrofit measures and as packages of measures combining these individual retrofits. 472 retrofit scenarios were analysed in total.

Table 1. Retrofit measures applied to the RB.

	Definition of the retrofit measure
<b>IN</b>	Thermal insulation applied on external walls (W), floor (F), roof (R) or on the whole envelope (E). Different levels of thermal insulation result in following overall heat transfer coefficients:
	IN1: $U_{\text{wall}} = 0.60 \text{ W/m}^2\text{K}$ , $U_{\text{roof}} = 0.39 \text{ W/m}^2\text{K}$ , $U_{\text{floor}} = 0.66 \text{ W/m}^2\text{K}$
	IN2: $U_{\text{wall}} = 0.48 \text{ W/m}^2\text{K}$ , $U_{\text{roof}} = 0.32 \text{ W/m}^2\text{K}$ , $U_{\text{floor}} = 0.48 \text{ W/m}^2\text{K}$
	IN3: $U_{\text{wall}} = 0.31 \text{ W/m}^2\text{K}$ , $U_{\text{roof}} = 0.18 \text{ W/m}^2\text{K}$ , $U_{\text{floor}} = 0.29 \text{ W/m}^2\text{K}$
	IN4: $U_{\text{wall}} = 0.16 \text{ W/m}^2\text{K}$ , $U_{\text{roof}} = 0.11 \text{ W/m}^2\text{K}$ , $U_{\text{floor}} = 0.17 \text{ W/m}^2\text{K}$
<b>GL</b>	Window glass replacement. Following glass alternatives were considered:
	GL1: $U_{\text{window}} = 1.8 \text{ W/m}^2\text{K}$ , $T_{\text{vis}} = 0.79$ , $\text{SHGC} = 0.56$
	GL2: $U_{\text{window}} = 1.6 \text{ W/m}^2\text{K}$ , $T_{\text{vis}} = 0.79$ , $\text{SHGC} = 0.56$
	GL3: $U_{\text{window}} = 1.6 \text{ W/m}^2\text{K}$ , $T_{\text{vis}} = 0.71$ , $\text{SHGC} = 0.44$
	GL4: $U_{\text{window}} = 1.3 \text{ W/m}^2\text{K}$ , $T_{\text{vis}} = 0.71$ , $\text{SHGC} = 0.44$
	GL5: $U_{\text{window}} = 1.1 \text{ W/m}^2\text{K}$ , $T_{\text{vis}} = 0.71$ , $\text{SHGC} = 0.44$
	GL6: $U_{\text{window}} = 0.9 \text{ W/m}^2\text{K}$ , $T_{\text{vis}} = 0.69$ , $\text{SHGC} = 0.48$
	GL7: $U_{\text{window}} = 0.9 \text{ W/m}^2\text{K}$ , $T_{\text{vis}} = 0.63$ , $\text{SHGC} = 0.39$
<b>SHD</b>	SHD1: Fixed aluminium shading device installation: 60cm width overhang or fins.
	SHD2: Installation of external semi-transparent textile blinds.
<b>BOI</b>	Central boiler replacement with a condensing boiler having 95% thermal efficiency.
<b>RF</b>	Replacement of the existing heating system with radiators to radiant floor system
<b>CHW</b>	Change of the individual domestic hot water systems to the central hot water system.
<b>AC</b>	Upgrade SEER value of split type air conditioners to 8.5 kWh/kWh by replacement.
<b>VRV</b>	Installation of a central variable refrigerant volume (VRV) system in substitution for split air conditioners. Gross rated cooling coefficient of performance (COP) is equal to 3.1.
<b>LED</b>	Installation of LED lamps to provide same illuminance levels in the spaces.
<b>SP</b>	Installation of 48 solar thermal panel at roof with 120m <sup>2</sup> total gross area.
<b>PV</b>	Installation of photovoltaic system at roof with 11 kW rated power

### Energy performance calculations

Energy performance of the RB under the retrofit scenarios were calculated using conduction transfer function algorithm in EnergyPlus building energy simulation tool. The thermal model constituted for the calculations regards each flat as a thermal zone and the common circulation areas as different thermal zones at each floor. Energy consumptions were calculated for space heating and cooling, lighting and DHW. In order to obtain results in primary energy, national primary energy conversion factors, 1 for natural gas and 2.36 for electricity, were used. Calculated primary energy consumption of the RB is 7.7 kWh/m<sup>2</sup>y for space heating, 92kWh/m<sup>2</sup>y for space cooling, 30.6 kWh/m<sup>2</sup>y for domestic hot water, 28.8 kWh/m<sup>2</sup>y for lighting and 1.9 kWh/m<sup>2</sup>y for fans and pumps.

### Global cost calculations

Global cost reflects the present value of the sum of investment, replacement, maintenance and operation costs and residual value of the building. The calculations were made using Net Present Value Method (NPV) according to EN15459 standard (CEN, 2007). The fixed

expenses and the costs related to the building elements that does not affect the energy performance of the building were not included in the cost calculations. Initial investment costs of retrofit measures can be found in research of Ganiç Sağlam et al. (2017) as indicated above.

Since the calculation beginning year is 2015, prices of that year were considered in this study. Market costs were used for investment costs of the system and components. For energy costs, average unit prices of the year were used. Tax included prices are 0.1213 €/kWh for electricity and 0.0368 €/kWh for natural gas in Antalya. For the economic rates, averages of the last five years were considered. In this context, inflation rate ( $R_i$ ) is 8.054% and market interest rate ( $R$ ) is 14.3%. Using these average economic rates and Equation 1, real discount rate ( $R_R$ ) was calculated as 5.78. Calculated global cost of the RB is 114.9 €/m<sup>2</sup>.

$$R_R = \frac{R - R_i}{1 + R_i} \quad (1)$$

### Determination of cost-optimal energy performance level

Cost-optimal level, the energy performance level which results in minimum global cost for the RB, is determined by comparing the primary energy consumption and global cost results obtained for RB retrofit scenarios. Findings are presented in Results section below.

### Sensitivity Analyses

Effects of the alterations in the discount rate and potential investment cost decreases on the cost-optimal results were examined within the sensitivity analyses. Besides the calculated discount rate (5.78%), the sensitivity analyses focused on two different discount rate alternatives: 3% as required by EU regulation and 9%.

Sensitivity analyses on investment cost decrease focused on a discount which is equal to value added tax (VAT) of the retrofit investments. Although the analyse seems as focusing on tax exemption, the same amount of investment cost decrease may also be obtained by autogenous decrease in the cost or as the result of technological development or may be triggered by other subsidy and incentives. In the analyses, effect of investment cost decreases for VRV (installation of central variable refrigerant volume system) and SP (installation of solar thermal system) measures were analysed since these measures were seen as the opportunity for decreasing the global cost of the retrofit scenarios which were slightly higher in comparison to the cost-optimal scenario. These options were also analysed under different discount rates.

## RESULTS

Results obtained by the cost-optimality calculations are presented in Figure 2. The cost-optimal result was achieved by the retrofit package combining GL7, CHW, LED and PV retrofits. This package results with 96.4 kWh/m<sup>2</sup>y primary energy consumption and 97.8 €/m<sup>2</sup> global cost. This package provides 40% energy saving and 26% cost saving with 4.3 years payback period. By 4.6 €/m<sup>2</sup> higher global cost afforded for VRV and SP measures, 52.6 kWh/m<sup>2</sup>y primary energy consumption level can be achieved. Further retrofit measure addition in the package results in rapid increase in global cost with unsatisfactory energy performance improvement.

Results of sensitivity analyses show that cost-optimal results for the RB retrofits are sensitive to the changes in discount rate as displayed with Figure 3 below. Decrease in the discount rate enables moving towards 61.8 kWh/m<sup>2</sup>y cost-optimally by adding VRV retrofit within the retrofit package. Another opportunity to achieve more ambitious cost-optimal energy

performance level is to ensure investment cost decrease around VAT for VRV and SP retrofits. With this cost decrease, 52.6 kWh/m<sup>2</sup>y primary energy consumption level is achievable in case the discount rate is equal to 3%. In order to achieve this level, SP retrofit should also be included in the retrofit package.

Figure 2. Results of cost-optimality analyses performed for the RB retrofits.

Figure 3. Results of sensitivity analyses.

When the discount rate is equal to reference assumption (5.78%), cost-optimal level remains at 61.8 kWh/m<sup>2</sup>y even an investment cost decrease is provided. However, only with 1 €/m<sup>2</sup> higher global cost, SP retrofit can be included in the retrofit package in order to achieve 52.6 kWh/m<sup>2</sup>y primary energy consumption level cost-optimally in case of an investment cost decrease in SP and VRV. Moreover, the payback period of this retrofit package (including GL7, VRV, CHW, LED, PV retrofits) decreases from 8.3 years to 7.5 years.

## DISCUSSION AND CONCLUSION

Results reveal that 6% variation in the discount rate corresponds to more than 30 kWh/m<sup>2</sup>y difference in the cost-optimally achieved primary energy consumption level. Therefore, strong forecasts on the economic indicators are required to point reliable targets for cost-optimal and NZEB levels.

Specific to Mediterranean climate, VRV and SP measures have a critical role to move towards higher energy performance level. In order to move towards 52.6 kWh/m<sup>2</sup>y primary energy consumption level cost-optimally, cost decreases for solar thermal system and VRV system should be provided for high-rise apartments. If an investment cost decrease is not expected naturally in time or as the result of technological development, it may be triggered by some subsidy and incentives put forward by policy-makers. Climate responsive tax exemption appears as an effective tool to stimulate building retrofits in Mediterranean building market.

## Evaluation of Efficiency and Renewable Energy Measures Considering the Future Energy Mix

Fabian Ochs<sup>1,\*</sup>, Georgios Dermentzis<sup>1</sup>

<sup>1</sup>University of Innsbruck, Innsbruck

### ABSTRACT

Sustainable and responsible use of resources is required in order to mitigate climate change. Micro-economic goals usually consider the capitalized investment costs and/or the purchased energy but disregard environmental impacts. However, on macro-economic scale, the aim must be the reduction of the (non-renewable) primary energy (PE) use and of CO<sub>2</sub>-emissions. There is need for an appropriate evaluation method for comparing and ranking different passive and active building technologies, e.g. according to their impact on the PE consumption. National conversion factors for PE/CO<sub>2</sub> differ significantly between different countries and are subject to change. Seasonal variations are not considered at all.

The electricity mix is and will be influenced to a higher extend in future by the available renewable energy sources, which are hydropower, wind energy and PV with strong differences in daily and seasonal availability. Without presence of seasonal storage, fossil fuels will predominantly cover the winter load. The electricity mix is also influenced by the load: buildings, have a high demand in winter, and lower in summer. The share of electricity for heating is still relatively low, but will increase with the more widely use of heat pumps and electric heating. Hence, savings in winter will have higher value.

This paper discusses - using a realized NZE multi-family building as an example - a PE evaluation method, that allows to include future development of the load (i.e. building stock) and electricity mix (share of REs) with seasonal variations and shows the impact on the ranking of different passive and active technologies.

### KEYWORDS

Renewable Energy and Efficiency in Buildings, Primary Energetic Evaluation, Monthly Primary Energy Factors

### INTRODUCTION

Sustainable and responsible use of resources is required in order to mitigate climate change. Micro-economic goals usually consider the capitalized investment costs and/or the purchased energy but the disregard environmental impact. However, on macro-economic scale, the (non-RE) primary energy (PE) use and CO<sub>2</sub>-emissions must be reduced. The potential of the energetic use of biomass for buildings is limited. A significant further increased use of biomass for buildings will not be possible as high density energy will be also required for processes and mobility in a future sustainable energy system (see also Feist 2014).

The electricity mix is influenced by both, the (seasonal and daily) availability of renewable energy (RE) sources such as hydropower, wind and PV and by the load (i.e. the building stock).

Available energy sources: hydro power availability is relative homogeneous (slightly lower in winter), wind energy is volatile and slightly higher in winter and PV features very strong differences in daily and seasonal availability.

Load: buildings have a high demand in winter and lower in summer. The share of electricity for heating is still relatively low (e.g. in the range of below 5 % in Germany (D) acc. to BEDW 2016 and also in Austria (At) acc. to Statistik Austria 2016). It will increase with the

more widely use of heat pumps and electric heating in nZEBs/NZEBs (see below for a definition). This will result in a stronger seasonal variation of the electricity load. Without presence of seasonal storage, the winter load will be covered predominantly by fossil resources. Hence, savings in winter have higher value.

### PREDICTING MONTHLY PRIMARY ENERGY CONVERSION FACTORS

There is a need for an appropriate evaluation method for comparing and ranking different passive and active technologies on micro- and macro- economic scale. National conversion factors for PE/CO<sub>2</sub> differ significantly between different countries and also between the EU member states and are subject to change. For example, the PE factor for electricity is 1.8 in Germany (ENeV) since 2016 (2.4 before), in Austria 1.91 since 2015 (2.62 before) (OIB-6, 2015, OIB-6, 2011). Seasonal variations are not considered at all.

For the electricity mix, the share of renewables within the time frame of consideration (e.g. 20 years) should be included and not as usually done the current (or past) status. A significantly increased share of RE electricity can be expected in the near future in particular in summer (PV), while in winter only a moderate increase is likely, unless there is a significant further extension of wind power or seasonal storage capacities are strongly build up.

If a large number of buildings use heat pumps (HP) for space heating and DHW preparation and produce electricity with on-site PV, both, the purchased electric energy and the share of renewables in the electricity mix depend on each other. Electricity that is used on site is not available in the grid and an increased share of fossil fuels in the energy mix have to be considered. PV electricity sold to the grid will replace fossil fuels more likely in winter, spring and autumn than in summer. Thus, a model for the PE/CO<sub>2</sub> conversion factor of the electricity mix needs to consider RE availability and the load curve. A possible approach of balancing PE demand (and CO<sub>2</sub> emissions) of a building with onsite RE generation is shown schematically in Fig. 1. Solar thermal (ST) energy is used to reduce the energy demand (heating, DHW + storage and distribution losses) that has to be covered by e.g. a heat pump (HP). Onsite PV can be used directly for appliances and auxiliary energies or to drive the HP. For higher own consumption, a (battery) storage is required, which is subject to losses.

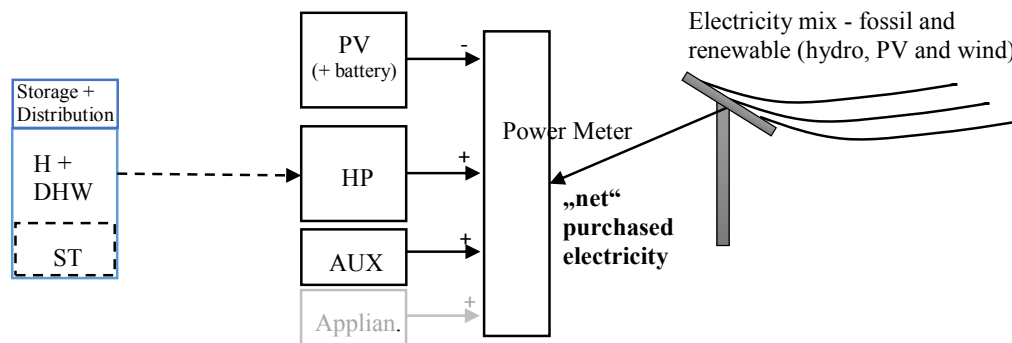

Figure 1 Possible approach for the calculation of the monthly net energy balance with heating (H) and domestic hot water (DHW) demand covered partly by ST; the remaining demand is covered by a heat pump (HP), which is partly powered by onsite PV, the remaining electricity demand for the HP, auxiliary energies (and appliances) is covered by the grid with volatile shares of renewable electricity

A monthly evaluation based on monthly primary energy factors is proposed, which can be used to calculate a more representative environmental impact of different efficiency and RE measures. The specific primary energy  $e_{PE}$  is calculated for each month (i)

$$e_{PE} = \sum f_{PE,i} \cdot w_{el,i} \quad (\text{eq. 1})$$

where  $f_{PE,i}$  is the primary energy conversion factor for each month (i) considering the energy mix in each month and  $w_{el,i}$  is the specific electric energy purchased in each month, see Fig. 2.

In two scenarios (A and B) with different shares of hydro, wind, PV and fossil energy, the PE conversion factor were calculated on monthly basis using e.g. the PE conversion factors shown in Fig. 2 and Table 1.

$$f_{PE} = f_{PE,hyd} \cdot W_{el,hyd} / W_{el} + f_{PE,wind} \cdot W_{el,wind} / W_{el} + f_{PE,PV} \cdot W_{el,PV} / W_{el} + f_{PE,fos} \cdot W_{el,fos} / W_{el} \quad (\text{eq. 2})$$

### CASE STUDY: NZEB Innsbruck Vögelebichl

The Passive House (PH) project Vögelebichl in Innsbruck, two multi-family houses (MFH) with together 26 flats of the social housing company NHT (see Fig. 3) was designed such that the optimum share of PV and Solar Thermal (ST) should enable a NZE balance for heating, DHW preparation and aux. energies. One roof of the MFH is covered by PV (99.8 m<sup>2</sup>), the other is partly used for PV (52.5 m<sup>2</sup>) and partly for ST (73.6 m<sup>2</sup>). Fig. 4 shows a simplified hydraulic scheme including the GW heat pump (two stage), solar thermal collector (SC) field as well as the low temperature heat distribution and the separate decentral fresh water preparation (DHW plate HX). The double stage heat pump is equipped with hot gas (HG) de-superheating. Depending on the operation mode (heating or DHW preparation), the flow of the heat pump enters the buffer store (BS) at the top or at 1/3 of the height from the top. The combined return of the heating and DHW loop enters the large 6 m<sup>3</sup> buffer store depending on the temperature level either at the bottom or at about 1/3 of the height of the store in order to enhance stratification. The electric backup heater (BH) is currently not used.

#### nZEB vs. NZEB

nZEBs and NZEBs are comparable in the sense that both aim at minimizing CO<sub>2</sub>-emissions and non-RE primary energy, nevertheless, their definitions differ quite much in detail and thus, their performance might eventually be quite different.

**nZEB:** nearly zero Energy Building according to EPBD, 2010. Each member state has a national definition with significant differences with respect to the energy use considered (heating, cooling, DHW, auxiliary, appliances), the maximum limits, the conversion factors etc. (see BPIE, 2016).

**NZEB:** Net Zero Energy Building. Generally an NZEB is a "grid-connected building which produces the same amount of energy on-site by renewable energy sources as it consumes on annual basis." (IEA SHC T40/HPT A40). There is a fuzziness in this definition regarding the interpretation of the system boundary, the energy flows, the weighting/conversion factors etc. Usually, Net Zero includes heating (and cooling), DHW supply and aux. energies (HRV, pumps, control, etc.) but excludes appliances. Even though, appliances have a large contribution to the overall electricity consumption (1500 kWh/a to 4500 kWh/a depending on the number of persons per household for a typical central European household, Statistik Austria 2016, BEDW 2013). According to this definition, a NZEB can consume relative high amount of (electric) energy in winter, when correspondingly a large PV area produces this amount as excess electricity in summer. This means, that according to the NZEB concept, the electric grid is considered as a loss-free seasonal storage, which is obviously not the case. In order to account for this weakness in this concept, additional performance indicators such as the load match factor or fraction of PV own consumption were suggested (see IEA SHC T40/HPT A40).

Remark: „net-zero“ as a goal can be a misleading concept, since optimization for net-zero may lead to one storey buildings, because reaching the net zero balance is more difficult compared to a multi-storey building (with smaller roof and façade area related to treated area). However, MFHs, which are more compact, are favorable from the overall energetic and macro-economic point of view (compare also Feist et al. 2014).

### SIMULATION AND MONITORING RESULTS

In Ochs et al. 2017, detailed monitoring results of the buildings (heating and DHW demand) and of the system (distribution losses, performance factors, solar thermal and PV yield) are reported and improvements after the first year of operation were discussed and design recommendations based on monitoring data and simulation results were given. It has to be noticed that the first year of operation is not representative (construction moisture, partial occupation, adjustment of control/set points, etc.) and should not be used for the analysis. After the initial phase and after implementing some first optimization measures (adapted set points, etc.), an operation of the buildings and the HVAC system with net zero energy balance can be expected. Fig. 5 (a) gives the simulated monthly energy balance with the introduction of the improvements. Fig. 5 (b) gives the resulting electric energy balance that is used for further analysis of the data. Net energy balance for heating, DHW and auxiliary energy is achieved with PV on the roof. PV on the façade is required, if appliances are considered, too.

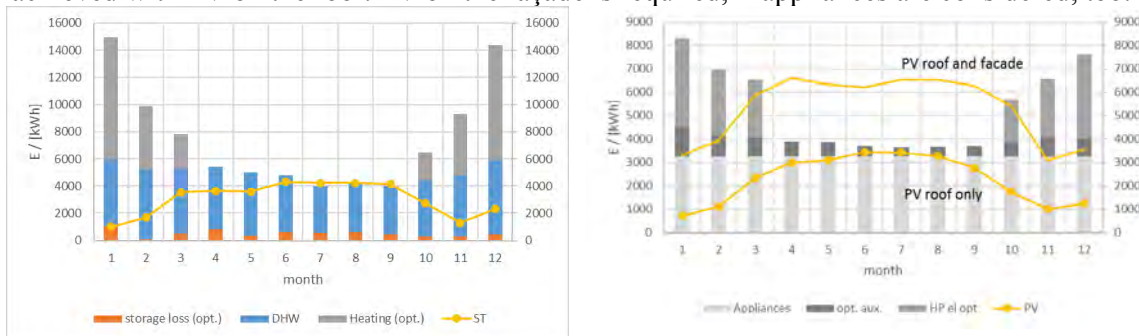

Figure 5 (a) simulated monthly thermal energy balance and (b) simulated monthly electric energy balance with PV on roof (as realized) and PV on roof and south façade (not realized)

### RESULTS and DISCUSSIONS

The specific PE ( $e_{PE}$ ) for heating and DHW production including the HP (after introduction of improvements, i.e. NZEB is achieved), appliances and with or without 300 m<sup>2</sup> of PV in south façade is calculated for the two scenarios (Fig. 2). It can be seen in Fig. 6 that in scenario B with higher share of renewables in the grid (all together 70 %), the additional PV in the façade yields less PE savings than in the scenario A (all renewables 30 %).

Figure 6 Specific PE ( $e_{PE}$ ) for heating and DHW supply including the improved HP, appliances and with or without 300 m<sup>2</sup> of PV in south façades for scenario A (10 % hydro, 10 % wind and 10 % PV) and scenario B (10 % hydro, 30 % wind and 30 % PV); monthly balance.

In scenario A, the additional PV in the façade reduces the annual specific PE demand from 32.7 kWh<sub>PE</sub>/(m<sup>2</sup> a) to 15.2 kWh<sub>PE</sub>/(m<sup>2</sup> a), or by 53.5 % while in scenario B, it reduces from 21.9 kWh<sub>PE</sub>/(m<sup>2</sup> a) to 11.2 kWh<sub>PE</sub>/(m<sup>2</sup> a) or by 49.2 %.

State of the art is to use a constant PE conversion factor, e.g. 1.8 in Germany and 1.9 in At. PE savings with a constant PE conversion factor are 42 % without and 74 % with PV in the façade compared to the case without any onsite PV). In scenario A, savings reduce to 37 % without and 71 % with PV in the façade and to 23 % (without) and 61 % (with) in scenario B. With constant (i.e. average) PE conversion factor, savings are accounted for with the same weighting independent of the season. Thus, savings in summer are overrated. Measures such as (even) better insulation level, reduced storage and distribution losses or (even) better HPs would further reduce the winter load and are favourable compared to more PV.

## CONCLUSIONS

Two MFHs in PH Standard with ST and HP system and onsite PV to achieve maximum PE savings were realized in Innsbruck and monitored for a period of more than two years. Net zero energy balance (for heating and DHW and auxiliary energies) could not be achieved during the first year of monitoring (2016), but predictions based on results after introduction of improvements show that Net Zero can be achieved. PH standard is key for achieving NZEB level for heating, DHW and aux. energies. If electricity consumption of appliances is included in the energy balance, additional PV on the south façade would be required.

NZEB do not significantly reduce winter grid load. The mismatch between (electricity) demand and PV yield has to be considered, e.g. by means of different electricity prices for purchase and sell or by seasonal/monthly PE conversion factors. A method is discussed allowing to compare different nZEB/NZEB concepts considering the time (season) of the electricity purchase from the grid in order to be able to optimize concepts towards reduced non-RE PE demand or CO<sub>2</sub>-emissions in winter when renewable electricity is rare. The future development of the electricity mix and the load (building stock) can be considered and possible scenarios can be evaluated.

## ACKNOWLEDGEMENT

This project is financially supported by NHT, Innsbruck, Austria. PHPP calculations and PH certification was done by PHI Innsbruck. The financial supports from the Austrian Ministry for Transport, Innovation and Technology and the Austrian Research Promotion Agency (FFG) through the IEA Research Cooperation to this work are gratefully acknowledged.

### **ABSTRACT**

The high initial investment required in existing building refurbishment can limit the initiative of the building owners and prevent the full exploitation of a huge energy saving potential. Public incentives can play an essential role in fostering the energy retrofitting of the existing buildings and in increasing the renovation rate of the building stock, effectively reducing the energy final uses, the dependence on the fossil fuels, and helping meet the national efficiency targets. Public subsidization are intended to enhance the economic performance in terms of global cost of the energy efficiency measures for the owner, in order to induce positive actions and move optimality from low to high energy efficient solution. In contrast, the overall economic efficiency is obtained with combinations of interventions, able to achieve a certain energy saving target for the entire building stock at the minimum initial Investment Costs (IC).

This paper tries to identify the overall economic efficiency in reducing the energy consumption of the existing stock and compares it with the efficiency of solutions optimal from the owner's perspective, in order to support more efficient subsidization strategies. Different mixes of three reference building archetypes, representative of the existing buildings, are considered to define different possible stocks, in order to analyse their impact on the efficiency of energy renovation solutions. Four groups of energy efficiency measures (EEMs) dealing with respectively the opaque envelope insulation, the windows substitution, the heat generating system replacement, and the mechanical ventilation introduction are defined and their combinations considered.

Government subsidies optimization

Stock Retrofit

Multi-objective optimization

### **INTRODUCTION**

Buildings, including households and services, are responsible for more than 30 % of world Total Final Consumption (TFC) (IEA, 2017), and an even larger share of 41 % (Eurostat, 2016) in the European Union (EU). Conversely, a largest share of the existing buildings is considered to be energy inefficient. In EU, 75 % of the buildings have been built before 1990 (i.e. before any EU building regulation) and over 97 % are in class B or worse (BPIE, 2017), so not ready to meet the challenging 2050 decarbonisation target, i.e. a reduction of greenhouse gas by 90 % with respect to 1990 (EU Commission, 2011). This can be obtained only through energy efficiency measures, aimed at a direct reduction in the use of fossil fuels, and at a deeper penetration of renewable energy sources. For these reasons, EU aims at increasing the current rate of renovation, close to 1% (BPIE, 2011), through new policies and

market tools. Government financial incentives play a crucial role to promote the energy retrofitting of existing buildings since they should remove the barriers due to the high up-front initial Investment Costs IC (Amstalden et al. 2007; Gamtessa 2013; Higgins et al. 2014). Incentives able to change the consumer's behaviour and investment convenience, such as financial (penalizing or rewarding) or non financial (as for instance on-site advice by experts) are required, together with stricter performance targets for new and renovated buildings. In Europe, a wide variety of financial incentives is applied to support the enhancement of buildings energy performance such as grants, subsidies, preferential loans, tax reduction and tax credit (BPIE, 2012). Besides their effectiveness in driving the decision maker toward the best solution, which can be affected by different factors that make it uncertain, their efficiency should be accounted for, in order to maximize their impact and limit their societal cost. For instance, Di Pilla et al (2016) analysed the incentives in the Italian context, investigating the optimal regional distribution of subsidies through linear programming.

In this work, the economic efficiency of possible incentives policies is analysed through a multi-objective optimization approach. For a given percentage energy saving target, the public authority perspective, aiming at minimizing the overall initial IC is compared with the owner's one, which aims at minimizing the global cost of each single building over its lifespan. Several stock compositions are defined as a mix of three archetypical residential building modules. Four groups of energy efficiency measures (EEMs) dealing with respectively the opaque envelope insulation, the windows substitution, the heat generating system replacement, and the mechanical ventilation introduction are defined and their combinations considered. No cooling system is considered, since the existing stock is assumed not to be conditioned, as is usually the case in Italy (STRATEGO, 2016), and the EEMs with an appropriate operation strategy of natural ventilation and shading systems have been recognized to be effective in limiting overheating occurrences below the initial conditions. The initial IC in the two optimization approaches is then compared as representative of the social cost for achieving the same savings target, and of the possible financial incentive required, which is generally defined as a percentage of the IC.

## METHODS

### Building Archetypes

The analysis focuses on the economic efficiency of the renovation of a residential building stock as a function of its characteristics. For this reason, different building stocks have been defined starting from three archetypical buildings described in Penna et al (2015). These represent a semi-detached house with a compactness ratio of 0.97, a penthouse with a compactness ratio of 0.63 and an intermediate flat in an apartment building, with a compactness ratio of 0.30. Concerning the building envelope and heating system components they represent a typical configuration of Italian households built prior to the first energy legislation. Hence, a non-insulated envelope, with single pane glazing system and a hydronic system with a standard gas boiler coupled with radiators and on-off control system define the initial configuration for all the archetypes. Before renovation, the semi-detached house has an energy demand for heating of  $269.17 \text{ kWh m}^{-2} \text{ yr}^{-1}$ , the penthouse needs about  $190.30 \text{ kWh m}^{-2} \text{ yr}^{-1}$  and the intermediate flat about  $113.81 \text{ kWh m}^{-2} \text{ yr}^{-1}$ .

Three different energy saving targets are considered for the stock, that are the reduction of 50%, 60% and 70% compared to the original primary energy demand.

Six off the shelf energy efficiency measures (EEMs) categories are considered:

- external insulation of the external opaque envelope with an expanded polystyrene layer. The insulation thickness is optimized independently for vertical walls, roof and floor in the range 0 to 20 cm and in steps of 1 cm;

- windows replacement with double or triple pane with either high or low solar heat gain coefficient;
- boiler replacement with either a modulating or condensing boiler with an outside temperature reset control;
- mechanical ventilation system installation with a heat recovery system.

The IC is derived from regional price list (Penna et al. 2015) for all the EEMs, and contributes to the global cost expressed by the Net Present Value (NPV), together with the annual energy cost, the maintenance cost, the replacement cost and the residual value for the pieces of equipment with longer lifespan. The simulations of the energy performance of the building stock are carried out in Trnsys considering the weather conditions of Milan (Latitude 45°27'51'' N, Longitude 9°11'22'' E), a city with a 4A climate according to Ashrae 90.1 classification (Ashrae, 2007). Sixty-six building stock configurations were considered by varying the share of each archetype in the range from 0 to 100% in steps of 10 %.

### **Optimization Algorithm**

A large number of optimization algorithms have been developed for solving multi-objective optimization problems however, according to Wetter and Wright (2004) the gradient-based optimization and the linear programming methods are not suitable to Building Performance Optimization (BPO). Evolutionary algorithms are the most popular optimization methods, and non-dominated sorting genetic algorithm (NSGA-II) is one of the most implemented in BPO (Nguyen et al., 2014). The NSGA-II, firstly developed by Deb et al, (2002), uses elitism by maintaining the current and the previous population. Then, after the population mating, the populations are sorted according to the non-domination concept and the best ranking solutions are selected as the next parent population.

In this research, we implemented the NSGA-II with some customizations such as sampling, external data-set and convergence criterion. Firstly, the code included a Sobol sequence sampling to overcome the clustering that can occur with other sampling techniques. Besides, an external data-set of the simulation runs is saved in order to avoid repeating expensive simulation runs during the BPO. Finally, the hypervolume measure (Zitzler and Thiele, 1999) was used as a stopping criterion.

### **Optimization with the authority's or with the owner's perspective**

In the Italian scenario, incentives are provided for energy refurbishment investment in the form of tax credit calculated as a percentage of the IC. This is independent of the energy saving actually achieved, provided the law minimum requisites are fulfilled, so that the economic efficiency of the intervention and most importantly of the action on the entire building stock is left to the owners' decision. However, the optimum of the building stock does not necessarily coincide with the individual optima of all the buildings. First, the building owner convenience is typically expressed by the global cost in the lifespan, while the social cost, in presence of incentives, is better represented by the IC. Second, when optimizing the interventions over the entire stock, the marginal return of an investment on a building can be very different from that on another, making it possible to prioritize the interventions on the different buildings according to criteria of overall efficiency.

For the above reasons, a first optimization considers the minimization of primary energy for heating ( $EP_H$ ) and, simultaneously, the initial IC for the entire building stock. These two indices are calculated by summing the energy performance and the IC of all the buildings renovation in the stock, and then dividing them by the total floor area of the building stock, in order to normalize the indicators independently of the stock size.

Each owner aims at achieving a given energy saving target in such a way to maximize the economic benefit during the building lifespan. Either energy efficiency requisites or public

incentives recognized to interventions able to overcome a minimum law target, will therefore foster the individual optimization of the EEMs for each building. This perspective does not necessarily lead to the most effective solutions from the point of view of the public authority. A second optimization run has then been conducted, with the optimal refurbishment of each building is evaluated by optimizing the energy and cost savings following the cost-optimal approach. The first objective is the reduction of the primary energy for heating ( $EP_H$ ) in order to reach the requested target. Moreover, the minimization of the global cost of the building, the total cost of the building over a 30-year lifespan, quantified through the NPV, is pursued. The energy savings and the total IC for the building stock is subsequently quantified as the sum of the values obtained for the optimal solutions of each individual building, and compared with those of the first optimization in order to understand the extent to which the individual point of view produces suboptimal results for the community.

## RESULTS AND DISCUSSION

Figure 1 (left) show on three-coordinate diagrams the absolute difference between the IC needed for the optimal solution of the two optimizations,  $\Delta IC$ , considering three specified targets for energy saving (e.g., 50%, 60% and 70%). Each side of the triangular plots reports the percentage of buildings with the same compactness ratio,  $S/V$  (e.g. 0.30, 0.63, 0.97), so the position of each point represents a different percentage composition of the building stock. The colour of the points follows from blue (no difference) to red (highest difference) highlights the difference in the IC ( $\Delta IC$ ) between the owner's and authority point of views. It should be noticed that the larger the difference, the more the retrofit measures in the optimal solution and the performance itself of each single type of buildings will differ in the two perspectives. For instance, for the target 50% the high values of  $\Delta IC$  (up to 1322 EUR/ 100  $m^2$ ) imply that it is possible to reach the target energy saving applying retrofit actions very different from the ones that optimize the NPV for the single building. Thus the target is reached by saving more energy in some types of buildings and less in others. Comparing the results of the three targets it is evident that the suggested approach is more convenient for the target of 50% and 70%, than for 60%. In the first case, it is possible to obtain a saving of more than 670 EUR/100  $m^2$  in 75 % of the reference stocks, and more than 922 EUR in 50 %. The largest benefits are when the building stock tends to have a smaller share of buildings with  $S/V=0.3$  and medium to high with  $S/V=0.63$ . In the last case, the NPV optimization or the IC optimization give similar results and savings are higher than 100 EUR/100  $m^2$  in 75 % of the reference stocks, and more than 159 EUR/100  $m^2$  in 50 %, with maximum savings lower than 400 EUR. The best performance of the whole stock optimization (authority point of view) is for 10 % of  $S/V=0.3$  buildings, 20 % of 0.63 and 70 % of 0.97. The best performance when target is 70 %, is for 10 % of  $S/V=0.3$  buildings, 30 % of 0.63 and 60 % of 0.97.

As regards percentage savings, (Figure 1, right), it can be seen that the impact of a whole stock optimization is quite high when the smallest target is considered. Savings are up to 22 %, with 75 % of the building stocks saving more than 14.8 %, and 50 % more than 18.7 %. Very low in percentage terms is the advantage for 60 and 70 %  $EP_H$  saving targets, reaching at most 4 %. With 50 % savings target it is also clear a trend, showing the maximum percentage saving at a similar value for many stock configurations up to a maximum share of  $S/V=0.3$  buildings of 40 %. Larger shares of compact buildings ( $S/V=0.3$ ) reduces the maximum advantage of the authority perspective approach. Trends get less clear when larger saving targets are considered.

## CONCLUSIONS

In this work the overall economic efficiency, in terms of IC, in reducing the energy consumption of the existing stock (authority point of view) has been assessed and

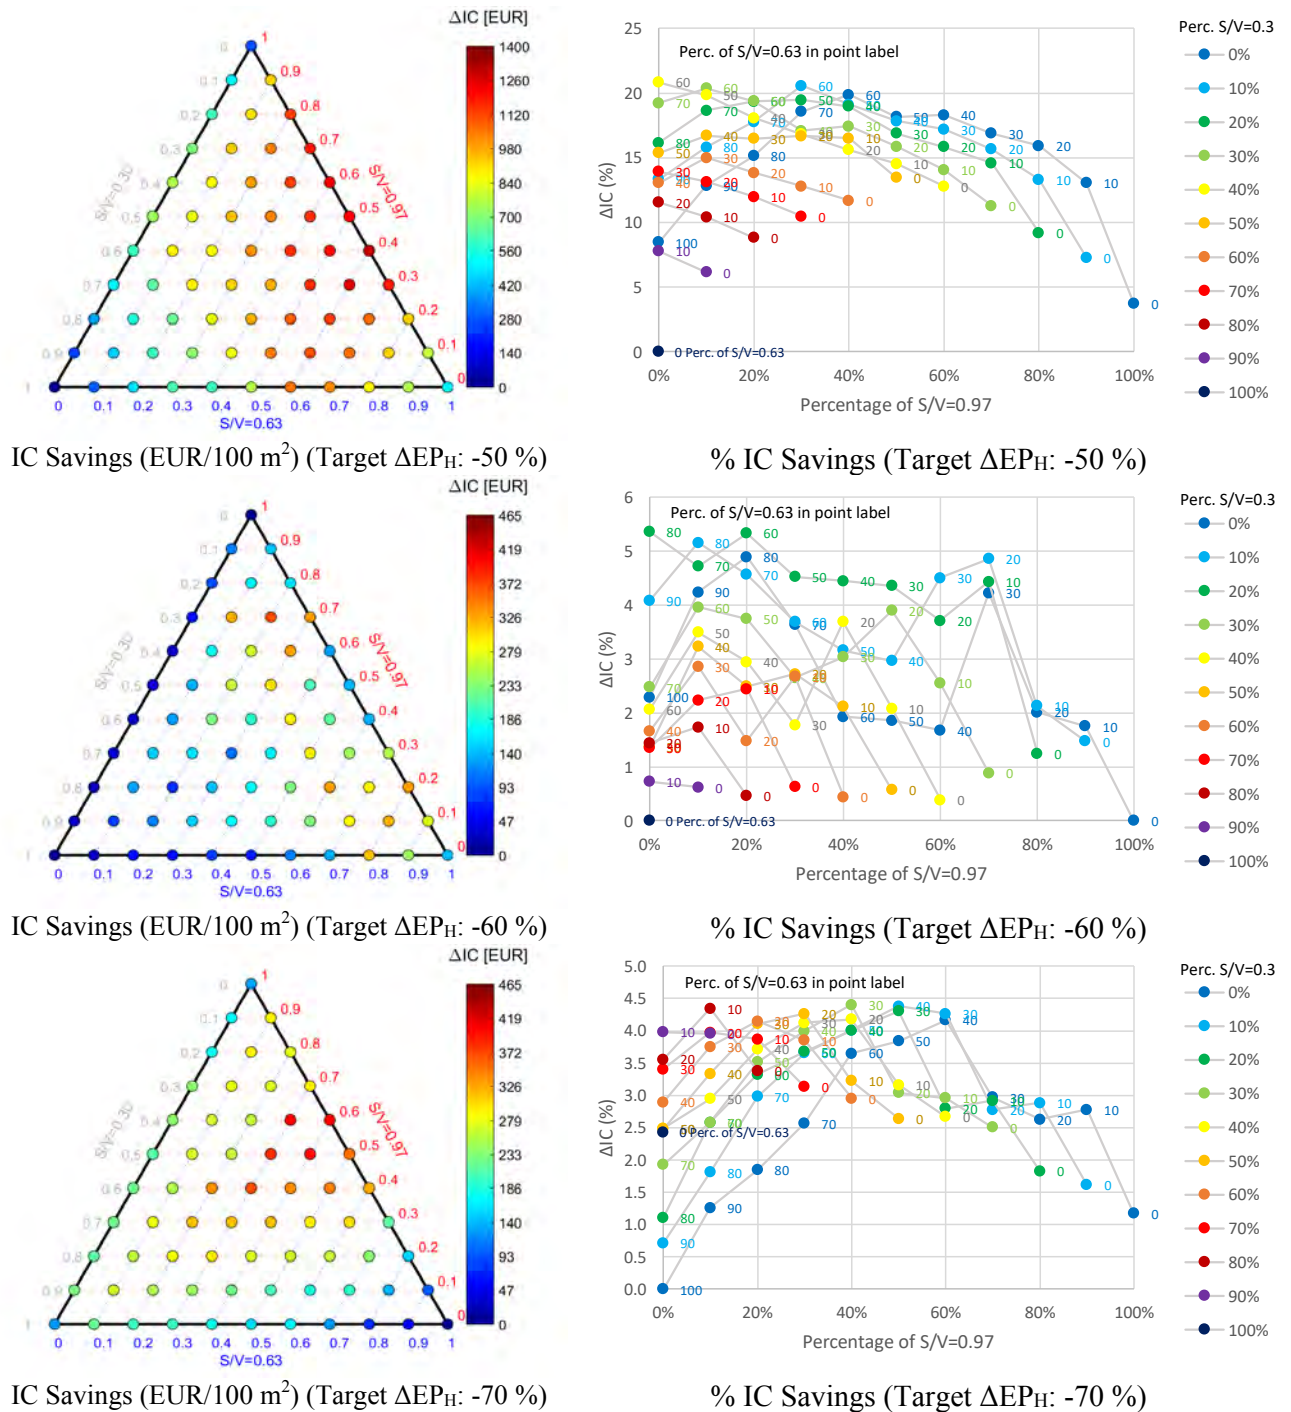

Figure 1: Absolute and percentage IC savings of the authority vs owner optimization perspective with the three EP<sub>H</sub> savings (50, 60, and 70 %).

compared with that of solutions optimal from the owner's perspective. Different mixes of three reference building archetypes have been considered to define different possible stocks, in order to analyse their impact on the efficiency of energy renovation solutions. Four groups of energy efficiency measures (EEMs) have been defined and their combinations considered. Three target energy savings have been considered, namely 50, 60 and 70 % with respect to the initial building stock performance.

The main findings show that in some cases the optimal solutions at a stock level do not coincide with those at an individual level. Depending on the target, the stock optimization (authority point of view) is always preferable to individual optimization (owner's point of view). Very large savings on the IC are obtained when optimizing the intervention on the entire stock for the lower target performance (50 %).

### **ABSTRACT**

In order to achieve the Paris COP21 agreement, retrofitting activities in the building stock have to be strongly enhanced, therefore individual building renovation roadmaps (IBRR) can be an instrument for guiding building owners through this process. The research question of this paper is: how ambitious should individual building renovation roadmaps be to achieve consistency with future scenarios of the building stock's energy performance? The methodology applied follows these steps: first, the bottom-up discrete choice building stock model Invert/EE-Lab ([www.invert.at](http://www.invert.at)) is applied to develop a scenario of building stock related energy demand, CO<sub>2</sub>-emissions and costs until the year 2050. The scenario is based on the assumption of current or only slightly strengthened policies and results in 77% CO<sub>2</sub>-emission reductions of the building stock from 2012 to 2050. In the second step, we selected representative building types from the Invert/EE-Lab model scenarios. For these building types, we developed IBRR (individual building renovation roadmaps) based on previous experience and literature research. Further, we calculated the building's new energy performance after the renovation measures defined in the IBRR. Finally, we analysed to which extent the energy saving through IBRR measures are in line with the simulated scenario. We carried out this study for the case of Germany. Moreover, we restrict the analysis to single-family houses. The results showed that - based on the approach of the IBRR - it would be required that annually about 4-6% of the buildings apply at least one refurbishment measure (change windows or insulate the roof, change heating system, etc.) in order to achieve a scenario, such as the one simulated by the model Invert/EE-Lab.

### **KEYWORDS**

Deep renovation, Individual Renovation Roadmap, Bottom-up modelling, Energy Performance for Buildings Directive (EPBD), Energy performance targets.

### **INTRODUCTION**

The building sector has been identified as one of the key sectors for achieving the energy and climate policy targets of the EU, as buildings are responsible for 40% of energy consumption and 36% of CO<sub>2</sub> emissions in the EU. In light of single family houses, they represent across the EU between 59,4% (in Slovakia) to 89% (in Italy) of the total building floor area (EU Buildings Datamapper, 2013). In this context, the recast of the Energy Performance of Buildings Directive 2010/31/EU (revised in 26.04.2018)(European Parliament, 2018) is an important legislative instrument at EU level, which supports deep renovation of existing buildings. Here, it is necessary to highlight the necessity of deep renovation (retrofitting), instead of esthetical or maintenance renovation. In a study on renovation rates of energy performance activities in the residential building stock in the Netherlands (Filippidou et al., 2017), the authors pointed out the need of packages for deep renovation measures, rather than single refurbishment measures. A study on the success for energy efficient renovation of dwellings in Norway emphasizes the importance of private homeowners to have access to

relevant and reliable advices, to make energy efficient choices in the process of renovation, as a role player in the process of increasing building renovation rates (Risholt and Berker, 2013). Fabbri et al., 2018 identified the lack of engagement and knowledge of the homeowners with energy efficiency issues as main barrier to increase energy performance of single-family houses, stressing the relevance of developing individual building renovation roadmaps (IBRR), which foresee the renovation measures over a period, according to building owner's desire. In Europe, there are already some demonstration projects, which focus on the key concept of IBRR, as an initiative to increase awareness about building's energy performance, and to encourage homeowners to deep renovate their houses. One of these are: in Germany, the concept of renovation roadmap (*Sanierungsfahrplan – SFP*), and in France, the low energy roadmap *Passeport Efficacité Énergétique (P2E)*. In this context, the iBRoad EU-funded project works on eliminating the barriers between house owner and building energy performance, by developing an Individual Building Renovation Roadmap (iBRoad) tool for single-family houses. This study aims to understand the role of these IBRR in the German case as an instrument to achieve national decarbonisation targets until 2050 for the energy performance of single-family houses.

## METHODS

To analyse on how ambitious IBRR (individual building renovation roadmaps) should be, in order to achieve national decarbonisation targets in the building stock, first, the dynamic bottom-up discrete choice building stock simulation model Invert/EE-Lab was used to simulate the a “current policy scenario” for the German building stock. Secondly, a norm based monthly energy balance calculation model was applied to calculate the energy savings resulting from the measures suggested in IBRR for reference buildings. As cooling energy demand in Germany's single family houses are low: 0.07 TWh (Olonscheck et al., 2011), the present study focused on space heating energy demand. Finally, we compared and aligned both results, by extrapolating the results of the selected reference buildings on Germany's single-family building stock.

### 1. Techno-economic bottom-up modelling of energy demand and CO<sub>2</sub> emissions for the building stock

Invert/EE-Lab is a dynamic bottom-up discrete choice building stock simulation tool. In particular, Invert/EE-Lab is designed to simulate the impact of policies and other side conditions in different techno-economic scenarios. These scenarios drawn with this tool build on much disaggregated representation of the national building stock by a large number of reference buildings. Based on several parameters such as the age distribution of the building components; heat supply; distribution technologies in the building stock; and the ratio between the total costs of purchase of new components and the energy-consumption related annual costs using the installed component, the share of buildings and components is determined, carrying out a renovation measure. For more information see [www.invert.at](http://www.invert.at) (Müller, 2015), (Kranzl et al., 2013) and (Steinbach, 2016). By setting the model with the current policy instruments, a scenario study developed for the European Project SET-Nav showed that 77 % CO<sub>2</sub>-Emission from the building stock during the analysed period 2012 to 2050 can be achieved (Hartner et al., 2018).

### 2. Choice of reference buildings and their individual building renovation roadmaps

In order to select representative reference buildings, Germany's single family house building stock was mainly classified according to building construction vintage, building geometry, gross and heated floor area, envelope quality and heating systems (Pfluger et al., 2017). For this, from the mentioned database of the German building stock, six reference buildings,

which together represent 33% of total energy demand of single-family houses, were chosen. Table 1 below shows the building characteristics and the relation between construction vintages and envelope's quality of the selected reference buildings B1-B6:

Table 1: Reference buildings characteristics selected from Invert/EE-Lab building stock typology database

Reference building	Construction vintage	Heated area [m <sup>2</sup> ]	U-value Exterior walls [W/m <sup>2</sup> K]	U-value windows [W/m <sup>2</sup> K]	U-value roof [W/m <sup>2</sup> K]	U-value floor [W/m <sup>2</sup> K]	Heating system
B1	1949 - 1957	139	0.93	2.57	1.11	1.01	Oil boiler
B2	1958 - 1968	140	1.44	2.90	0.92	0.97	Oil boiler
B3	1969 - 1978	147	1.21	2.57	0.63	0.85	Oil boiler
B4	1979 - 1983	148	0.80	4.30	0.43	0.81	Oil boiler
B5	1984 - 1994	146	0.68	2.57	0.30	0.55	Oil boiler
B6	1995 - 2001	142	0.50	1.60	0.22	0.34	Oil boiler

The renovation roadmap measures for the reference buildings listed above were defined based on literature (Hoier et al., 2013) and considering the achievement of national building code standards (EnEV, 2014). Table 2 shows the stepwise renovation measures:

Table 2: Individual building renovation roadmap

Renovation step	Renovation measures	
1	Roof insulation	A survey within the iBRoad Project scope, which aimed understanding potential users, showed that a time horizon of individual building renovation roadmaps between 5 and 10 years is most favorable for
2	Walls, floor insulation and air tightness increase	
3	Window replacement	
4	Insulation heat distribution system	
5	Heating system replacement	

building owners (Fabbri et al., 2018). Because of that, in the present study assumes a total of 10 years renovation period with two years renovation time-step (period between renovation measures are made). Building elements present different renovation cycles, opaque envelope elements have renovation cycle of 50 years, while window's renovation cycle are about 36 years and heating systems 30 years (Hoier et al., 2013). In the assumed 10 years renovation period, only one renovation cycle was considered.

### 3. Building Energy Performance Calculation Model and Extrapolation

The energy performance of the reference buildings due IBBR was assessed using a norm based monthly energy balance calculation model. This multi-zone model was developed in Matlab and calculates the monthly balance of energy performance of buildings. Energy need, delivered energy and primary energy demand for heating, cooling, ventilation, domestic hot water and lighting are assessed based on the calculation methodology specified on the DIN V 18599, which is a an aggregation of the norms (DIN V 4108-6/ DIN V 4701-10 und -12, EN 832, ISO 13790) (Garcia, 2017). After assessing building's new energy performance for the IBBR, a linear extrapolation method was applied, where the calculated energy demand [kWh/m<sup>2</sup>a] was multiplied by the number of existing buildings of each reference building according to the building stock typology database from Invert/EE-Lab, also into consideration, the percentage of reference building on the total single-family houses construction vintages, as showed in **Fehler! Ungültiger Eigenverweis auf Textmarke.** below.

Table 3: Reference Buildings and its representativeness in the building stock for the base year 2012

Construction vintage	Number of buildings per Construction vintage [Tds]	Reference building for the Construction Vintage	Percentage of Reference building's on the Building Vintage	Percentage of Reference building's on Reference building the SFH building stock
1949 -1957	162	B1	26%	2%
1958 -1968	407	B2	36%	7%
1969 -1978	451	B3	39%	6%
1979 -1983	518	B4	80%	7%
1984 -1994	743	B5	79%	7%
1995 -2001	962	B6	94%	5%

This method allowed obtaining an estimation of the total energy needs for space heating, aligning them with the scenario estimated by the techno-economic bottom-up modelling with Invert/EE-Lab.

## RESULTS

The graph 2 illustrates the energy needs and CO<sub>2</sub>-emissions caused by space heating of each reference building (B1 until B6) and their effects due to the five steps IBRR, according to the renovation steps and measures described in Table 2 above.

Graph 1: Effects on the a) energy needs, on the b) CO<sub>2</sub> emissions, for space heating due to the individual renovation roadmap (IBRR)

The results show a wide range on energy needs for space heating between the reference buildings in the status quo (base year 2012). Reference building B2 has the highest energy need (266 kWh/m<sup>2</sup>a) while reference building B6 the lowest (81 kWh/m<sup>2</sup>a), which can be expected since envelope quality differs according to the building construction vintages. Renovation measures on the envelope quality (renovation steps 1 until 3) lead to 25% until 70% energy needs reduction, in reference buildings B6 and B2 respectively. The effects of the renovation measures “insulation of the heat distribution system” and “heating system change” are better observed on the final energy and on primary energy. In step 5, we considered a roadmap, where the oil boiler is substituted by a biomass boiler, which has a lower thermal efficiency, but has significantly lower CO<sub>2</sub> emission factors. As a result from the individual renovation roadmaps, CO<sub>2</sub> emissions are reduced to 5 until 6 kgCO<sub>2</sub>/m<sup>2</sup> depending on the building. The current policy scenario calculated with Invert/EE-Lab, which only considers single-step major renovation of buildings, resulted a reduction from 260 TWh to 132 TWh on the total energy needs for single-family houses space heating. The extrapolation of the IBRR results indicates that such a scenario is also achievable with the approach of stepwise renovation, guided through IBRR. **Fehler! Verweisquelle konnte nicht gefunden werden.** depicts the comparison of energy needs for space heating between Invert/EE-Lab model and the IBRR extrapolation, for each building construction vintage:

Graph 2: Comparison between Invert/EE-Lab and the individual renovation roadmap (IBRR) extrapolation

The graph shows the energy needs for space heating according to the building construction vintages in both years, 2012 (base year) and 2050, for both approaches (Invert-EE/Lab and IBRR). For the base year (2012), Invert/EE-Lab and IBRR present similar energy needs for space heating, exceptionally for the construction vintage 1958-1968, where a difference of

8.140 GWh can be seen. Regarding the trend of the energy needs, between 2012 and 2050 occurs a significant decrease on the energy needs in all building construction vintages, especially on the buildings constructed in 1850-1918, 1958-1968 and 1969-1978. In the Invert-EE/Lab model, buildings constructed after 2012 did not carry out any renovation measures, as the model prioritizes building renovation in buildings with higher specific energy need (kWh/m<sup>2</sup>), which is the case of older building construction vintage. Finally, the graph shows that for the analysed building construction vintages represented by the reference buildings B1 until B6, Invert/EE-Lab current scenario's can be achieved, as the points representing scenario for 2050 Invert/EE-Lab (in blue) and IBRR (in red) are overlapped.

## DISCUSSIONS

The results showed that - based on the approach of the IBRR – it would be required that annually about 4-6% of the single-family building stock, according to the building construction vintage, need to apply at least one retrofitting measure (change windows or insulate the roof, change heating system, etc.), in order to achieve the scenario simulated by the model Invert/EE-Lab. This annual building stock renovation rate results deliver from a static calculation, as the extrapolation considers the same number of buildings from 2012 until 2050, meaning no demolition of old buildings. The definition of a 10-years IBRR period is a significant parameter for the obtained results, rather than the time step between the measures. Concerning the IBRR concept, it should consider national, regional and cultural particularities, political incentives and available technology and therefore it is specific for each country. Especially by the renovation measure “change of heating system”, the analysis should be extended and study a mix of different measures as connecting to district heating net or installing a heat pump. In the present study, only one possibility by changing the oil boiler to biomass oiler was considered. Also, when developing IBRR to buildings situated in hotter climate zones as Germany, measures related to the cooling energy demand should also be considered, as well as cooling energy demand scenario analysis. In regard to the ambitiousness of IBRR, this paper considers renovation standards according to the national building codes. However, if ambitious CO<sub>2</sub>-reductions were aimed (>90% CO<sub>2</sub>-Emission) not only more energy efficient IBRR would be needed, but also higher annual percentage of at least one retrofitting measure.

## CONCLUSIONS

Results show that for the analysed construction vintage (1949-2001), annually about 4-6% of the single-family building stock need to apply at least one retrofitting measure, in order to achieve CO<sub>2</sub>-Emission reduction according to the current policy scenario. Uncertainties are related to the calibration of the base year (2012) between both approaches Invert-EE/Lab and IBRR. More accuracy on the results can be assured by extending the reference buildings to all

construction vintages provided by the single-family houses building stock of Invert-EE/Lab, in a way that each building construction vintage from 1850 until 2012 has at least one reference building. Also, the chosen reference buildings for the vintages 1949-1958, 1959-1968 and 1969-1978 represent less than 50% of percentage of energy needs on the building construction vintage. This means, choosing more than one reference buildings for these groups can increase accuracy. In all, IBRR can become an important instrument to achieve national targets, as it reduces some barriers for renovation activities in single-family houses, by increasing the application of annual deep renovation measures in the existing single-family houses.

### ABSTRACT

Extreme cold climates and Canada's sparsely populated Northern regions have limited human and infrastructural capacity making it difficult to build energy-efficient homes. Despite such differences, homes are built based on codes and standards developed for Canada's South. In 2008, a by-law was passed in Yellowknife, Canada requiring a minimum EnerGuide Housing (EGH) rating of 80 for all new single-family and two-family residential buildings. The EnerGuide's Energy Rating Service (ERS) program is an energy assessment program for residential housing formerly known as the EnerGuide Rating for Houses (EGH). Homes are rated between 0 to 100; lower numbers represent homes that are less efficient and 100 represents an airtight and well-insulated house that is net-zero energy. 1002 homes from the City of Yellowknife evaluated since 1950s were studied from the ERS database, Performance metrics studied include energy intensity, EGH rating, ACH rating, window types, the thermal resistance of the building envelope, primary heating and hot water heating equipment's efficiencies, total electricity used, and total energy used. The analysis identified the current state of housing in Yellowknife, past and present housing trends, and determined the effect of the city of Yellowknife's new building by-law had on housing performance. The preliminary finding shows a pathway to significantly improve the energy efficiency of the housing stock in Yellowknife. This regulation shows other municipalities in Canada that legislations pushing energy efficient buildings can be very effective.

### KEYWORDS

Remote Communities, Extreme Cold Climates, Energy Efficient Housing, Policy

### INTRODUCTION

The Canadian northern region is remote with limited human and infrastructural capital, little demand for private housing and small incentives for suitable northern building products. Temperatures drop to -50°C for extended periods; homes must have high performing building envelope with minimized thermal bridges and air leakage. There are housing standards adopted in northern regions that were developed for Southern regions of Canada with warmer climates. With growing concerns about climate change and the region's desire to become less dependent on fossil fuels, governments have identified new housing standards as urgent (Government of Nunavut, 2007). As part of a research program, a protocol for low energy homes for northern Canadian regions was developed (Thirunavukarasu et al., 2016). This paper outlines a section of the research, which examined the impact of the city of Yellowknife's building by-law no. 4469 had on the energy performance of housing. The by-law, adopted in 2008, required a minimum EnerGuide Housing (EGH) rating of 80 for all low-rise residential buildings. This paper presents the impact of by-law no. 4469 on the housing performance to show methods that improve significantly the energy efficient of homes.

## METHODS

The EnerGuide's Energy Rating Service (ERS) or the EnerGuide Rating for Houses (EGH) program, developed by Natural Resource Canada (NRCan), is an energy assessment program for residential housing. The program evaluates the housing size, location, orientation of the home, building envelope (area, average insulations levels in walls, ceiling, floors,) window types, air leakage (measured), mechanical systems (heating, domestic hot water and ventilation), occupant behaviors, appliances, and lighting loads (Parekh et al., 2000). The total energy consumption is estimated based on the above inputs into HOT2000 software platform, validated by Natural Resource Canada (NRCAN). The program assumes, for single family homes, 2 adults and 2 children occupancy, 225 liters/day hot water load and an electric load of 24kWh/day.

The EGH rating is calculated as the ratio of estimated total energy consumption to benchmarked total energy consumption of the building. The benchmarked values are based on heating degree days for the location. Homes are rated between 0, indicating high energy consumption, and 100 indicating a net-zero energy home. Homes rated EGH 80 represent home built to ENERGY STAR standards. The EGH rating allows a standardized energy labels for homes. Data collected through certified evaluators upload information into the ERS database. The database is a comprehensive tool to track and manage residential energy evaluations and allows for identification of trends over time and region. 1002 homes evaluated for EGH rating from the City of Yellowknife were data mined from the ERS database – the last evaluated home included in this study was built on July 1<sup>st</sup>, 2015.

By-law no. 4469 required a minimum EGH rating of 80 for low-rise residential units. Pre-drywall blower door testing for air leakage and submission of construction plans to city for recommendations. The study compares performance metrics of 225 homes built from 1990 to 2009 to 102 homes built between 2010 and 2015. The parameters include ACH rates obtained through blower door testing, thermal resistance levels of building envelope, and mechanical systems efficiencies obtained through on-site verification, EGH rating, energy intensity ( $\text{kWh/m}^2$ ), total annual electricity use ( $\text{kWh/m}^2$ ), and total annual energy consumption ( $\text{kWh/m}^2$ ) calculated using software.

## RESULTS

102 homes evaluated are built after 2009 when by-law no. 4469 took effect. Figures 1a to 1g plot performance metrics based on construction dates from 1950 to 2015. There is a gradual improvement in the air leakage rate, thermal efficiency of the building envelope, and the annual energy consumption. Primary heating and hot water equipment's efficiencies remained constant 2009, then improved by 5 to 10%. After 2008, there is a 'clustering effect' as seen in Figure 1a, 1b, 1c, 1d, 1e and 1g.

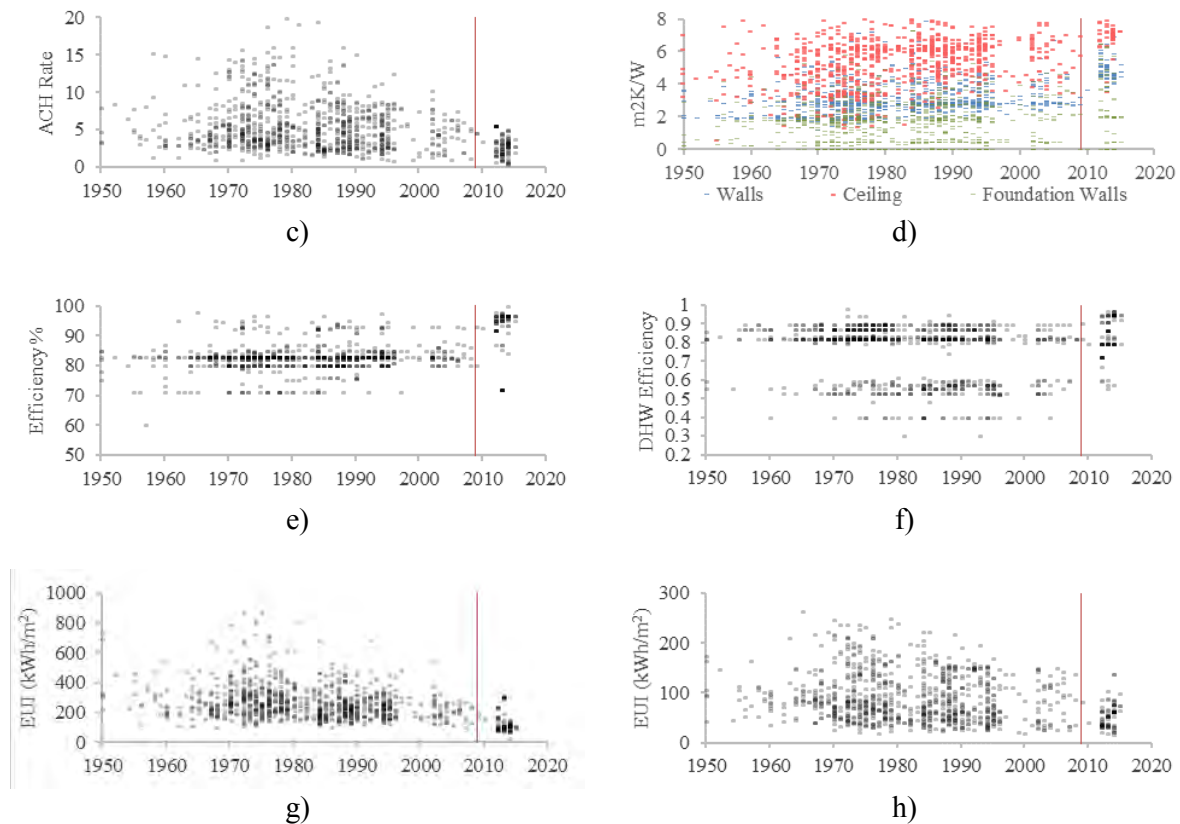

Figure 1. Performance metrics for homes since 1950 to 2015 (a) EGH rating, (b) home footprint ( $\text{m}^2$ ), (c) ACH Rate @ 50 pa, (d) Thermal resistance for walls, ceiling and foundations, (e). primary heating equipment efficiency, (f) primary DHW equipment efficiency, (g) annual energy use intensity, (h) Annual electricity use.

Figure 2. Percentage box plot shows minimum, 25% percentile, median, 75% percentile and maximum values for performance parameters between 1990 to 2015. Values for minimum, median and maximum are labelled on the graph.

Figure 2 presents the percentage box plot comparing 225 homes built in 1990 to 2009 and 103 homes built in 2010 to 2015. Impact of by-law no. 4469 is further evident in Figure 2. The median EGH rating rose from 69 to 81, the median ACH rate reduced by 36% from 4.4 to 2.8.

Primary heating and hot water equipment efficiency increased by 10% and 5% to 96% and 87%, respectively. Higher efficiencies were achieved by installing condensing boilers for heating and switching to instantaneous condensing hot water heaters from conventional storage-type water heaters. Thermal performance of the exterior walls increased from 2.9 m<sup>2</sup>K/W to 4.6 m<sup>2</sup>K/W. The minimum thermal performance of the exterior wall in homes built after 2009 was 3.6 m<sup>2</sup>K/W, greater than the median for homes built between 1990 and 2010. Median thermal performance of the ceiling increase by 35% (2.2 m<sup>2</sup>K/W). Median energy intensity is reduced by 37% after the by-law was adopted. Newer homes used 10% less total annual electricity than homes built between 1990 to 2009. EnerGuide's rating systems has a standard assumption for household lighting and plug loads – so, this research did not assess any energy efficiency steps to reduce lighting and plug loads.

Figure 3. Distribution of window types as a percentage between 1950 to 2015

Figure 4. Percentage box plot shows minimum, 25% percentile, median, 75% percentile and maximum values for performance parameters between 1990 to 2015 comparing triple glazed to double glazed windows. Values for minimum, median and maximum are labelled on the graph.

After 2009, shares of triple-glazed, low-E, argon windows (TG) installed in homes increased from 22% to 84%. Between 1990 and 2009, double-glazed, low-E, argon windows (DG) were most common – although, notice a greater variation in windows install between 1950 to 2009. Between 2010 and 2015, 98% of all windows install were either DG or TG. Figure 4 evaluates

EGH, ACH rates, and energy intensity of homes using TG and DG for homes built from 1990 to 2009 and from 2010 to 2015. First, homes built after 2009 had higher EGH rating and lower ACH rating for both window types. Energy intensity reduced only for TG after 2009. 14 homes built after 2009 installed DG; which may explain the higher variance in energy intensity for DG. Homes built from 1990 to 2009 had similar EGH rating, ACH rating and energy intensity levels regardless of window type used.

## DISCUSSION

The data shows a clear pathway to increase energy efficient homes for the North with 75% of homes built after 2010 reaching ENERGY STAR performance (Figure 2.) Although cost was not considered in this study, as fuel is imported in the northern regions of Canada, electricity cost per kilowatt-hour (kWh) can be up to 10 times as much as in southern cities (Northwest Territories Power Corporation, 2015). Significant energy savings can be achieved for little added cost by building high performing envelope systems, performing pre-drywall blower door testing and installing triple pane windows. Energy savings through the building envelope can reduce size of the mechanical systems and more efficient mechanical systems such as condensing boilers and instantaneous hot water heaters is chosen. Further optimization of solar design parameters (Thirunavukarasu et al., 2016) can further reduce energy consumption for little added cost.

Figure 5. Percentage box plot showing performance of homes in non-compliance (N) and compliance (Y) with by-law.

This study shows that since by-law no. 4469 was passed, 84% of homes used triple glazed, low-e, argon windows, reduced air leakage, and increased thermal efficiency of the building envelope. Although the by-law faced resistances from local builders, general opinions of builders in 2015 were supportive (Thirunavukarasu et al., 2016). Of the 102 homes evaluated since 2010 to July 1<sup>st</sup>, 2015, 69 homes built met the by-law requirements.

Homes not in compliance with the by-law either had twice the average ACH rate of homes in compliance with the by-law (see Figure 5) and/or used less efficient conventional hot water heaters and/or had little to no insulation levels on foundation walls.

## CONCLUSION

This paper presents the results analyzed for 1002 houses from the EnerGuide's Energy Rating Service (ERS) for Yellowknife, Northwest Territories and the impact of by-law no. 4469 by

evaluating 225 homes built from 1990 to 2009 and comparing to 102 homes built between 2010 and 2015. By-law no. 4469 required a minimum EGH rating of 80 and city offered pre-drywall blower door testing for air leakage, and pre-construction submission of plans for recommendations from the city.

This by-law shows other municipalities in Canada that legislation for more energy efficient buildings can be very effective when combined with verification methods such as blower door testing.

### **ABSTRACT**

In this paper, the potential of model order reduction for simulating building performance is assessed, via a case study of modelling heat transfer through a massive masonry wall. Two model order reduction techniques – proper orthogonal decomposition and proper generalized decomposition – are investigated and compared. Moreover, to illustrate the performance of model order reduction techniques, the accuracies of the two model order reduction techniques are respectively compared with a standard finite element method. The outcomes show that both of the two model order reduction techniques are able to provide an accurate result, and the proper generalized decomposition tends to be more versatile than the proper orthogonal decomposition method.

### **KEYWORDS**

Model order reduction, proper generalized decomposition, proper orthogonal decomposition, finite element method, heat transfer

### **INTRODUCTION**

Today, 30% of the European building stock consists of ‘historic’ buildings built prior to World War II (Ribuild.eu, 2018). These buildings are typically far less energy-efficient than new buildings, and they hence account for a large share of the total energy consumption of buildings. One important measure to reduce their energy consumption is to install internal insulation. However, internal insulation is often associated with moisture damage, and much care should be taken when applying this solution. This paper is part of the EU H2020 RIBuild project, which aims at developing effective and comprehensive guidelines for internal insulation in historic buildings. Given that a multitude of scenarios and factors can be easily evaluated with numerical analyses, the use of numerical simulations for hygrothermal performance assessment tends to be the best option. However, the standard numerical methods for space and time discretization are usually very time consuming due to the high non-linearity of the equations, the multi-dimensional spatial domains and the long simulation time intervals required, in order to reduce the computation time as much as possible, an efficient solver for modelling the hygrothermal behavior of the wall is needed. Therefore, a faster surrogate model is highly desired.

Instead of using the standard numerical models, Van Gelder et al. (2014) employed statistical regression and interpolation based surrogate models (such as polynomial regression, Kriging etc.) to reduce the simulation time. However, these statistical surrogate models can only deliver static results: for the heat transfer through a wall, they may predict the yearly total heat loss, but not the temperature profile at each moment in time. Hence, to obtain the dynamic behavior with a simplifying surrogate model, model order reduction techniques as alternatives of the statistical surrogate modelling are investigated. In this paper, two model order reduction methods (proper orthogonal decomposition (POD) and proper generalized decomposition (PGD)) are

investigated and compared. The first method belongs to a family of a posteriori methods - it is built based on the preliminary results of the original time-consuming model. The second method is an a priori method which can be established by a suitable iterative process. Instead of the standard finite element method (FEM), we will use both POD and PGD to simulate the building thermal performance, exemplified through a case study of modelling the heat transfer through a massive masonry wall.

Below, first a brief introduction of POD and PGD are put forward, with focus on the potential use for the modelling of wall heat transfer. Subsequently, the calculation object and the case study with its input parameters are introduced, as that forms the central application in this study. Next, the results of using POD and PGD for simulating the wall heat transfer are presented and a discussion with respect to the interpretation of their accuracies follows. Finally, conclusions on which method is considered most optimal are formulated.

### **POD AND PGD FOR MODELLING WALL HEAT TRANSFER**

The thermal performance of a building component can be assessed by analyzing the transfer of heat through building materials. Heat transfer is mainly related to the normal flows of heat conduction, convection, radiation and advection. Thus, assessing the thermal performance of a building component requires to get numerical simulation results of the heat transport equation based on the component geometry, the boundary conditions and the material properties. The conventional thermal simulation models are mainly based on numerical simulation methods for space and time discretization, for instance, the FEM. As mentioned before, these standard numerical methods can be very time consuming due to the high number of degrees of freedom after the spatial and temporal discretization. Therefore, in this paper we investigate two model order reduction methods (POD and PGD) which reduce the degrees of freedom of the complex system and still mimic the dynamic behavior (such as time evolution of temperatures,...).

#### **Proper orthogonal decomposition**

The POD method was first proposed by Kosambi (1943), and has been successfully applied in a variety of engineering fields, such as image processing, signal analysis, data compression and recently in building physical engineering (Tallet et al., 2017). POD is also known as Karhunen - Loeve decomposition, principal component analysis, or singular value decomposition, and the connections of these three methods are provided by Liang et al. (2002). A brief tutorial of POD can be found in (Chatterjee, 2000), a detailed introduction of its theory and related application for modelling heat transfer process are respectively presented by Liang et al. (2002) and Fic et al. (2005). The basic idea of POD is approximating a high dimensional process by its 'most relevant information'. In this paper, we extract the 'most relevant information' by making use of principal component analysis (PCA). After the PCA, the POD modes are constructed by selecting the most important  $k$  components, here  $k \ll m$ , where  $m$  is the number of the mesh elements. As a result, these POD modes can be used to construct a reduced model for simulating different problems (for instance, variations in the boundary conditions or material properties or longer simulation period).

#### **Proper generalized decomposition**

Despite the POD method being able to provide a reduced basis and save the computational time when simulating similar problems, this method has an important drawback: to construct a POD, 'a priori knowledge' – the snapshots of the large original model – is needed. This disadvantage in turn leads to an extra computational cost and limits its application to 'different but similar problems'. On the contrary, Ladeveze (1985) proposed a different strategy, called 'radial

approximation'. This method is based on the hypothesis that the solution of the considered problem is given by a finite sum representation:

$$u(\mathbf{x}, t) = \sum_{i=1}^N \mathbf{X}_i(\mathbf{x}) \cdot T_i(t) \quad (1)$$

Here,  $u$  is the solution of the target problem,  $\mathbf{X}_i$  usually stands for the spatial parameters,  $T_i$  represents the temporal parameter. Next, injecting equation (1) into the weak formulation of the differential equation and starting from an initial point based on the related initial and boundary conditions, the solution  $u(\mathbf{x}, t)$  can be constructed by successive iterative enrichment methods. The procedure is stopped when the convergence criteria are reached. As a result, this strategy allows to approximate the solution without any 'a priori knowledge'. Inspired by this strategy, Ammar et al. (2006) generalized this method to the multidimensional situation and named it proper generalized decomposition (PGD). A detailed tutorial of PGD is proposed by Chinesta et al. (2013), and an application of PGD for simulating thermal processes is provided by Pruliere et al. (2013). In addition, two reviews of PGD are provided by Chinesta et al. (2010) and Berger et al. (2016), with attention for general and physical engineering applications respectively.

### CALCULATION OBJECT AND CASE STUDY

For investigating the performance of POD and PGD for hygrothermal simulations, a calculation object hence needs to be formulated. Since the reference situation prior to retrofit is often a massive masonry wall, and that configuration is adopted here as calculation object. In order to judge the feasibility of internal insulation in historic buildings, the hygrothermal performances of internally insulated massive walls – heat loss, mould growth, wood rot, ... – need to be investigated (Vereecken et al. 2015). To simplify the calculation complexity in this study, this paper limits that performance assessment to the transmission of heat loss through the wall. Since quantifying the heat loss requires solution of the temperature profiles of the wall, both the temperature profiles and heat losses over the entire year are taken as the targeted outputs. To do so, the thermal behavior of the wall is simulated with FEM, POD and PGD, wherein the conductive heat transfer equation is solved under the relevant interior and exterior boundary conditions. The simulation result of the FEM is taken here as the reference solution: more specifically, this reference solution is calculated by the FEM with 200 mesh elements and a fixed time step of one hour.

As mentioned before, since POD is constructed for simulating different problems, in this paper, several POD models are constructed by using snapshots of different time intervals (one year, one month, one day, half day, six hours and three hours). Except for the time interval of one year, all the other scenarios are performed 12 times: once for every month. In addition, each of the one day, half day, six hours and three hours are taken at the start of each month. In order to evaluate the performance of different model order reduction methods as a function of the number of modes, both of the POD and PGD models are calculated with 1 to 15 modes.

For the comparison case study of PGD and POD, the detailed information of the input parameters is mentioned here. For the material properties, the density, thermal capacity and conductivity of the wall are  $2087 \text{ kg/m}^3$ ,  $870 \text{ J/kgK}$  and  $1.07 \text{ W/mK}$ . The boundary conditions are kept restricted to combined convection and radiation, governed by climate data of Gaasbeek (Belgium) at the exterior surface, and by the indoor air temperature as described in (EN 15026) at the interior surface. The related interior and exterior surface transfer

coefficient are  $8 \text{ W/m}^2\text{K}$  and  $25 \text{ W/m}^2\text{K}$ , respectively. In relation to the component geometry, the thickness of the wall is  $0.2 \text{ m}$ .

## RESULTS

To compare the accuracies of PGD and different POD models, the average temperature difference between the FEM solution and different model order reduction models, as a function of the number of modes, is shown in Figure 1. For getting a more direct view of the performance of POD and PGD methods, different profiles of temperature are compared at different moments, and the result is presented in Figure 2. In addition, since in practice the cumulated heat loss is usually considered as an indicator of the thermal performance of the wall, the relative deviation of heat losses between the reference solution and different model order reduction models are shown in Figure 3.

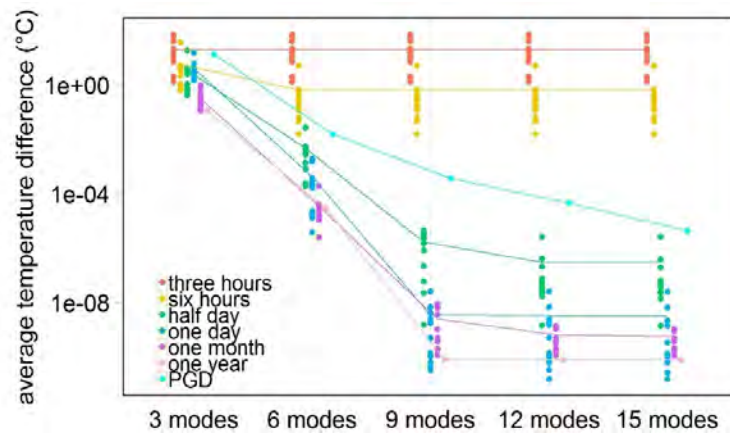

Figure 1. Average temperature differences between reference solution and different model order reduction approximations.

Figure 2. Temperature profiles of the reference solution and PGD solution (solid lines), POD solution constructed from 6 hours' snapshots (dashed lines) and from 3 hours' snapshots (dotted lines). All the reduced models are construed by 15 modes.

Figure 3. Relative deviation of heat loss between reference solution and different model order reduction approximations.

## DISCUSSIONS

Figure 1 illustrates that, except for the POD constructed from the 3 and 6 hours' snapshots, the accuracy of the other reduced order models increases as the number of their construction modes raises. However for the POD, after 9 modes this improvement becomes negligible. In addition, one can see that the accuracy of the POD increases as the time duration of its snapshots raises. In relation to the PGD, one can see that a relatively accurate result can be reached with a sufficient number of construction modes. Figure 2 confirms the result of Figure 1, it is shown that visually there is no difference between the reference solution and PGD approximation. On the other hand, larger differences can be respectively found between the reference solution and the solution calculated by the POD with the 6 and 3 hours snapshots. Furthermore, compared with Figure 1, a very similar result can be found in Figure 3 - except for the POD constructed from the 3 and 6 hours' snapshots, the relative errors of the other reduced order models decreases as the number of their construction modes increases and these relative errors can be reached below 1% with a very limited number of modes. These findings indicate that the performance of all the model order reduction methods do not vary much for quantifying the heat loss instead of calculating the temperature profile.

In summary, combined the results of all the Figures, we can conclude that, with enough number of modes the PGD method can provide a relatively accurate result. In relation to the POD, only when the number of snapshots is really insufficient (three and six hours), an inaccurate result may be obtained. As a consequence, for using the POD method to obtain an accurate result with the smallest size of snapshot, an error estimation method is thus needed. On the other hand, since the PGD model is constructed based on a suitable iterative method, an error controller is naturally embedded in this method. Therefore, together with the advantage that the PGD model is constructed without any 'prior knowledge', this method tends to be more versatile than the POD.

## CONCLUSIONS

In this paper, we investigated the performance of two model order reduction methods (POD and PGD), based on a case study of modelling heat transfer through a massive masonry wall. It is shown that, both of the two methods can provide a very accurate result. In addition, since the construction of PGD does not rely on any 'a priori information', this method tends to be more versatile than the POD and should be preferred.

### **ABSTRACT**

The retrofit design of buildings and districts cannot exclude the occupants' perspective if comfortable and healthy conditions have to be obtained. For this reason, the NewTREND<sup>1</sup> project developed a collaborative platform for the energy efficient buildings and districts retrofit that includes the users' perspective. Three modules have been developed for thermal comfort, acoustic comfort and behavioural assessment. These modules are integrated into a Simulation and Design Hub that, after gathering data from on-site measurements, builds a simulation model of the district, calculates yearly results and exposes them to the design team through a dedicated District Information Model server and user interfaces. These modules perform deep investigations on the occupants' sensation and behaviour, based on both measured and simulated datasets and provide comparisons of comfort performances, considering different retrofit scenarios and related uncertainties. In details, the thermal comfort module performs analysis according to both predictive and adaptive models, evaluates the variability around the design conditions together with sensitivity analysis that highlights which parameters are the most critical for the retrofit design. The acoustic module provides a complete tool to predict and assess the indoor acoustic comfort, taking into account the performance of building envelope and the impact of district noise. Finally, the behavioural module empowers the building energy simulation with co-simulation capabilities that reproduces the real occupants' behaviours in relation to comfort conditions. The final goal of the framework is to support the decision-making process in selecting the optimal retrofit option that achieves the targeted energy efficiency without infringing the occupant's expectation in terms of comfort and well-being.

### **KEYWORDS**

Thermal Comfort, Acoustic Comfort, Behavioural Modelling, Monitoring, Simulation.

### **INTRODUCTION**

Buildings have the main goal of providing comfortable conditions for the occupants. The lower is the comfort sensation the higher will be the probability that occupants occur in non-efficient behaviours and low productivity because of the degraded well-being. Thus, maintaining the optimal thermal conditions in all occupied spaces is a key feature. On the other side buildings account for the 40% of the total energy consumption and they have to become as much efficient as possible so to use the minimum energy to provide comfortable conditions. Considering that, more than the 35% of European buildings have been built before the 60's and more than the 80% before the 90's (BPIE, 2011), they do not include materials and technologies capable of high performance or they have degraded with. In this context, the renovation and retrofit interventions are to be considered as priority to achieve the objective

<sup>1</sup> <http://newtrend-project.eu/>

of reducing the global energy consumption and striving to the resilience required for facing climate changes. Comfort plays an important role in buildings renovation. In fact, the recent report “Feel Good, Live Well - The UK home, health and wellbeing report”<sup>2</sup> points out that over 95% of homeowners and renters make some effort to look after their health and wellbeing and health and wellbeing issues in their existing homes they would like to change are in the first position. In this context, the NewTREND project proposes a Collaborative Design Platform to enable wide retrofit actions of buildings and districts, including comfort and well-being into the multicriteria assessment framework. This paper presents the platform and three tools dedicated investigate the occupants’ perspective.

## METHODS

### The NewTREND cloud platform

The main aim of the NewTREND cloud-based platform is to support the collaborative design and to promote the dialogue between the different subjects involved in a retrofit project. In this perspective, a District Information Model (DIM) server has been developed to store data and to make them available for the designers. In parallel, a Simulation & Design Hub (SDH), creating a simulation model of the district, allows effective comparisons between retrofit options at both building and district level and guide the decision makers in choosing the best strategy. These targets are achieved using dynamic simulations (IESVE software) which provide yearly energy assessments and calculations of Key Performance Indicators (KPIs). These components are merged in a Collaborative Design Platform, which provides the access to all the embedded tools and the visualization of the results through an intuitive Graphical User Interface. Figure 1 reports a scheme of the platform.

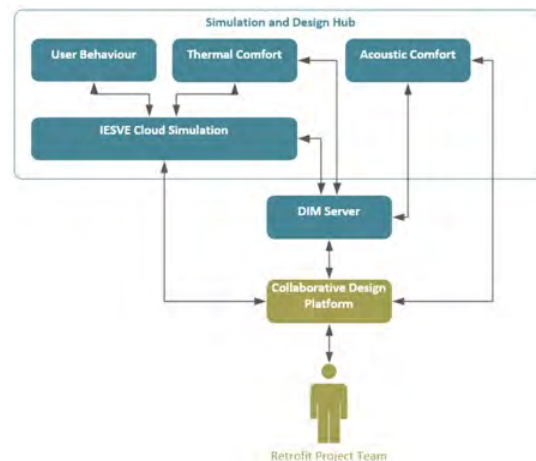

Figure 1. Scheme of the NewTREND platform.

A key improvement of this methodology concerns the inclusion of the occupants’ perspective in the decision-making process. In fact, the evaluation of different retrofit scenarios is investigated considering both users’ comfort (thermal and acoustic) preferences and the human-building interaction. According to this people-centred perspective, three modules have been developed. The thermal comfort and acoustic comfort modules perform a post-processing analysis on the simulation data to provide simple comfort indicators for the different design alternatives. The behavioural module includes the human component inside the simulation process since it is directly coupled with the IESVE engine.

<sup>2</sup> <https://www.multicomfort.co.uk/media/1096/saint-gobain-uk-home-health-and-wellbeing-report-summary.pdf>

### **Thermal Comfort Module**

Thermal comfort is a subjective quantity which has to be measured and assessed using a statistical approach. The tool offers an evaluation of the thermal comfort conditions for each room of the studied building. The algorithms post-process the data provided by the IESVE simulation or measurements, according to the user selection both in terms of comfort model (i.e. predictive and adaptive) and season (i.e. heating, cooling). The tool displays KPIs related to the thermal comfort assessment for each investigated retrofit scenario, calculated as the percentage of occupied hours out of the optimal ranges provided by predictive and adaptive comfort models according to EN 15251 (2007). It receives the input data from the IESVE cloud energy simulation and, after the post-processing analysis, stores the results in the DIM server. In addition, this module provides a sensitivity analysis, based on Monte Carlo method, to determine which parameter has the highest impact of thermal comfort. In this way the designer has the possibility to address specific issues to be solved with the retrofit. The tool has been tested simulating a room of a monitored building to guarantee the reliability of the obtained results (Naspi et al. 2018a). After simulating the actual thermal condition, two retrofit configurations have been selected and applied. The KPIs related to the three different scenarios are illustrated and compared to investigate which solution is to be preferred.

### **Acoustic Comfort Module**

The acoustic comfort module is composed of algorithms for the assessment of indoor acoustic comfort at building level, according to equations of EN 12354-3 (2017). The improvement of the acoustic comfort is obtained by applying building envelope interventions on the basis of the evaluation of district noise levels (through measurements - EN 16283-3 (2016) - or predictive calculation models<sup>3</sup>). After simulating the current building condition, the tool performs post-retrofit simulations according to the retrofit interventions selected by the user. The output of each simulation process is a specific KPI, calculated by assignment of a score according to the measured/calculated indoor sound pressure level, which allows the assessment of the indoor acoustic comfort and the comparison between the pre and post retrofit configurations. The KPI provides to the designers a clear identification of the best retrofit option on the building envelope to improve the indoor acoustic comfort. The tool, integrated in the SDH, communicates with the DIM server to receive the required input data. The investigation of the potentialities of the tool occurred following several steps. At first, an extensive data collection by acoustic measurements has been performed in a residential building, settled in Ancona (Italy), to evaluate the actual comfort condition calculating the acoustic KPI. Then, applying different retrofit scenarios, the tool simulates the post-retrofit conditions and offers a comparison of pre and post scenarios through the KPIs.

### **The Behavioural Module**

The module consists of two behavioural functions that predict occupants' interaction with windows and electric lights in offices. The algorithms have been developed using experimental data acquired for a full year in a University building in Italy. People presence, environmental parameters and the status of the devices have been continuously recorded (10 min sampling time) in three offices equipped with sensor networks (Naspi et al. 2018a). Following the approach proposed by (Wang et al. 2016), the influence of environmental variables and time-related events on users' behaviours has been investigated. Window adjustments are driven by both indoor and outdoor temperature; while the lights are switched on and off in relation to the decreasing of the work-plane illuminance and to the users' departure, respectively. Identified the triggers, the coefficients of the equations have been

<sup>3</sup> Directive 2002/49/EC. Directive of the European Parliament and of the Council of 25 June 2002 relating to the assessment and management of environmental noise. Official J Eur Communities 2002; L189: 12-25.

tuned using regression methods. The co-simulation approach between the module and the IESVE engine allows the data exchanges during the simulation run-time. This approach offers a considerable modelling improvement since the operational schedules are dynamically defined at each time step, according to the module outputs. The integration and the predicting capabilities of the module have been tested simulating a portion of the case study. Ventilation and lighting profiles are stochastically defined; while heating and occupancy ones are set according to ASHRAE standards (2004). The results obtained using the behavioural module have been compared to those related to a standard simulation (i.e. deterministic results). Then, both of them have been evaluated in relation to the monitored data to assess which approach would have made the best predictions.

## RESULTS

To demonstrate the functionalities of the tools, they have been applied to assess different retrofit scenarios to a building of the UNIVPM campus, located in Ancona (centre of Italy), and built in the seventies.

### Thermal Comfort

Thermal comfort module was applied to heating season. Figure 2 shows that, before retrofit, the building is uncomfortable since the average operation is at the limit of the lowest comfort zone. This is also confirmed by the KPI, which is for more than the 60% of the time in “cold” conditions, calculated considering the category II as reference ( $\pm 0.5$  PMV as boundaries). The first retrofit configuration (Retrofit 1), concerning the application of envelope thermal insulation, moves the building to category II. This intervention produces only a partial improvement of the comfort conditions since the KPI is not sufficiently high. The second retrofit scenario (Retrofit 2) concerns the windows replacement and the improvement of the heating system. The design condition and its deviation reach the higher building category ( $\pm 0.2$  PMV). Also, the KPI shows a number of cold hours lower than the 2% of the total building operation.

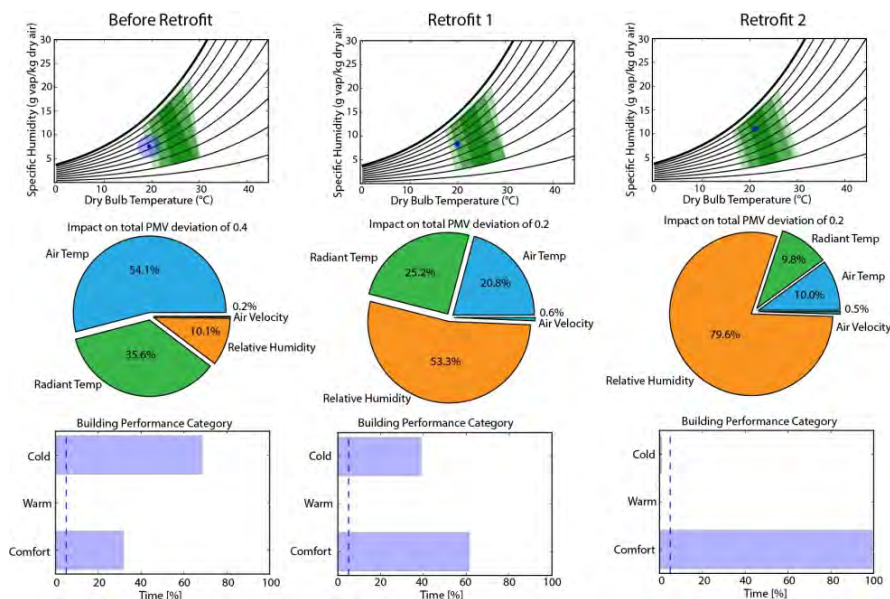

Figure 2. Results from thermal comfort analysis for heating season with predictive model.

### Acoustic Comfort

The main outcomes of the acoustic comfort tool are the comparisons both between actual and retrofitted conditions and between different retrofit designs, using KPIs. Figure 3 shows the

influence of four types of interventions, with increasing impact. The first two scenarios concern only one action: the addition of an external insulation layer (case 1) and the substitution of the windows (case 2). The last two retrofit options are connected to concurrent operations: addition of an external insulation layer, substitution of windows and small elements. The key difference between case 3 and case 4 regards the features of the windows, which are much more performing in the second instance.

Figure 3 KPIs comparison of pre and post scenarios.

The analysis highlights that the external insulation has no impact on improving the acoustic condition while changing the type of windows provides an increase of 28.5% in the KPI value. The preferred comfort assessment is reached in case 4. In fact, combining several interventions and enhancing the features of the components, the KPI raises of 51.4%. Such assessment, clearly identifying the most effective acoustic retrofit solution, aids the users in selecting the design strategy and in avoiding time and money wastes.

### Behavioural Module

The lighting and ventilation profiles obtained applying the behavioural module are compared both to standard profiles and to real users' behaviours. To perform the comparison, a sample of 14 days during the non-heating season has been selected (to avoid the influence of fixed heating profiles on the results). Figure 4 presents the lighting and ventilation profiles during two representative days. The real users' behaviours (blue dashed line) have been examined in relation to the behavioural (red solid line) and standard (grey dotted line) profiles.

Figure 4. A two-day comparison of lighting and ventilation profiles.

Table 1 summarises the analysis for all the 14 days, reporting the percentage of time with lights on and windows open and the percentage difference (i.e. error) between simulated and real actions. The outcomes highlight that both the simulation approaches tend to overestimate the lighting use and to underestimate the window openings. However, the behavioural module minimises the discrepancy with actual data, especially for the lighting use ( $\Delta=+5.1\%$ ), with a consequent deviation of 10% on the prediction of energy consumption, compared to standard profiles (Naspi et al. 2018b).

Table 1. Errors of Standard and Behavioural profiles in relation to the real data.

Lighting Profile	% of time lights ON	$\Delta\%$ with real	Ventilation Profile	% of time windows OPEN	$\Delta\%$ with real
Real	8.5	--	Real	24.9	--
Standard	42.4	+33.9	Standard	1.9	-23
Behavioural	13.6	+5.1	Behavioural	8.2	-16.7

## DISCUSSIONS

The tools presented in this work are useful to support the retrofit design with deep investigations of comfort issues. Acoustic and thermal comfort modules can be a support for the selection of the optimal retrofit solution, addressing buildings pathologies. Also, the behavioural module provides a substantial empower to the simulation results since it reproduces the human-building interaction more accurately than standard profiles.

## CONCLUSIONS

The paper presents the framework of the NewTREND cloud platform and, in particular, three embedded tools. The thermal comfort and acoustic comfort tools provide clear and effective evaluations between different retrofit scenarios using KPIs. The behavioural module reproduces the human-building interaction during the simulation, overwriting standard schedules. These tools, including the human component under different perspectives, support the decision-making process and aid the design team in selecting the optimal retrofit option in terms of energy efficiency and occupant's comfort expectations.

## ACKNOWLEDGMENT

This research has received funding from the NewTREND (New integrated methodology and Tools for Retrofit design towards a next generation of Energy efficient and sustainable buildings and Districts) project (<http://newtrend-project.eu/>) under the Horizon 2020 research and innovation programme (GA no. 680474).

### **ABSTRACT**

Green roof technology plays a large role managing stormwater runoff in urban areas, where impervious surfaces cause substantial amounts of stormwater runoff to enter combined sewer systems. If the stormwater flow exceeds the capacity of treatment plants, this often results in the discharge of raw sewage into nearby bodies of water. Green roofs can reduce the occurrence of raw sewage discharge by decreasing the amount of mixed wastewater and stormwater flowing into combined sewers. Engineers and designers are looking for ways to improve the performance of green roofs and to understand parameters such as field capacity and time to onset of runoff. A better understanding of field capacity could be used to test hydrologic models that predict how much water a green roof could store under different conditions and to estimate how much runoff could be reduced.

In this project, a drip-type rain simulator is used to estimate field capacity of a plot of soil and sedum taken from the green roof on the Onondaga County Convention Center in Syracuse, NY. Three soil moisture sensors placed into the plot are used with different rain intensities to track the increase in soil water content during rain and the decrease following the end of the rain. The experimental results show that the field capacity of the Convention Center green roof is about 0.081 m<sup>3</sup> water / m<sup>3</sup> soil. This value is lower than expected and additional testing is underway. It is also shown that as rain intensity increases, time to onset of runoff decreases. With additional experiments to be conducted in Summer 2018, results of this work can be used by engineers to design and install green roofs with field capacities that complement average rain intensities and peak rain intensities and effectively reduce runoff.

### **KEYWORDS**

Rain Simulator, Green Roof, Field Capacity, Runoff

### **INTRODUCTION**

Green roofs play a significant role in urban stormwater management. They can store incoming precipitation, which reduces the amount of stormwater runoff flowing to combined sewers (Mentens et al. 2006). It is important to determine how much water a green roof can store during rain events in order to estimate how much runoff can be reduced. This information is important for developing improved engineered soil as well as to further advance hydrologic models like USEPA SWMM.

Rain simulators are used to produce different intensities of rain in well-controlled laboratory experiments. Operating a rain simulator with a small plot from a green roof can help

determine the performance of the green roof under various rain intensities. A drip-type rain simulator is used in these experiments to control rain intensity, drop size, and field conditions, such as slope of the roof (Bowyer-Bower and Burt, 1989).

Field capacity is an important parameter in hydrologic modeling and can be useful for simulating infiltration and evapotranspiration. The field capacity depends on soil texture, soil structure, and organic content and is measured in units of  $\text{m}^3 \text{water} / \text{m}^3 \text{soil}$  (Narasimhan, 2009). There are many definitions of field capacity, but for the purpose of this paper it can be described as the maximum volumetric soil water content held against the force of gravity after all excess water has been drained (Fazackerley and Lawrence, 2011). According to Veihmeyer and Hendrickson (1931), this value can be measured two days after a rain event in pervious soils.

This project utilizes soil moisture sensors that are inserted into a plot of the full depth of soil with vegetation (7.6 cm soil depth, plot area 35 cm x 58 cm) taken from the green roof on the Onondaga County Convention Center in Syracuse, NY. The plot is used with a drip-type rain simulator to determine field capacity of the green roof soil under three different rain intensities.

There are two main objectives of this project. The first is to determine the field capacity of a large, extensive green roof in a four-season climate in the Northeastern US using a rain simulator in a laboratory setting. This experimental result is compared to a theoretical value based on fundamental characteristics of the soil. The second objective is to determine how different rain intensities affect the time to onset of runoff. This research is important in preparing to use computer models to predict the hydrologic performance of this green roof in both cold and hot weather. The roof is well-instrumented to provide experimental data over a wide range of conditions for comparison with computer model results to improve our understanding of the hydrology of green roofs.

## METHODS

### How rain intensities were chosen

Rain event data were collected from the Convention Center green roof tipping bucket from 2015 to 2017 in order to determine the range in rain intensities to simulate. As seen in Figure 1, four mm/hr was chosen because it represents a peak rain intensity in the 50<sup>th</sup> percentile. Fourteen mm/hr was chosen because it is a relatively high peak intensity (80<sup>th</sup> percentile). Finally, an intensity of 81 mm/hr was chosen to examine the effects of extreme peak intensities (98<sup>th</sup> percentile).

Figure 1: Fraction of rain events on the Convention Center green roof from 2015 – 2017 with peak rain intensities less than the indicated value (N=373). Each rain event has a total accumulation of 0.1 mm or greater.

### Rain simulator and experimental setup

As seen in Figure 2, the rain simulator consists of a water source that feeds into a drip former box. There are small holes in the box for droplets to fall through. The plot from the green roof is placed underneath the box.

The rain simulator is calibrated directly before each experiment to ensure a constant and accurately measureable rain intensity. The first step in calibrating the rain simulator is to place a known volume of water in the drip former box and then allow additional water to flow into the box to exactly balance the droplets falling out below the box. A bucket is used to collect the droplets while the water in the box is monitored to ensure a constant volume. A specific intensity is attained by maintaining a calibrated constant volume in the drip former box. A greater water volume and thus greater height of water in the box will result in higher intensities. Smaller intensities are obtained by inserting small pieces of fish line into the holes in the bottom of the box.

Figure 2: Drip-type rain simulator with plot from Convention Center Green Roof in Syracuse, NY

Before the green roof plot is placed under the simulated rain, three soil moisture sensors are inserted at equal depths into the side of the plot. For two experiments (reaching 4 mm/hr and 81 mm/hr intensities), Campbell Scientific 615 soil moisture sensors were used. These sensors were calibrated with one new CS655 sensor, which has a  $\pm 3\%$  volumetric water content accuracy with manufacturer calibration. The 14 mm/hr experiment used three CS655 sensors. After a desired rain intensity is reached, the green roof plot is placed at a fixed distance below the drip former box at a 1% slope to mimic the slope of the green roof, and volumetric water content data are collected.

As the experiment continues, it is noted when runoff occurs. The plot is kept under a constant rain intensity until runoff becomes steady and volumetric water content has reached a constant value. At this point, the rain is stopped and the soil moisture sensors continue to collect data for 48 hours so that field capacity is determined. Evapotranspiration is assumed to be negligible because the plot is left in a dark basement laboratory, where relative humidity is expected to be high, while data are being collected.

### Calculation of field capacity based on soil characteristics

Dingman (2002) provides the following equation for field capacity:

$$\theta_{fc} = \phi * \left( \frac{|\psi_{ae}|}{340} \right)^{\frac{1}{b}} \quad (1)$$

where  $\theta_{fc}$  is the soil field capacity,  $\phi$  is the porosity,  $\psi_{ae}$  is the air-entry tension in cm, and  $b$  is the exponent describing the moisture characteristic curve. The data collected in the rain simulation experiments can be compared to this model.

## RESULTS

Figure 3 shows volumetric soil water content measured during a period of 48 hours for three rain intensities: 4 mm/hr, 14 mm/hr, and 81 mm/hr. The point shown in the first 5-hour period represents when runoff is first observed for each experiment. During each test, the water content increases during the simulated rain event, levels out once soil is saturated and rain is stopped, then gradually decreases until the decline can be considered negligible and field capacity is measured. The results of Figure 3 show that the water content in all three experiments reaches a maximum of around 0.12 when the soil is fully saturated and that the field capacity reached is about the same for the three intensities, as shown by the dashed lines, at 48 hours.

The findings presented in Table 1 show that the field capacities reached for the three intensities range from 0.069 to 0.088, averaging 0.081. Table 1 also indicates that as rain intensity increases, time to onset of runoff decreases.

Table 1: Field Capacity and Time to Onset of Runoff for Different Rain Intensities

Rain Intensities	4 mm/hr	14 mm/hr	81 mm/hr
Field Capacity	$0.086 \frac{m^3}{m^3}$	$0.088 \frac{m^3}{m^3}$	$0.069 \frac{m^3}{m^3}$
Time to Onset of Runoff	2 hours 42 minutes	1 hour 30 minutes	14 minutes

## DISCUSSION

As seen in Figure 3, there is a noticeable increase in soil water content during each simulated rain event. A greater rain intensity gives a sharper increase in water content. Figure 3 shows that after water content has reached a maximum value of 0.12, the curve remains at this value for a short time and rain is stopped. At this point, a gradual decrease in water content can be noted in the three graphs. All three plots show an initial steeper decrease directly after the rain is stopped followed by a more gradual decrease. At the time when the curve becomes less steep, percolation occurs and the water begins moving out of the large soil pores and is being replaced by air (Zotarelli, 2010). The water content curves continue to decrease as water slowly drains from the soil. After 48 hours, the drainage rate becomes negligible and field capacity is determined (Dingman, 2002). At this point, the large soil pores are filled with both air and water, and the smaller pores are still full of water (Brouwer et al. 1985). In general, green roof soil is made up of mostly large pore spaces rather than the small pore spaces that contribute to water retention at field capacity (Stovin et al. 2015). The mass median diameter of the soil particles at the Convention Center green roof is 4.0 mm, suggesting a similar size for pore spaces (Wu, 1987). The soil porosity is  $0.512 \frac{m^3}{m^3}$ .

The results in Table 1 show that the rain intensity does not seem to have an impact on field capacity. A particle size analysis of the green roof soil indicates the soil texture to be similar to sand, which provides parameter values used in Equation 1. From this equation, the predicted field capacity of the Convention Center green roof is 0.17. This value is also smaller than the typical value of 0.3 noted by Jarrett (2009), although roughly double the value measured in the current work. There is some uncertainty in the value generated by the equation. Further analysis of the green roof soil texture will be completed in future work.

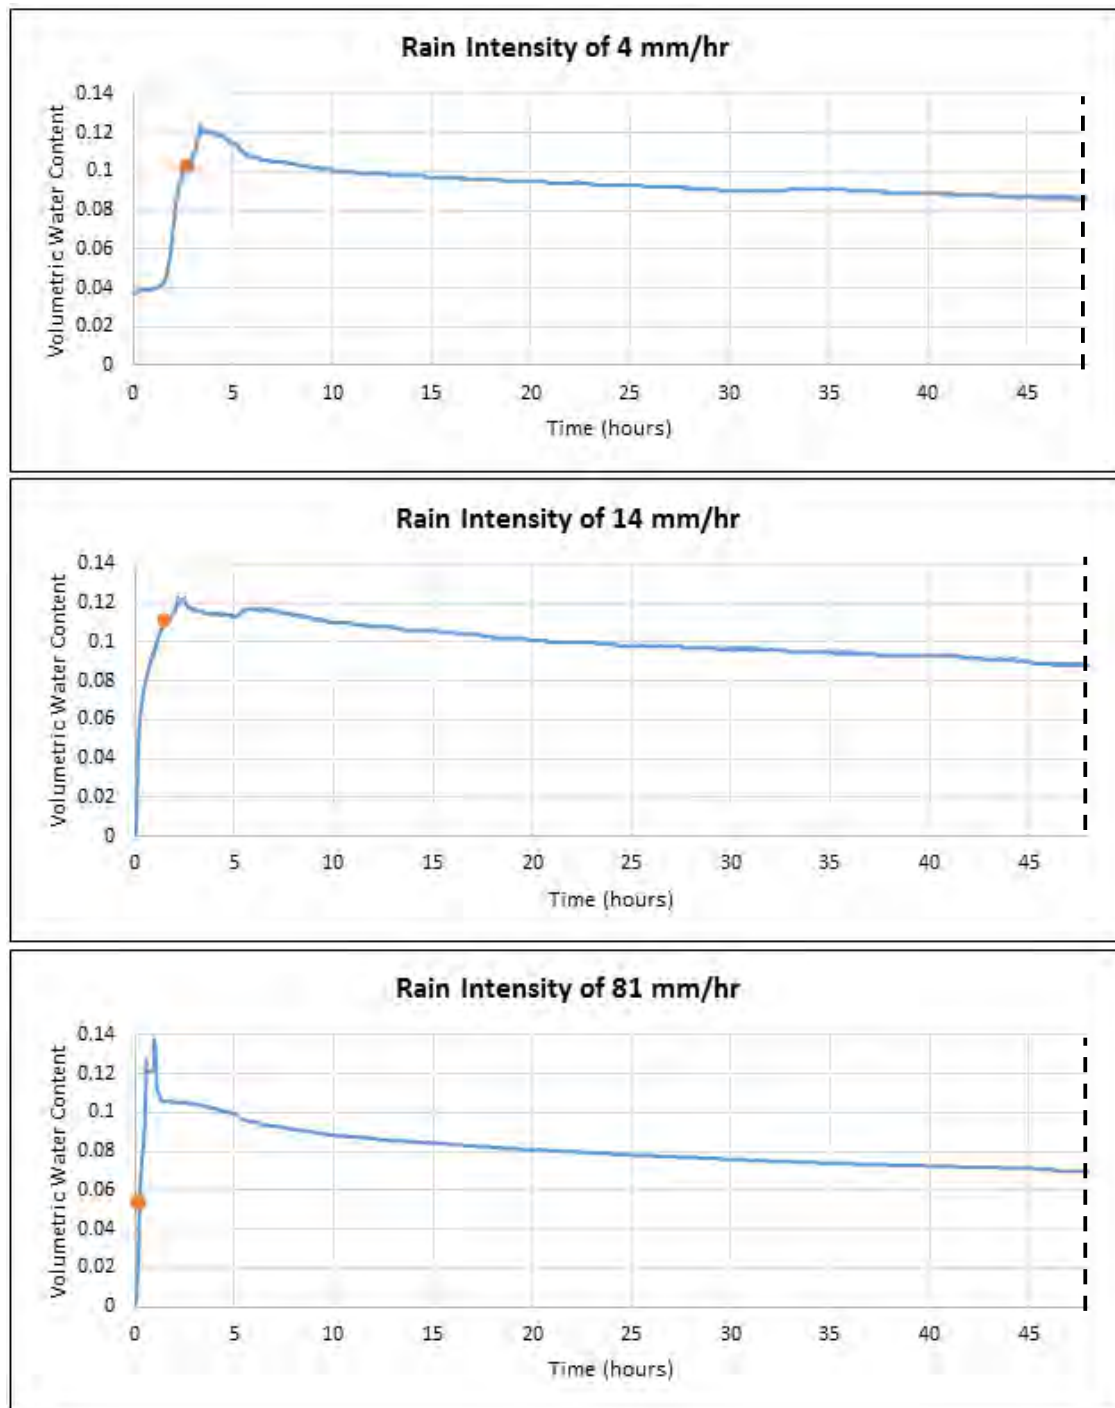

Figure 3: Volumetric Water Content vs. Time for Rain Intensities of (a) 4 mm/hr (b) 14 mm/hr, and (c) 81 mm/hr

The average field capacity of a green roof is said to be about 0.3 (Jarrett, 2009). Therefore, the field capacity measured in this project is low. Experiments are currently underway to investigate this low value.

## CONCLUSIONS

A critical parameter of green roof models is the estimation of field capacity. The findings of this work indicate that the field capacity for the green roof on the Convention Center in Syracuse, NY is about 0.081. This result can be incorporated into green roof models to predict maximum soil storage capacity under various conditions. The results of this project also show that the time to onset of runoff decreases as rain intensity increases. This information will help green roof designers improve the performance of engineered soil and estimate how much runoff can be reduced. In addition, the use of a rain simulator and soil moisture sensors can be valuable for collecting data on a small scale for a green roof that does not have a monitoring system installed. This can be valuable for modeling green roof performance in a variety of climates.

## ACKNOWLEDGMENT

This work was supported in part by NSF grant #1444755, Urban Resilience to Extremes Sustainability Research Network (UREx SRN), by the NSF EMPOWER NRT program, and by the Syracuse University Water Fellowship. The authors acknowledge Onondaga County Department of Facilities Management, especially Han Phan and Archie Wixson, for the use of the Convention Center green roof. The authors also acknowledge the help of Joshua Saxton and Yang Hu at Syracuse University.

### **ABSTRACT**

The natural lighting of buildings plays an important role in creating a comfortable indoor light environment and reducing the energy consumption of artificial lighting. Teaching buildings have special requirements for the indoor light environment. Classroom glare, corridor backlit, and low natural illumination in corridor are light pollution problems easily appear in teaching building, which cannot be ignored in the design of teaching building. Regarding the issues above, the paper took the Arts and Sciences Building of Xinyang Normal University as an example, through the architectural modeling, space forms, facade effects and other features, used VELUX simulation software to simulate the illuminance and daylighting parameters of different sunroofs and provided solutions for classroom glare and corridor lighting. Ultimately, the paper analyzed the building lighting energy saving schemes based on regional climate and environment, and found out the best balance point for the energy saving design of lighting and thermal environment, meanwhile, provided valuable and practical reference for lighting design of corridor skylights in the region.

### **KEYWORDS**

Teaching building, Natural lighting, Design strategy, Hot-summer and Cold-winter

### **INTRODUCTION**

The architect Ludwig Mies Van der Rohe said: "The history of architecture is the history of human struggle for light, the history of the window." The lighting discussed in the article refers to the use of direct, reflective or other aids to provide natural light to the interior of a building.

It is an important energy-saving means to optimize the design of lighting and shading for public buildings with different functions. A good architectural light environment can improve the visual comfort of indoor personnel, which also has a very important influence on people's physical and mental health. The teaching buildings have many problems in natural lighting, such as large lighting power consumption and glare which greatly reduce the quality of indoor light environment.

For the study of the top lighting of public buildings, most of them are concentrated in the skylight design for the space with large depth. It also has many research methods and design strategies on indoor glare. In specific climate such as hot-summer and cold-winter area, for the special lighting issues of teaching building including corridor skylight design, glare of side windows and corridors lack of systematic research and solutions. Computer simulation is been used to analyse the influence of inner corridor various factors on the natural lighting (Zhifang Zhang, 2011). Hao Xie summarized several design points of the public building skylight. How to put forward the corresponding design technology strategy for the special needs of education building in light environment is the key to solve the indoor natural lighting problem.

## METHODS

### Educational building lighting standards

*Architectural lighting design standards (GB50033-2013)* stipulated that the corridor lighting of the teaching building should not be lower than the standard value of the lighting level V. In this project, the illuminance of the area with roof lighting shall be 75lx, and the lighting factor shall be 0.5%.

### Description of project

The comprehensive building for liberal arts and sciences to be built is in Xinyang Normal University, including the roof skylight of Building A1, the corridors of Buildings D and F, and the side windows of the classroom. The Building A1 has 12 floors, and the corridors are illuminated by both sides of the windows. To achieve the Architectural Lighting Standard, increase indoor comfort, 10-12 layers will add the skylight to meet the indoor light environment requirements through the reasonable design of natural lighting. The side windows in classrooms and corridors glare easily when it's sunny. Therefore, effective shading equipment is needed to avoid glare and create a good learning environment for students.

Figure 1. The model of Arts and Sciences Building

### Specific design content

#### Simulation software selection and parameter setting

The solar radiation conditions are determined according to the location of the area. In the corridor lighting simulation, set the height of the reference surface to 1.5m, and the selected weather conditions for the winter solstice cloudy day. VELUX natural lighting simulation software is used to simulate the illuminance, daylighting factor and other parameters of different skylights, in order to compare their lighting effects.

#### Corridor skylight design

The design of the skylight is based on the building lighting standards in the area, and considering the balance of skylight lighting and heat collecting effects. Through simulation optimization, the skylight design schemes suitable for the teaching corridor of the area are analysed showed in Table 2.

Table 1. Advantages and disadvantages on skylights

Type of top light	Advantages	Disadvantages
Flat skylight	High lighting efficiency	Easy to glare, higher heating load
Rectangular skylight	Uniform daylighting, easy on ventilation	Complex roof structure
zigzag skylight	No glare	Low lighting efficiency in winter

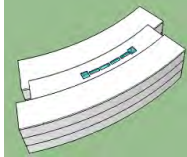

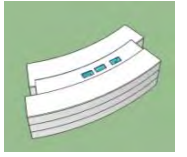

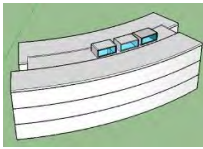

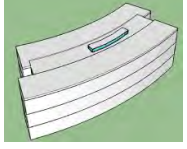

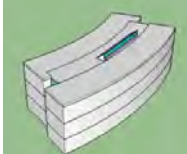

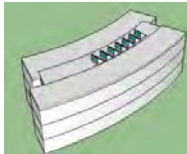

Figure 2. Position of corridor skylight

Table 2. Design of the corridor skylight.

Type of skylight	Design 1		Design 2	
	Graphic	Design parameter	Graphic	Design parameter
Flat skylight		Total area: 20 m <sup>2</sup> Two pieces 2×2 m <sup>2</sup> Four pieces 1×3 m <sup>2</sup> Area ratio of window to floor: 1/23		Total area: 24 m <sup>2</sup> Three pieces 2×2 m <sup>2</sup> Area ratio of window to floor: 1/19
Rectangular skylight		North and south Total area: 52.3 m <sup>2</sup> Area ratio of window to floor: 1/8.8		Window all around Total area: 32.42 m <sup>2</sup> Area ratio of window to floor: 1/14.3
zigzag skylight		Total area: 28.42 m <sup>2</sup> Incline: 40° Interior surface: White latex paint		Total area: 24.71 m <sup>2</sup> Incline: 40° Interior surface: White latex paint

### Corridor glare design research

Due to the climate characteristics of the hot-summer and cold-winter areas, shading facilities are required to not only cover the sun radiation in the summer, but also allow the solar radiation to enter the interior as much as possible in winter. Therefore, The selection of shade strategies should be based on the climate characteristics of the area.

Figure 3. a) Corridor plan in Building D , b) Classroom plan in Building F

## RESULTS

### Simulation result of corridor skylight

The VELUX simulation software was used to simulate the mentioned skylight design scheme, and the minimum illuminance during the day and daylighting factor values under different skylight forms were obtained. The simulation results are shown in the Table 3.

Table 3. Corridor skylight lighting parameters simulation results

Type of skylight		Flat skylight	Rectangular skylight	zigzag skylight
Plan 1	Minimum illuminance during the day (lx)	65.1	17.0	31.0
	Lighting factor (%)	1.1	0.2	0.6
Plan 2	Minimum illuminance during the day (lx)	84.6	13.8	21.4
	Lighting factor (%)	1.3	0.2	0.4

Figure 4. Illuminance during cloudy winter solstice. a) Plan 2 of Flat skylight, b) Plan 1 of zigzag skylight, c) Plan 2 of Rectangular skylight

### Shading measures

After simulating the natural illumination in classrooms and corridors, it is found that the classroom relies on one side window to light has different illuminance values. The area close to side window is brighter. On the contrary, the area farther from the side windows is darker. The indoor light environment is not ideal. It is clear that corridor will generate backlight without shading measures. The simulation results are shown in the Figure 5.

Figure 5. Illuminance during summer solstice day. a) Corridor, b) Classroom

According to the characteristics of building space, several applicable shading strategies are selected and optimized.

### Higher lighting side window

It is the side window set above the sight line that can be used in corridors and classrooms to improve the illumination inside. According to *Architectural lighting design standards(GB50033-2013)*, The total area of the windows on both sides in corridors is

determined to be  $6.3 \text{ m}^2$ , The size of each side window is  $2\text{m} \times 1.6\text{m}$ , and 1.9 meters above the ground.

### Reflector

It can provide more natural light for the interior space while preventing excessive direct light from entering the room which may create glare. The addition of reflectors can significantly improve the uniformity of reference surface illumination. Indoor illumination uniformity from small to large is arranged as: non-reflective plate < internal reflector < external reflector < internal and external reflector.

Figure 6. a) The principle of reflector, b) Separately controlled venetian blinds.

### Venetian blinds

The user adjusts the appropriate blade angle according to different seasons to maximize the sunlight, so that the interior space of the classroom gets sufficient diffuse light. For buildings that do not have separate lighting windows and landscape windows, separately controlled blinds can be used to maximize the advantages of the upper and lower windows. Blinds used for outdoor shading are usually made of galvanized steel, anodized aluminum or colored aluminum and plastic (PVC). For ease of adjustment, the width of the external shading blade is usually about 100mm, and the pitch of the blade is set to 90mm (Wei Yu, 2012).

Venetian blinds are mainly horizontal and vertical. Research test findings shows venetian blinds of different rotation angles can block sunlight at different height angles and directions.

Table 4. The commonly setting method of venetian blinds

Venetian from	Rotation method
Horizontal blinds	Parallel to normal (Level $0^\circ$ )
	Rotate $45^\circ$ counterclockwise (Level $45^\circ$ )
Vertical blinds	Parallel to normal (Vertical $0^\circ$ )
	Rotate $45^\circ$ counterclockwise (Vertical $45^\circ$ )
	Rotate $45^\circ$ clockwise (Vertical $-45^\circ$ )

### DISCUSSIONS

From the above simulation results, it is found that when choosing plan 2 of plat skylight whose area is  $24\text{m}^2$ , the natural illumination of the corridor can meet the requirements of the lighting of the whole year. Both rectangular skylight designs are unable to meet the requirements of natural light throughout the year for the three-tier walkway. However, their windows open around to avoid glaring, moreover, they are easy to open that promote natural ventilation and reduce mechanical ventilation and cooling energy consumption. The skylight area used in the two designs of the zigzag skylight is the smallest area, and the simulation

results do not meet the requirements. Due to the limitation of the skylight design position, it is difficult to increase its area. The zigzag skylight design with a window angle of 40° and interior surface of white latex paint is slightly lower than the requirement. The winter illumination may be slightly lower, but the zigzag skylight is easy to open that can improve indoor ventilation.

For some public buildings such as office and teaching buildings, the choice and design of shading measures, if the main consideration is summer shade, an outdoor reflector is generally installed to block the light with high solar elevation angle in summer and reduce building cooling load. At the same time, it reflects light to interior ceiling and enhances secondary reflections. When using a reflector to introduce light, it can also be used together with a reflective ceiling to form a light guide system.

Through the analysis of corridor skylight design and the side window shading measures of the project, the application technology of the teaching building light environment in the hot-summer and cold-winter area can be obtained and is summarized as follows.

- a) The flat skylight has the best lighting effect. If the natural ventilation in the corridor is good, the skylight can be selected. The rectangular skylight and the serrated skylight can be selected to improve the natural ventilation in the corridor.
- b) It is more suitable to adopt higher side lighting window and vertical blinds in order to solve the problem of backlighting in corridors. For the east side window of the corridor, it can be set with vertical blinds rotated at a certain angle to avoid direct sunlight in the morning which may generate backlighting, and to make the corridor brighter.
- c) In order to solve the problem of classroom glare, you can choose high side windows, reflectors and venetian blinds.

## CONCLUSIONS

Improve the natural lighting quality of teaching buildings is the key to creating a good learning environment and improving people's visual comfort. Through the rational use of auxiliary equipment for daylight and sunshade, natural light can be effectively used and controlled, which can not only achieve the purpose of energy conservation, but also can produce distinctive architectural lighting effects. The paper took the Arts and Sciences Building of Xinyang Normal University as an example, with the method of computer software simulation, analysed the lighting design strategy of the corridor in teaching building and shading measures applied to avoiding glare of the corridors and classrooms, ultimately concluded the light environment design technology strategy suitable for the teaching building in the hot-summer and cold-winter area which supported the light design of teaching building in that area.

## **Analysis of thermal bridges in insulated masonry walls: a comparison between vacuum insulated panels and expanded polystyrene**

Adrian Bucur<sup>1</sup>, Ligia Moga<sup>1</sup>

<sup>1</sup>Faculty of Civil Engineering/Technical University of Cluj-Napoca, Romania

\*Corresponding emails: [bucuradrian90@yahoo.com](mailto:bucuradrian90@yahoo.com), [ligia.moga@ccm.utcluj.ro](mailto:ligia.moga@ccm.utcluj.ro)

### **ABSTRACT**

The paper presents a comparative study between the thermal performances of a couple of masonry walls with no insulation and then insulated with vacuum insulation panels and expanded polystyrene. The research purpose is to demonstrate the superior thermal performance of the vacuum insulation panels compared to common thermal insulation, in initial state and even after 25 years in service. It also provides the steps to determine the effective thermal resistance of the buildings elements insulated with vacuum insulation panels, considering both local and geometric thermal bridges. Results emphasize that even after 25 years in use, the walls insulated with vacuum insulation panels with reduced thickness possess a greater thermal performance than that of the walls insulated with expanded polystyrene with common thickness. This is one of the reasons for which this material should be improved and developed further for the future buildings envelopes.

### **KEYWORDS**

vacuum insulation panels, thermal bridges, steady-state, effective thermal resistance

### **INTRODUCTION**

Vacuum insulation panels are composite nano insulation materials, consisting of a nanoporous core encapsulated by a sealing envelope with multiple functions such as airproofing, waterproofing and radiation thermal transfer blocking. Their thermal conductivity in initial state is 4 mW/(mK), about 8-10 times lower than those of the common thermal insulation materials such as expanded polystyrene or mineral wool. Also, even if the envelope is damaged and the panel is filled with air, its thermal conductivity is the same as for the core material, i.e. 20 mW/mK for fumed silica, which is still approximately half of that of the expanded polystyrene.

In this paper, a comparative study is made between the thermal performances of several brick masonry walls without insulation and then thermally insulated with expanded polystyrene (EPS) and vacuum insulation panels (VIP), in different thicknesses. For each situation there are determined the effective thermal resistances, taking into account the walls thermal bridges by computing the related linear heat transfer coefficients. There are considered two types of thermal bridges given by the walls corner intersection with a concrete column (see Figure 1) and also by the walls intersection with a balcony slab (see Figure 2). At the same time, there are computed the effective thermal conductivities of the VIP, considering the local thermal bridges developed on their edges. These thermal bridges are analysed and computed in several other studies (i.e. Tenpierik and Cauberg, 2010; Sprengard and Holm, 2014).

The layers of the analysed elements may be observed in the following figures. A levelling rendering is applied on the masonry walls and then the VIP are installed. The panels are protected on their exterior side by a layer of EPS and a decorative rendering. The mounting of

the panels on the levelling layer and of the EPS on the panels is made by adhesion. The balcony slab has a width of 1.00 m and is insulated both at its inferior and superior side.

Figure 1. Wall corner intersection - i) insulated with EPS, ii) insulated with VIP

Figure 2. Balcony slab-wall intersection - i) insulated with EPS, ii) insulated with VIP

The analysis is made for the following situations: the walls and balcony slab without thermal insulation, insulated with EPS having a thickness of 10 cm, 20 cm and 30 cm and insulated with VIP of 2 cm, 3 cm and 4 cm, the latter being analysed both in initial state and also after 25 years in service. The maximum chosen thickness of the vacuum insulation panels is the highest one for the adhesion procedure. For larger thicknesses, the material requires a mounting system which develops supplementary local thermal bridges. In the case of balcony slab - exterior wall intersection where EPS is the analysed insulation, on the superior side of the exterior cantilever slab it is considered a layer of extruded polystyrene with a thickness of 15 cm.

## METHODS

First of all, there is computed a mean effective thermal conductivity of the VIP. The determination considers the thermal bridges developed on the panel edges using a method from literature (Tenpierik and Cauberg, 2007).

The design value of the centre-of-panel thermal conductivity is  $\lambda_{cop}=4$  mW/(mK) in initial state after production and  $\lambda_{cop}=8$  mW/(mK) after 25 years in service, for the panels with envelopes consisting in metallised polymer films (MF) (Heinemann et al, 2010). The difference is given by an inherent decrease of the material thermal performance in time due to the increase of the water content and internal pressure. Two types of panel envelope are considered in analysis: MF2 having a thickness of  $t_f=84\mu\text{m}$  and a thermal conductivity of  $\lambda_f=0.54$  W/(mK) and MF3

having a thickness of  $t_f=97\mu\text{m}$  and a thermal conductivity of  $\lambda_f=0.39 \text{ W/(mK)}$  (Berge and Johansson, 2012). The panels have no gaps or seams between them, therefore their possible influence on the edge thermal bridge is not considered. Having this data, there are computed the linear thermal transfer coefficients  $\psi_{VIP}$  related to the thermal bridges developed on the panel edges. Then, there are determined the effective thermal conductivities of the VIP having the following dimensions:  $300\times 600 \text{ mm}$ ,  $600\times 600 \text{ mm}$  and  $600\times 1500 \text{ mm}$  and an average value is calculated. The computation is made with the following formula:

$$\lambda_{VIP.eff} = \lambda_{cop} + \frac{\psi_{VIP} \times d \times P}{A} \quad [\text{W/(mK)}] \quad (1)$$

where:  $\lambda_{VIP.cop} [\text{W/(mK)}]$  is the design value of the centre-of-panel thermal conductivity,  $\psi_{VIP} [\text{W/(mK)}]$  is the linear thermal transfer coefficient developed on the panel contour,  $d [\text{m}]$  is the panel thickness,  $P [\text{m}]$  is the panel perimeter and  $A [\text{m}^2]$  is the panel area.

A next step in the analysis is the determination of the linear thermal transfer coefficients  $\psi$  related to the considered walls thermal bridges: walls corner and wall-balcony slab intersection. First of all, the unidirectional thermal resistance of the wall is determined:

$$R_{unidir} = \frac{1}{\alpha_{int}} + \sum_i \frac{d_i}{\lambda_i} + \frac{1}{\alpha_{ext}} \quad [\text{m}^2 \cdot \text{K/W}] \quad (2)$$

where:  $d_i [\text{m}]$  is the layer  $i$  thickness,  $\lambda_i [\text{W/K}]$  is the layer  $i$  thermal conductivity,  $\alpha_{int}$  and  $\alpha_{ext} [\text{W/m}^2 \text{K}]$  are the superficial heat transfer coefficients at the interior and exterior surface of the wall

Table 1. Thermal conductivities of the materials used (C107/3, 2008)

Material	$\lambda [\text{W/(mK)}]$
Brick masonry	0.55
Reinforced concrete	1.74
Renderings: interior, exterior, leveling, protection	0.93
Screed floor, sloped floor	0.93
Decorative rendering	0.7
Expanded polystyrene	0.044
Extruded polystyrene	0.04

The determination of the linear heat transfer coefficients  $\psi$  is based on a two-dimensional steady-state modelling in Therm software in accordance with EN ISO 6946:2017. The geometric models were designed according to the details presented in Figure 1 and Figure 2, for each layer being given its corresponding thermal conductivity. Also, the models were built taking into account the recommendations of the C107/3 standard which states that the cross section limits have to be placed at minimum 1.20 m relative to the central element. The interior temperature is considered  $T_i=20^\circ\text{C}$  and the external one  $T_e=-18^\circ\text{C}$ . The walls superficial heat transfer coefficients are  $\alpha_{ext}=24 \text{ W/m}^2\text{K}$  (exterior side) and  $\alpha_{int}=8 \text{ W/m}^2\text{K}$  (interior side). The limits of the cross-sectioned elements (wall, interior slab) are considered to be adiabatic. After the input data is introduced, the software generates the discretization mesh, computing the temperature and thermal flow values in each of its elements, using the Finite Element Method. The model computation is characterised by the following parameters: the maximum dimension of the grid elements is 25 mm, the maximum number of iterations is 50 and the maximum computation error is 1%. Using the program output data, the linear thermal transfer coefficients are computed with the following formula:

$$\psi = \frac{l_{therm}}{R_{therm}} \frac{B}{R_{unidir}} [W/mK] \quad (3)$$

where:  $l_{therm}$  [m] is the thermal bridge length,  $R_{therm}$  [ $m^2K/W$ ] is the output  $R$ -value from Therm,  $B$  [m] is the effective dimension of the linear thermal transfer coefficients  $\psi$  and  $R_{unidir}$  [ $m^2K/W$ ] is the unidirectional thermal resistance

Finally, using the computed linear heat transfer coefficients, the effective thermal resistances of the walls are calculated for a 2 story building in accordance with EN ISO 10211:2017. Each level is composed of four walls having the same geometrical characteristics: two walls of  $3m \times 3m$  and two walls of  $3m \times 6m$ . Also, the two stories are separated by a reinforced concrete slab with a balcony cantilever on the building contour, having a width of 1m. The balcony slab is at an inferior level compared to the interior slab, according to the analysed details. The layers and thicknesses of the walls and slabs correspond to the ones presented before (see Figure 1 and Figure 2). The analysis is made for two inferior level walls and two superior level walls, the other four walls of the system having the same characteristics. Each wall has a corner thermal bridge for each of their lateral margins. The inferior level walls have a thermal bridge at their superior edge given by the intersection with the balcony slab. In the same way, the superior level walls have a thermal bridge at their inferior edge. The free margins (section margins) of the walls are considered to be adiabatic.

## RESULTS

Table 2. Linear heat transfer coefficients  $\psi$  related to the panel edges thermal bridges. Effective thermal conductivities  $\lambda$  of the panels considering these thermal bridges

Panel dimensions [mm]	Envelope type	$\psi_{VIP}$ -initial- [mW/(mK)]	$\psi_{VIP}$ -25 years- [mW/(mK)]	$\lambda_{VIP,eff}$ -initial- [mW/(mK)]	$\lambda_{VIP,eff}$ -25 years- [mW/(mK)]
300 x 600 x 20	MF2	1.33	1.25	4.265	8.250
300 x 600 x 20	MF3	2.05	1.93	4.409	8.386
300 x 600 x 30	MF2	0.95	0.91	4.284	8.273
300 x 600 x 30	MF3	1.47	1.41	4.442	8.423
300 x 600 x 40	MF2	0.73	0.71	4.294	8.284
300 x 600 x 40	MF3	1.15	1.12	4.461	8.448
600 x 600 x 20	MF2	1.33	1.25	4.177	8.167
600 x 600 x 20	MF3	2.05	1.93	4.273	8.257
600 x 600 x 30	MF2	0.95	0.91	4.189	8.182
600 x 600 x 30	MF3	1.47	1.41	4.295	8.282
600 x 600 x 40	MF2	0.73	0.71	4.196	8.189
600 x 600 x 40	MF3	1.15	1.12	4.307	8.299
600 x 1500 x 20	MF2	1.33	1.25	4.124	8.117
600 x 1500 x 20	MF3	2.05	1.93	4.191	8.180
600 x 1500 x 30	MF2	0.95	0.91	4.132	8.127
600 x 1500 x 30	MF3	1.47	1.41	4.206	8.197
600 x 1500 x 40	MF2	0.73	0.71	4.137	8.133
600 x 1500 x 40	MF3	1.15	1.12	4.215	8.209

According to these results, in the following computations a mean effective thermal conductivity is considered:  $\lambda_{VIP,eff,0} = 4.25$  mW/(mK) – for initial state;  $\lambda_{VIP,eff,25} = 8.25$  mW/(mK) – after 25 years in use.

c) balcony slab-wall intersection – superior level edge

Figure 4. Average effective thermal resistance of the analysed walls

## DISCUSSIONS

The results regarding the thermal bridges developed on the panel contour  $\psi_{VIP}$  validate the findings from another studies (Tenpierik and Cauberg, 2007; Sprengard and Holm, 2014), for the panels having  $\lambda_{cop}=4$  mW/(mK), with MF type envelope and with no gaps or seams between them. One may observe that the thermal bridges developed on the VIP edges after 25 years in service are slightly lower (between 2.60%-6.40%) than those of the new panels, a phenomenon which is more prominent as its thicknesses are lower (see Table 2). At the same time, the envelope type influence the panel thermal performance. Between two panels with same geometrical characteristics, the one with MF2 type foil has a lower linear thermal transfer coefficient with about 54-58% than the one with MF3 type foil. Another aspect revealed by the results is that the linear heat transfer coefficients related to the panels edges decrease with the increase of its thickness.

As a consequence of these local thermal bridges, the panels effective thermal conductivity is greater for those with MF3 type foil, compared to that of those with MF2 type (see Table 2). The difference raises with the increase of the panel thickness and decrease with the increase of the panel 2D dimensions: for 300×600mm – difference of 1.5-2%, for 600×600mm – difference of 1-1.5% and for 600×1500mm – difference of 0.8-1%. At the same time, the panel effective

thermal conductivity is greater than the centre-of-panel thermal conductivity with 0.124-0.461 mW/(mK) for the new panels and with 0.117-0.448 mW/(mK) after 25 years in service.

The thermal bridges of the analysed details are lowered by the use of thermal insulation (see Table 3). In most cases, the thermal bridges of the wall corner detail ( $\psi_1$ ) with VIP are lower than those of the same detail with EPS. Also, the thermal bridges at the inferior level edge of the balcony detail ( $\psi_{2,1}$ ) with VIP have similar values to those with EPS. At the same time, the thermal bridges at the superior level edge of the balcony detail ( $\psi_{2,2}$ ) with VIP have a rather constant value, regardless of their thickness or age and they have higher values compared to the details insulated EPS.

The effective thermal resistance of the walls insulated with VIP decrease with about 35% after 25 years in use, compared to their initial state, as shown in figure 4. However, one should note that even in this situation, the thermal performance of VIP is comparable to that of the EPS, but for a reduced insulation thickness of approximately 80%. The walls insulated with the panels having a thickness of 4 cm develop an increased effective thermal resistance which recommend this solution for the higher thermal efficiency building systems.

## CONCLUSIONS

One of the directions in this research field is the continuous improvement of the existing thermal insulation solutions and the development of new ones in order to increase the overall thermal performance of the buildings. In this regard, the VIP may represent a leap forward, considering its superior thermal performances.

The study reveals that even the VIP develop larger thermal bridges and their performance decrease over time, the building elements insulated with this solution have a superior effective thermal resistance compared to common solutions such as EPS. Therefore, the VIP may be a suitable replacement for the traditional insulations, especially when there is required a reduced insulation thickness.

### ABSTRACT

Applications of PCM-to-air heat exchangers (PAHXs) were discussed in literature for free cooling application due to their latent thermal storage abilities. This paper aims to justify the generalization of a numerical model of PAHX and to compare the thermal performance of two different configurations of PAHX system. A generalized numerical model is developed and validated based on general apparent heat capacity method. The validation results show good agreement of the generalized approach in terms of averaged error with the experimental data. Model potential and limitations are discussed, and further recommendations are proposed to improve model accuracy. The paper ensures the significant potential of a PAHX ventilated façade configuration in free cooling applications.

### KEYWORDS

Latent thermal storage, PCM-to-air heat exchangers, phase change materials, free cooling.

### INTRODUCTION

The general awareness of using latent heat thermal energy storage (LHTES) systems has been growing widely due to their increased storage capacity, system efficiency and durability. Phase Change Materials (PCMs) are being used in building applications due to their latent thermal storage abilities. One of the efficient passive cooling concepts is utilizing night cold energy to be re-supplied at hot period of the next day; this needs involving a thermal storage process. Integrating this free cooling concept with a LHTES system can provide an acceptable indoor environment for building occupants. Applications of PCM-to-air heat exchangers (PAHXs) have been widely discussed in literature for free cooling applications. Those applications can be classified into two main configurations: system equipment as a part of ventilation systems, and ventilated facades as improved building envelopes. Both types involve convective heat transfer process between air and PCM.

It can be inferred from literature of integrated PAHX ventilation system configuration that maintaining supplied air temperature that achieves indoor thermal comfort is a current system limitation. Several studies reported that insufficient difference between phase change temperature (PCT) range and inlet temperature during charging affects system storage abilities and overall thermal performance (De Gracia et al. 2015; Waqas and Kumar, 2011). Using a hybrid system of PAHX and a direct evaporative cooling unit, Panchabikesean et al. (2017) experimentally found that the hybrid system increased the cooling potential by reducing the inlet air temperature during PCM solidification. Some studies confirmed the potential of using multiple PCMs in free cooling systems to satisfy workability under high inlet temperatures (Mosaffa et al. 2013). Regarding long-term applications, applying same PCM affects the annual system performance due to changing of ambient temperature profiles in various seasons, consequently, standalone PAHX system cannot maintain indoor thermal comfort all year-round; thermal management is required in such cases (Osterman et al. 2015). On the

other hand, PAHX ventilated envelope configuration showed some achievements in free cooling applications, De Gracia et al. (2013) showed that direct free cooling had a high potential in reducing the cooling loads, however, insufficient difference between night temperature and PCT during solidification results in low system energy storage. Some other studies assured the system cooling potential when combined with night ventilation strategy (Jaworski, 2014; Evola et al. 2014, El-Sawi, et al 2013).

It can be inferred from the literature that PAHX ventilated façade configuration has lower performance than the ventilation system configuration. This paper investigates the performance of the two configurations of PAHXs. By monitoring system outlet air temperature, the current work investigates PAHX system parameters of both configurations that achieve same thermal performance. The main goal of this paper is the justification of a general numerical model of PAHX to be used efficiently in both configurations by designers and building developers. Also, this paper investigates the effect of numerical model generalization on the overall PAHX thermal behavior.

## METHODS

In this study, a generalized numerical model for PAHX is proposed and validated based on developments of an earlier version of the model. The model proposes an energy balance approach over number of control volumes to represent the system three media of heat transfer: air flow, encapsulation material and PCM. Full model nodal discretization and heat balance equations are described in detail in (Stathopoulos et al. 2016). Expression of latent heat storage during the phase change of the PCM is achieved by monitoring the change of heat capacity ( $c_p$ ) values over the temperature range for each control volume. This apparent  $c_p$  method assumes fixed rate of heating/cooling during the latent heat transfer process. An earlier version of the numerical model was proposed by Stathopoulos et al. (2016) based on an improved apparent  $c_p$  method that proposes multiple values of  $c_p$  due to different heating/cooling rates. This method is based on measurements data using Differential Scanning Calorimetry (DSC). Using a developed version of model, this study is performing a comparison between general apparent  $c_p$  model and improved apparent  $c_p$  model proposed by Stathopoulos et al. (2016) to test the thermal performance of the two configurations of PAHXs: integrated ventilation system configuration, and ventilated envelope configuration.

## Model potential and limitations

The model has good potential in terms of predicting the outlet air temperature due to the accurate evolution of  $c_p$  values over temperature. PCM thermal conductivity, density and volume are interpolated over temperature through phase change range. The model can auto-generate air density value according to air temperature. However, the early version of model discussed by Stathopoulos et al. (2017; 2016) showed some limitations in terms of its dependency on experimental data. Inlet air temperature and volume flow rate were represented to model every time step; these values were obtained from experimental data. Also, both cooling and heating curves for  $c_p$  were determined based on different cooling/heating rates of DSC measurements. Although these procedures provided better model accuracy, the dependency on experimental data obstructed the model applicability for broad investigations instead of single case study. Moreover, the model used a fixed input value for convective heat transfer coefficient,  $h$ . As mentioned by authors, the model also neglected the natural convection inside PCM, and long-wave radiation heat transfer between PCM plates. In this paper, further developments are made in terms of generalization of the model to be applicable for broad investigations. Also, the developed model promotes the applications of different PAHX configurations.

### Justification of general apparent heat capacity method

Heat capacity value is a key factor in model accuracy. Stathopoulos et al. (2017) proposed the improved apparent  $c_p$  model using the experimentally obtained values of  $c_p$ , shown in figure 1-a, as model input. They also divided the system to three consequent parts (inlet, middle and outlet) assigning different cooling/heating curve for each part. Towards model generalization, the  $c_p$  values are reconsidered as average values for each curve maintaining the same approach of multiple curves for  $c_p$ , as presented in figure 1-b. In this case, an average value of  $c_p$  is introduced for each curve. Moreover, this approach still requires knowledge and access to the measured values of  $c_p$  to calculate the average values. Towards tackling the model limitation of obstructing the broad applications, current model developments assume having two curves for heating and cooling, as shown in figure 1-c. This approach assumes one fixed rate for cooling/heating along the system, which is the original assumption of apparent heat capacity method. This assumption was previously discussed by Stathopoulos et al. (2017) and was claimed to have less accuracy than the improved apparent  $c_p$  method due to the differences in heat transfer rate along the PCM plate. Despite the expected less accuracy, this approach can be beneficial to formulate a platform for system designers based on data sheets of  $c_p$  cooling and heating curves provided by PCM suppliers. In this paper, investigations for the general apparent  $c_p$  approach will be conducted to justify its acceptability and validity with experimental data.

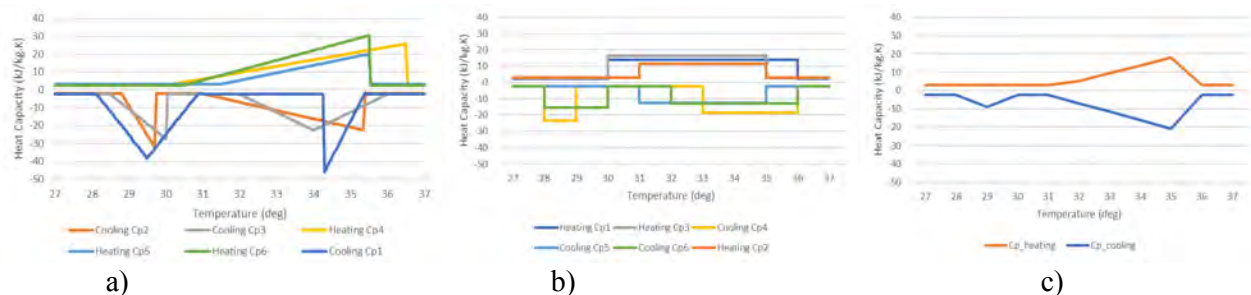

Figure 1. Heat capacity heating and cooling curves for PCM Microtek 37D a) improved apparent  $c_p$  method, b)  $c_p$  average values, c) general apparent  $c_p$  method

### Experimental installation

The experimental investigation of PAHX ventilation system type (configuration 1) was illustrated in-detail in (Stathopoulos et al. 2016). A flat plated encapsulation of 16 aluminum PCM plates were investigated under various airflow rates. Microtek 37D paraffin was used as PCM (melting temperature 37.0°C and latent heat of 230 kJ/kg). The total dimensions of the heat exchanger were 1.05m in length, 0.75m in width and 0.25m in height; it contained 31.8kg of PCM. Airflow and air temperature were actively regulated and controlled to the desired velocity and temperature. Inlet temperature varied from around 44.0°C during melting phase and 26.0°C during solidification phase. The available experimental data are for around 15 hours (1.0 hour introductory – 9.0 hours for melting – 5.0 hours for solidification). Sensors were installed within the heat exchanger to measure: PCM and encapsulation surface temperatures in three locations (inlet, mid, and outlet parts), inlet and outlet air temperatures, and airflow rate.

### RESULTS

Figure 2 presents the results of the validation for different numerical models with the experimental results. The results show the evolution of system outlet air temperature under volume airflow rate of around 300 m<sup>3</sup>/h during both melting (discharging) and solidification

(charging). There are three presented numerical models based on the different  $c_{p,p}$  values discussed earlier: 1- the improved apparent  $c_{p,p}$  model tested by Stathopoulos et al. (2016) with experimentally obtained values of  $c_{p,p}$ , 2- the model that is based on developed average values of  $c_{p,p}$ , and 3- the generalized apparent  $c_{p,p}$  model that is based on simplified  $c_{p,p}$  values. The results show that considering an average value for each  $c_{p,p}$  curve is very close to the improved apparent  $c_{p,p}$  model. The generalized apparent  $c_{p,p}$  model shows some discrepancy with the original model and experimental results due to the simplified approach of  $c_{p,p}$ . For investigating the discrepancy level of the generalized model, a percent error test is performed for both improved and generalized apparent  $c_{p,p}$  models. Figure 3-a shows the percentage of error of both models compared to experimental data. The results show that both models exceed 10% of error percentage with the experimental data only at the start of each phase changing. Otherwise, the error for both models remains below 10% with the experimental data. In terms of the average error, improved apparent  $c_{p,p}$  model shows average errors of 3.2% and 3.7% during melting and solidification respectively with the experimental data. While the general apparent  $c_{p,p}$  model shows average errors of 3.9% and 4.6% during melting and solidification respectively with the experimental results. In comparison with the improved model, the generalized apparent  $c_{p,p}$  model shows up to 7% of percent error.

Figure 2. Validation of different models with experimental data

### Comparison to ventilated envelope configuration

Using the generalized apparent  $c_{p,p}$  model, a comparison between the previous investigated PAHX ventilation system unit (configuration 1) and a ventilated envelope PAHX type (configuration 2), shown in figure 4, is held to monitor the thermal performance of the two configurations. In both configurations, inlet air temperature is fixed to two values: 44.0°C during melting and 26.0°C during solidification. Airflow rate is fixed to 300 m<sup>3</sup>/h. RUBITHERM RT35 is used as a storage medium with thermal properties mentioned in table 1. Two curves for heating and cooling for  $c_{p,p}$  values are applied and presented at figure 5. The total PCM volume is 0.052 m<sup>3</sup>. PAHX ventilated façade configuration variables are mentioned in figure 4, with total PCM volume of 0.064 m<sup>3</sup>. It is worth mentioning that the objective of this investigation is the comparison between the two configurations and not obtaining the best thermal performance of the system. The results, shown in figure 3-b, prove that with almost the same volume of PCM, both configurations show significant conformity with values of outlet air temperature profile.

Figure 3. a) Percent error analysis of original and generalized models b) Outlet air temperature of PAHX different configurations

Table 1. Thermal properties of PCM RUBITHERM RT35

Melting range	Solidification range	Heat Storage Capacity	Specific heat capacity	Density	Thermal conductivity	Volume expansion
29-36 °C	36-31 °C	160 kJ/kg	2.0 kJ/kg.K	0.86 solid / 0.77 liquid	0.2 W/m.K	12.5%

A complementary study is conducted to test the indoor thermal performance of a ventilated façade PAHX type with the given configuration using TRNSYS. A standalone test unit of volume 27.0m<sup>3</sup> (3.0\*3.0\*3.0) is proposed with a northern window of 1.0m<sup>2</sup> and a heavy construction of stone walls (0.3m thick) and concrete roof slabs (0.25m thick). Two systems are compared: the PAHX ventilated façade system, and a conventional ventilation system with the same airflow and inlet temperature as the numerical model. The results show that 4.6% of the cooling loads can be saved during 5.0 hours of PAHX system operation.

Figure 4. Ventilated envelope PAHX configuration

Figure 5. RT35 apparent  $c_p$  curves

## DISCUSSIONS

With the validation of the general apparent  $c_p$  model, the discrepancy at the end of each phase change process is noticed. It means that with the simplified  $c_p$  approach the system tends to consume its storage capacity faster than the actual behavior. Accordingly, it can be noticed from the percent error analysis that the general apparent  $c_p$  model shows up to 10% as a level of discrepancy, and 3.9% and 4.6% as average errors during melting and solidification respectively with the experimental data due to consideration of system storage capacity. However, one of the advantages of the general model is its in-dependence of the spatial time constrains. Time step, discretization length and investigation duration can be adapted to desired conditions. Regarding general model limitations, the model still uses a fixed input value for convective heat transfer coefficient. Also, the natural convection inside PCM during melting and liquid phase is still neglected. It is expected that model accuracy can be enhanced when heat transfer coefficient is calculated according to airflow conditions. Also, it can be inferred from the results of comparison between the two configurations of PAHX system that the governing parameter in determining PAHX thermal performance is the volume of PCM. Both configurations have almost the same PCM volume and, as reported in results, the both outlet temperature profiles show the same behavior with great level of consistency, especially during solidification process. PAHX ventilated façade configuration shows promising

potential for free cooling applications; it is recommended to improve the model by developing the convective and radiative heat transfer boundaries.

## CONCLUSIONS

A generalized numerical model of PCM-to-air heat exchangers is developed and validated in this paper based on general apparent heat capacity method. A simplified approach for implementing heat capacity cooling and heating curves is presented and validated with experimental data. The general approach showed some discrepancies with experimental data. Using a percent error test, the average error of the general model was 3.9% and 4.6% during melting and solidification processes respectively. Referring to its ability of broad applications, the developed general model is very beneficial to building designers due to its in-dependence from experimental data as model inputs. Using the developed general model, a comparative analysis between PAHX ventilation system configuration and a ventilated envelope PAHX configuration is conducted. The study proved that PAHX ventilated façade type has promising potential for free cooling applications.

## ACKNOWLEDGEMENT

The authors would like to express their gratitude to Concordia University for the support through the Concordia Research Chair – Energy & Environment, and to Egyptian missions' sector.

### **ABSTRACT**

This work highlights the BIPV potential in two urban areas with different characteristics at the city of Prague. Representative building blocks were selected and CitySim software tool was used for the assessment of the hourly irradiation profiles on each surface over one year period. Considering appropriate irradiation thresholds, suitable surfaces were then quantified. Integration criteria are discussed and suitable BIPV applications are proposed considering not only energy performance but also their impact on the quality of built environment. Results indicated that only 5.5% of the total area can be used in Vinohrady and 13.7% in Jizni Mesto contributing on average by 32% and 31% on the hourly electricity demand respectively.

### **KEYWORDS**

Building-integrated photovoltaics, solar potential, architecture, load matching

### **INTRODUCTION**

The building sector is the major consumer of energy, accounting for around 40% of the worldwide consumption (UNEP, 2012). On the road towards Low or Zero Energy Buildings, renewable energy harvesting becomes compulsory and thus photovoltaic systems are expected to be the main technology to generate on-site electricity. PV systems have great potential to be used in the city context through various BIPV products (Shukla et al., 2017). Rooftop PVs are so far considered to be the most common application since it provides the best annual energy harvesting. However, due to significant decrease in prices and technological improvements in PV industry, building facades now represent good potential especially for high-rise buildings. Successful integration of PVs into a building requires both technical and architectural knowledge.

In this context, a suitable procedure is needed to assess the solar potential and propose PV concepts based on the characteristics and cultural aspects of the location. This paper aims to analyse the PV potential of two locations within the city of Prague. Considering the solar availability and shadings for the surrounding buildings, the available area for installation is determined and suitable PV applications are proposed considering all the constraints imposed from the locations and building morphologies. Finally, suitable index is used to investigate the interaction between on-site generation and building's electricity demand on hourly basis.

### **METHODS**

#### **Location characteristics**

Two urban areas in the city of Prague with different characteristics were selected and used for analysis and comparison. A representative building block, constitute of residential buildings,

was selected for each location as presented in Fig.1. Case one, Vinohrady, is within a high dense area of the city centre with considerable architectural and cultural value. Houses built around 1900 are characterized by sloped roofs in different shapes and heights. Case two, Jizni Mesto, is a suburban area built in 1970es. Prefabricated high rise buildings are characterized by simple shape, flat roofs and big vertical facades with balconies on South and West orientation.

Figure 1. Aerial view of the selected locations in a) Vinohrady and b) Jizni Mesto.

### Solar PV potential

Appropriate 3D models for each building block were prepared based on the geometry of the buildings, including dimensions and shape of the roof superstructures (dormer, chimney, etc.). Building surfaces were divided according the floor level, excluding areas that for some reason cannot be considered for PV integration (e.g. north facade). Radiation on building surfaces is commonly influenced by the near environment and thus were the heights of the surrounding buildings, trees and elements in each direction were considered in the model for the evaluation of shading. Afterwards, the 3D model was imported to CitySim Pro, an urban energy modelling tool developed at LESO-PB/EPFL, for further analysis. Incoming solar radiation was calculated in hourly values, according to the type of the building surface and the climate data collected by a nearby meteo station. For each building surface was defined by its area, orientation and tilt angle. Finally, percentage of solar obstruction were calculated as the ratio of the solar radiation within the surrounding context to the one without the surrounding obstacles. Hourly values were solar weighted, annual shading index ( $SI$ ) was derived according to Eq.1, where  $F_{sh,i}$  is the hourly shading factor of each building surface,  $G_i$  is the hourly and  $G_t$  the annual solar radiation respectively.

$$SI = \frac{\sum_{i=1}^{N=8760} F_{sh,i} G_i}{G_t} \quad (1)$$

Once the radiation values on each surface are available, they can be analyzed to assess the PV potential. For this purpose, an irradiation threshold was used indicating the minimum amount of annual radiation required for PV system to be beneficial. Such thresholds are somewhat arbitrary; conservative value of 800 kWh/m<sup>2</sup>annually is proposed by many authors (Li et al., 2015), while others define it as a percentage of the horizontal insolation (Vulkan et al., 2018). Considering the technological progress and enormous decline of PV costs within last decade, approximately 58% according to (Maturi et al., 2017), lower values such as 650 kWh/m<sup>2</sup> (Kanters et al., 2014) are still reasonable. To this end, PV potential calculated as the relative fraction (percentage) of the roofs and facades of the buildings that can be used for PV integration. Based on the area of the suitable surfaces a simple model was applied to quantify the annual energy output ( $E_{PV}$ ) of each building block according to Eq.2:

$$E_{PV} = \eta * PR * \sum_{i=1}^{n_{threshold}} (I_i * A_i) \quad (2)$$

,where  $\eta$  is the PV conversion efficiency,  $PR$  is the performance ratio representing all system losses (mismatch, inverter...),  $n_{threshold}$  is the number of surfaces exceeding irradiation threshold,  $I_i$  is the cumulative insolation (kWh/m<sup>2</sup>.year) and  $A_i$  the relative area (m<sup>2</sup>) of surface  $i$ .

Afterwards, data for the annual electricity consumption of representative buildings in each location, were collected and analyzed in hourly basis according to the occupants (REMODECE, 2008) and typical user profiles (Staněk, 2012). Based on the peak loads and the selection criteria that apply in each location, PV systems were sized properly, while load match index (Voss et al., 2010) was used as indicator of the hourly self-consumption of the PV generated energy.

### BIPV integration criteria

It is evident that excessive use of PV systems can often have an adverse effect on the build environment and thus criteria and recommendations about dimensioning and positioning are needed. In order to select an appropriate BIPV application, both technical, architectural and economical aspects should be included. In case of Jizni Mesto, there is no limitations arising from the near environment and thus several scenarios and PV technologies can be considered (Fig.2). High performance modules can be installed on flat roof of the buildings horizontally to camouflage the installation or tilted to optimize performance. On vertical facades, PV modules should be grouped together in an ordered way creating unique textures (e.g. horizontal stripes). In this context, ceramic panels or solar glazing in various colours (Jolissaint et al., 2017) could be a solution, providing good durability and aesthetic quality. Finally, complementary building elements such as windows and existing balconies are well suited to support PV integration representing good compromise in terms of energy performance and aesthetics. In addition, optimized semi-transparent PV elements could be used as shading devices to increase indoor thermal comfort by mitigation of overheating during summer, but still to provide daylighting and to make use of passive heating during winter (Skandalos et al., 2018).

Figure 2. Examples of architecturally integrated PV systems in the two building blocks: (1) PV balconies. Source: Etsprojects; (2) Coloured PV-façade. Source: Swissinsio; (3) Roof-added PVs. Source: Cromwellsolar; (4) PV tiles. Source: Tradeford; (5) PV shutter and PV blinds. Source: COLT international, Solargaps; (6) PV terrace. Source: (López and Frontini, 2014).

On the other hand, BIPV integration in the sensitive built environment such as Vinohrady district, is a more challenging task. Applicability of conventional PV modules in buildings with strong architectural or cultural value is limited. Since the full integration and imperceptibility of the technical elements from the public domain is the most important criteria for the acceptance of the BIPV within the historical context (Munari Probst and Roecker, 2015), small scale highly innovative PV products are needed. Suitable surfaces are limited to the sloped roof, flat terraces and vertical facades facing to the courtyard. Based on the geometry of each surface, BIPV applications such as solar glazing or PV tiles, balustrades and PV shutters (Fig.2) constitute effective practices of integration in the building envelope providing a balanced solution between technical and architectural standards as defined in (Frontini et al., 2012).

## RESULTS & DISCUSSION

### Solar PV potential

Results from solar analysis in both locations are presented in form of annual irradiation colour map (Fig.3). As expected, best solar resources were observed for sloped roofs facing south (Vinohrady), exceeding the  $1200\text{kWh/m}^2$  annually. However, different roof typologies were recognised and thus solar potential varies according to its slope and orientation. Relative results for the flat roofs of Jizni Mesto were slightly lower (around 10%), but still exceed the irradiation thresholds. Conversely, facades in both locations found to receive significantly lower level of irradiation, especially the ones on East and West façade. This is also explained from the increased shading factors. Average solar obstruction can reach up to 57% for a building in Vinohrady (high density) and 22% in Jizni Mesto respectively. Consequently, only a small portion of the total building area can be considered as suitable for PV integration. Percentages for buildings in each location vary between 5-18% in Vinohrady and 15-27% in Jizni Mesto respectively.

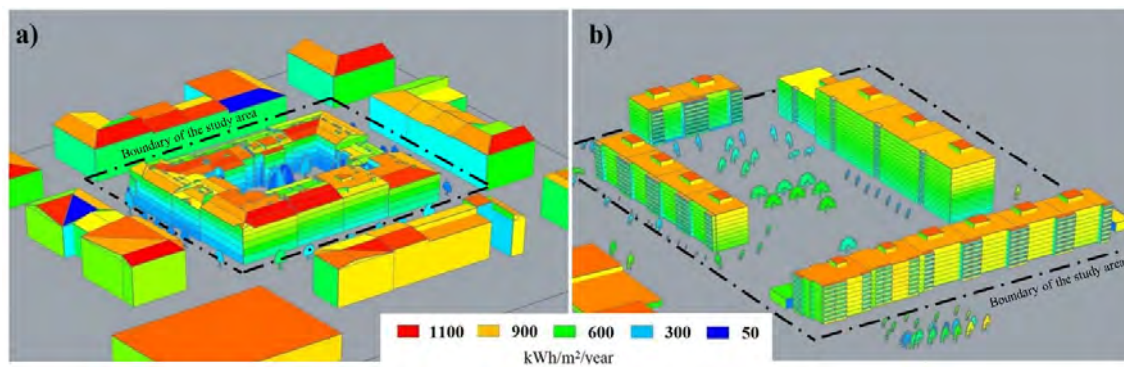

Figure 3. Annual solar irradiation map for each building block in a) Vinohrady and b) Jizni Mesto.

With respect to the hourly irradiation profiles, maximum PV potential in each location was calculated and presented in Fig.4. PV modules were assumed to be installed at the same plane with the building surface considering typical values for the conversion efficiency ( $\eta$ ) according to the BIPV application ( $\eta=15\%$  for roofs and  $\eta=8\%$  for facades/balconies/glazing). For Vinohrady, annual PV generation could be up to 440MWh with peak generation in July (62 MWh). However, 58% of that energy is related to the building surfaces facing streets and thus could not be considered according to the criteria discussed in previous section (Fig.4a). Similar results for the Jizni Mesto revealed 2.7 times higher PV potential (1100 MWh/annually) with relative contribution from roof, façades and balconies by 49%, 45% and 6% respectively (Fig. 4b).

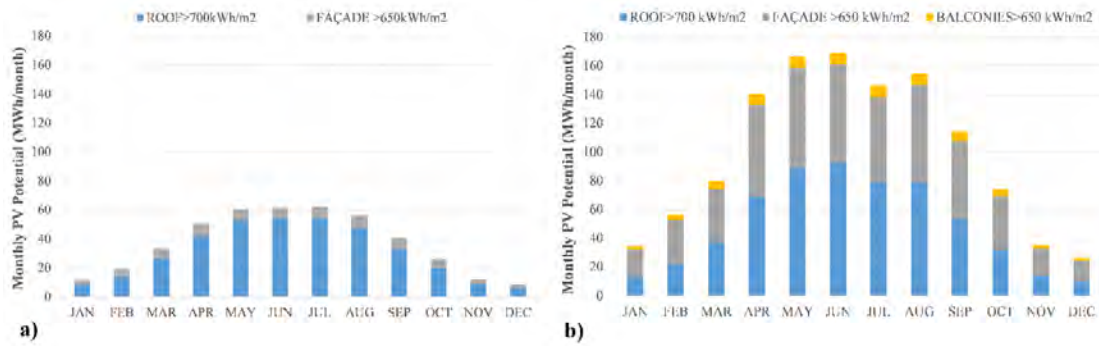

Figure 4: Monthly PV potential for the building block in a) Vinohrady and b) Jizni Mesto based on the selected irradiation thresholds.

### System evaluation

Hourly peak loads were calculated and used as indicator, together with the criteria discussed in previous section, to size properly the PV systems in each building. Consequently, suitable PV systems were considered and results regarding the interaction between electricity consumption and generation are presented in Fig.5 for both locations. Despite the PV potential in Vinohrady, available space is limited to only 5.5% of the total building area due to the integration criteria applied. It is obvious that the generated energy is not enough to cover the loads of the building block (Fig.5a). However, almost all the generated PV energy can locally be used within the building block and it is enough to compensate on average by 38% (max value of 49% per building) the hourly electricity demand. In case of Jizni Mesto, there is no such limitations and thus 19% of the area can be used according to the irradiation thresholds. In that case, PV generation is enough to cover the electricity demand during the summer period, but also leads to excess of energy for 35% of the PV operation time (hourly). Therefore, better interaction between generated and consumed electricity is needed to increase the self-consumption of the buildings providing more efficient performance. If maximum load matching is taken into account, integration will be limited to only 13.7% of the total building area leading to lower PV generation (Fig.5b). Alternatively, excess of energy can be used for cooling purposes since peak production coincides with peak cooling demand. Analytical results, regarding maximum load match index (hourly intervals) between the buildings in Jizni Mesto found to be 43%.

### CONCLUSIONS

Two representative building blocks, with different characteristics and level of preservation in the urban context of Prague, were selected and analysed for their hourly solar radiation per unit area according to the local weather data. As expected, most of the potential is intrinsically related to roofs, while façades suffer more the shadowing effect caused by the surroundings. According to the integration criteria and energy consumption applied in each location, suitable PV systems were proposed. Only small part of the building area can be used, varying from 5.5% for Vinohrady and 13.7% for Jizni Mesto. Interaction between electricity demand and consumption revealed that proposed PV systems could compensate on average by 32% the hourly energy demand in Vinohrady and by 31% in Jizni Mesto. It is evident that even in areas with sensitive built environment adoption of solar energy is still possible for balancing local electricity needs. Further work is needed to assess the indirect effect (thermal, daylighting) of the proposed solutions. Also economic assessment based on the actual market conditions (BIPV prices, installation costs and electricity tariffs) will also reveal the profitability of the proposed solutions.

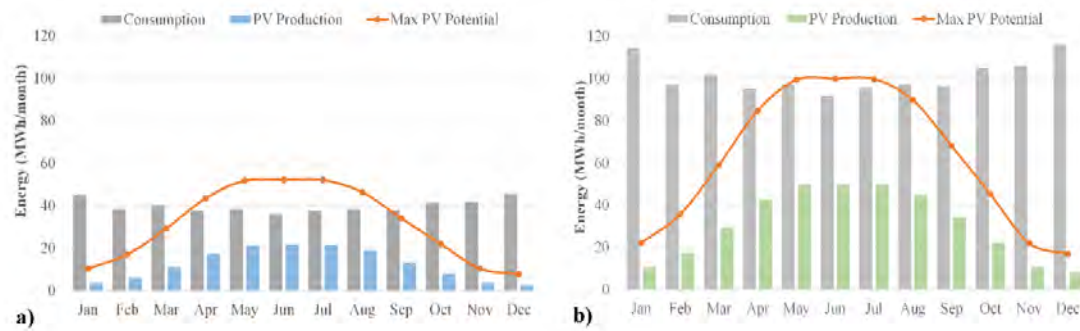

Figure 5: Annual electricity consumption and generation of the proposed PV system together with maximum potential according to irradiation threshold ( $800\text{kWh/m}^2$  year) based on monthly data for a) Vinohrady and b) Jizni Mesto.

### **ABSTRACT**

In the last decades a variety of high-energy efficient solutions for building envelopes were developed and tested for enhancing indoor thermal comfort and improving indoor environmental quality of private spaces by learning from nature. To this aim, adaptive solutions, conceived thanks to green and bio inspiration, were designed and constructed in various climate conditions and for a variety of building uses. Given the huge population flow toward urban areas, well-being conditions in the public spaces of such dense built environment are being compromised, also due to anthropogenic actions responsible for massive environmental pollution, local overheating, urban heat island, etc. Moreover, this process is exacerbated by temporary phenomena such as heat waves. Therefore, outdoor spaces are becoming increasingly less comfortable and even dangerous for citizens, especially if they are affected by general energy poverty, with no chance for active systems management for air conditioning, or health vulnerability. In this view, this study concerns the first concept for the development of a simple and adaptive nature-inspired solution for outdoor thermal comfort enhancement and local overheating mitigation for pedestrians. The system will be evaluated in terms of the cradle-to-cradle approach and the initial performance assessment is carried out via thermal-energy dynamic simulation. The final purpose will be to design outdoor “alive” shading system to be applied in open public spaces, with evident physical and social benefits.

### **KEYWORDS**

Bio-inspired solutions; Biomimetics; Biophilic cities; Outdoor thermal comfort; Thermal-energy dynamic simulation.

### **INTRODUCTION**

Nowadays, a topic with increasing relevance is how an exterior space affects physical, physiological, and psychological well-being. The achievement of comfortable outdoor spaces and microclimate in urban environments is, indeed, fundamental since those spaces are where social activities happen, people gather/socialise, but also connect the indoors with nature (sun/green spaces). Architects and designers were inspired by nature since long before the term biomimicry (biometrics or bio-inspired architecture) was introduced. In the past, architecture featured ornamental design influenced by nature, and this tendency was accentuated by turn-of-the century Catalan Modernism (Spain) or Art Nouveau (Belgium) as examples. Nowadays, a methodological approach to assess innovation was developed through merging bio-inspiration and sustainability based on the reintegration of basic bio-inspired principles into material systems of humankind (Horn et al. 2018). Biomimetics is a rapidly growing discipline in engineering, and an emerging design field in architecture. In

biomimetics, solutions are obtained by emulating strategies, mechanisms, and principles found in nature (Badarnah 2017). Therefore, the study of green infrastructures providing benefits not only in terms of outdoor thermal comfort, but also for the built environment located in their close proximity may represent a further mitigation and wellbeing opportunity.

In this context, plants have also the capability to transform global solar radiation that reaches their surfaces into biomass, oxygen, air humidity, etc. (Pacheco-Torgal et al. 2015). Furthermore, biophilic spaces, those that learn from nature and emulate natural systems, must be considered for the development of cities. In fact, a biophilic city is a city in which residents are actively involved in experiencing nature (Beatley & Newman 2013). Moreover, biophilic urbanism can complement urban greening efforts to enable a holistic approach, which is conducive to comprehensive, intentional, and strategic urban greening (Revee et al. 2015). Different studies about outdoor thermal comfort showed that the sun sensation coming from solar radiation has the most significant influence on human thermal sensation in outdoor spaces (Yang et al. 2013). On the other hand, pedestrians usually inclined to green areas within the urban environment. This increase of vegetation, combined to other solutions, showed the most significant impact in summer overheating mitigation and urban resilience to anthropogenic climate change (Piselli et al. 2018).

Within this background, there is a lack of information about how greenery shading systems can influence outdoor thermal comfort in the inter-building space. Therefore, the purpose of this work is to study a simple and adaptive system of bio-inspired architecture connected to the building for the improvement of thermal comfort in the outdoor inter-building space. Therefore, this strategy is able to mitigate the build environment and the urban heat island phenomenon (UHI) as bottom-up approach. The other aim of the paper is to simulate the outdoor thermal comfort with greenery, since there are no previous studies concerning that. Moreover, the selected materials are meant to produce the minimum impact in terms of cradle-to-cradle vision.

## METHODS

### Description of the concept

The design was created with different spaces that can provide thermal comfort to outdoor users (Figure 1). Two main objectives were pursued: (i) to reduce the incidence of the direct solar radiation to achieve higher visual comfort, and (ii) to mitigate surface temperatures of the connected buildings and the air temperature in the inter-building space to achieve thermal comfort. In fact, the system did not seek to create a stand-alone piece at the outdoor. On the contrary, the intervention tried to strengthen the key assets of surrounding buildings, creating an extension of the existing buildings that it may be.

Figure 1. The shading system proposed.

The shading system was composed of two interwoven systems of ropes running freely between the two buildings. The ropes connected on the middle creating a bench where people

could sit. The new three-dimensional surfaces created shadings of varying densities that reconfigure the original outdoor space into a more confined and enclosed space. The confined space changed constantly with shadows produced by the rope and greenery systems (using deciduous plants) depending on the season since the solar irradiance is different for each one. Thus, the inter-building space became an ever-changing stage that responded to the movement of the visitor, the changing patterns of light through the day, and the outdoor thermal comfort depending on the season. The selected specie, i.e. Boston Ivy (*Parthenocissus Tricuspidata*), is a deciduous specie well adapted to the Mediterranean Continental climate.

The performance of the system was simulated in this study to demonstrate its potential in sites requiring context-specific real-time responses. The system was modelled under the case study climate context of Lleida, Spain, with Continental-Mediterranean weather conditions, i.e. Csa (warm temperate, dry and hot summer) zone according to Köppen-Geiger climate classification (Kottek et al. 2006). To improve the efficacy of the proposed system in terms of cradle-to-cradle, the materials selected for the prototype corresponded to: (i) Wood structure to support the shadow shading system. This wood structure includes a bench integrated in the basement structure with a substrate for the climbing plants that will grow on it. (ii) Ropes made of natural fibres for the shading system. (iii) Climbing deciduous plants.

### **Thermal-energy dynamic simulation**

For the system modelling and thermal-energy assessment, EnergyPlus v8.1 simulation engine (Crawley et al. 2000) with DesignBuilder v4.7 graphical interface (DesignBuilder software Ltd, 2016) were selected. The following steps were followed in the simulation process:

- Building geometry modelling based on the designed drawings and technical specifications.
- Characterization of the architectural elements and their thermal properties.
- Proposed shading system modelling and characterization: the rope-based shading system with greenery was modelled as a solid obstacle, characterized by rope properties. This configuration was considered an acceptable approximation due to the unavailability in the software of a model for stand-alone green infrastructures implemented in outdoor areas, i.e. not integrated in the building envelope.
- Run of hourly simulations for the hottest week in summer (i.e. July 15th to July 23rd), with the more regular outside temperatures along the season.
- Analysis and comparison of the performance of different scenarios for the outdoor shading system in terms of thermal conditions under the shading and external surface temperatures of the shaded buildings.

The statistical weather file of the city of Lleida from the EnergyPlus database (U.S. DOE BTO, 2016) was used for triggering the model in the calculations. Different scenarios were defined for the proposed system in order to evaluate the impact of shading percentage of the system, i.e. the amount of vegetation growth on the rope-based system. To this aim, the different scenarios were modelled by varying the transmittance capability of the solid obstacle. Therefore, the studied scenarios (Figure 2) were those proposed by Ng et al. (2012):

- Covered 0%: Without greenery, i.e. solar radiation transmittance equal to 1.
- Covered 33%: With greenery covering 33% of the structure, i.e. solar radiation transmittance equal to 0.67.
- Covered 67%: With greenery covering 67% of the structure, i.e. solar radiation transmittance equal to 0.33.
- Covered 100%: With greenery covering 100% of the structure, i.e. solar radiation transmittance equal to 0.

The purpose of the numerical simulation was to study the influence on the surface temperatures of the buildings connected and shaded by the system (east and west walls were selected since are those which receive more solar radiation in summer) and to study the variation of temperatures below the system depending on the coverage. To this aim, the inter-building area below the shading system was modelled as an internal thermal zone, characterized by thin air layer envelope and high air infiltration and ventilation to approximate outdoor conditions to the best.

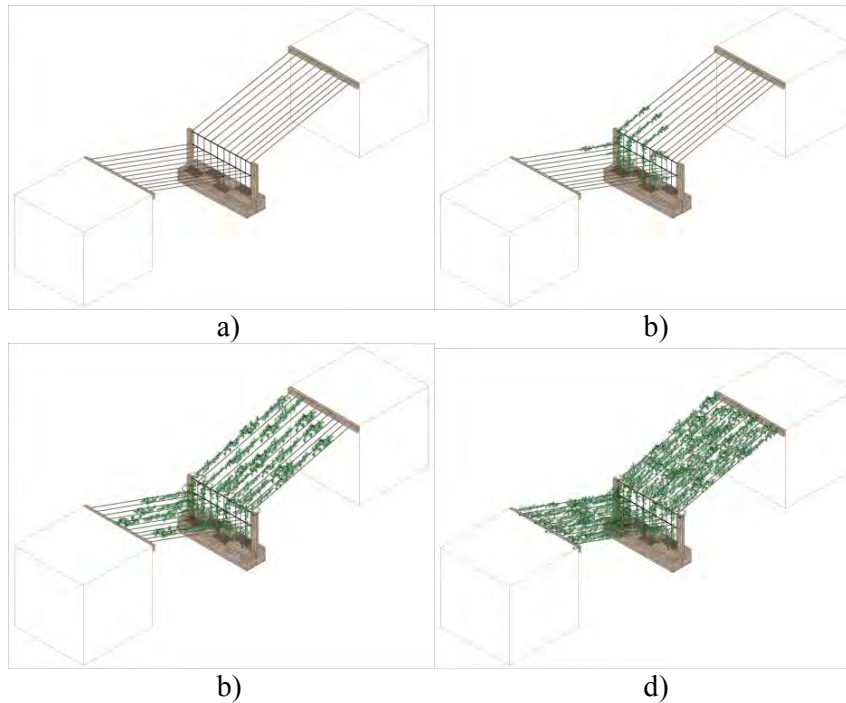

Figure 2. The four different scenarios of the shading system. a) Without greenery, b) With greenery covering 33%, c) With greenery covering 66%, d) With greenery covering 100%.

## RESULTS AND DISCUSSION

As the external wall surface concerns (Figure 3), significant differences were observed between the four scenarios. More in detail, the maximum variation in the surface wall temperatures was found in the west facade, since among the considered orientations it is the one that receives the highest solar radiation in summer (Pérez et al. 2017). The peak temperatures showed significant variation depending on the shading scenario, while the minimum temperatures were similar.

Figure 3. Daily variation of west facade temperature.

In particular, a difference of 16°C was found between the scenario without shadow (i.e. Covered 0%) and the one totally Covered (i.e. Covered 100%), where the surface temperatures reached 54°C and 38°C, respectively. Concerning the scenarios Covered 33% and Covered 67%, the maximum surface temperature reached 48°C and 42°C, respectively. These results highlight that the external temperatures of the walls of existing buildings can be reduced thanks to the implementation of the proposed shading system. Accordingly, this is expected to be associated to a significant decrease in the indoor ambient temperature.

On the other hand, in the east facade, a difference of 7°C was found between the scenario Covered 0% and the Covered 100% (with peak temperatures up to 43°C and 36°C, respectively). In this facade, each day shows two peaks, the first following the solar incidence and the second one corresponding to the maximum outside air temperature. As expected, the solar incidence has a stronger influence when no shadowing system is used (wall temperatures reaching up to 39°C), while with the system this temperature decreases up to 22.5°C. When the solar incidence decreases, the outside temperature effect is very strong, but in this case all scenarios reach similar temperatures (around 34-35.5°C).

Figure 4. Daily variation of east facade temperature.

Regarding the air temperature in the inter-building space, i.e. under the shading system, the maximum temperatures ranged from 33°C for the Covered 100% scenario, to 34°C for the Covered 67%, to 36°C for the Covered 33%, up to 38°C for the system without greenery, i.e. Covered 0%. Therefore, the shading effect associated to the implementation of the greenery was able to provide an outdoor air temperature reduction up to 5°C.

Figure 5. Daily ambient temperature under the shading system.

## CONCLUSIONS AND FUTURE DEVELOPMENTS

This study presented the concept of a simple and adaptive bio-inspired vegetated shading system for inter-building spaces. The purpose of the study was to analyse the effect of varying the greening percentage on the shading system on the air temperature of the inter-building

area covered by the system and the connected buildings surfaces, through numerical modelling tools usually considered for indoor thermal-energy dynamic simulation. Simulations showed, as expected, that both the wall surface temperature and the air temperature under the shading system decreased when percentage of covering due to the greenery increased. Therefore, the theory of the benefits of a greenery system in summer is confirmed also for inter-building spaces. Since this study was carried out via numerical simulation, more exhaustive experimental research is needed to confirm these results. Therefore, reliable data will be available for architects, urban planners and engineers on the implementation of new concepts inspired by nature for both indoors and outdoors well-being.

### **ABSTRACT**

It has been generally perceived that decision-making processes for implementing sustainable solutions to building elements should be in design and pre-construction phases. This perception hinders the transformation of current non-sustainable buildings into sustainable ones. It has been realized that retrofitting existing buildings can be more beneficial in terms of time and cost compared to new construction. This study aims to show that implementation of Building Information Modeling (BIM) for energy analysis improves the retrofit planning process. This study explains that in practice, BIM tools provide significant opportunities for creation of Building Energy Modeling (BEM); and the outputs of BEM analysis can be readily used in selection of energy efficiency measures. The case study approach is used in this study. Accordingly, 3D energy models of the Istanbul Grand Airport Project have been created. A heuristic optimization depicts a clear picture of why it is necessary to incentivize transforming BIM to BEM for decision-making processes of retrofitting. Correspondingly, the study findings show that BIM implementations can provide cost and time savings for energy analysis practices.

### **KEYWORDS**

Building Information Modeling, Building Energy Modeling, retrofitting, heuristic model

### **INTRODUCTION**

Energy analysis tools are integral to the process of identifying and implementing building energy savings measures (Evan, 2003). Such tools have many uses; typically, they are used for design of new building or renovation of existing ones with detailed design analysis (Sanquist & Ryan, 2012; Evan, 2003). Appropriate utilization of building energy analysis tools leads to accurate and cost-effective energy analyses, which depict the total energy use and savings opportunities. The origins of building energy software trace back to the 1970s. Before then, energy analysis was managed by hand at significant cost and time. According to Evan (2003), in the 1980s, the first-generation of simulation-based analysis and design tools emerged. From late 90s until now, rapid proliferation of tools targeted at a broader spectrum of users and the advent of web-based tools. Through web and literature searches, commonly used whole building energy simulation software tools in North America are compiled: TREAT, Sefaira Architecture, EnergyPlus, Pleiades+COMFIE, Autodesk Insight 360, EDAPT, TRNSYS, eQuest, TRACE 700, REM/Design, Open Studio, EDGE Excellence In Design, Design Builder, HA (Carrier).

Moreover, the opportunities can be magnified using recent innovations in energy management tools that provide greater access to energy use data as well as analytics and increased intelligence to optimize systems (Woo & Gleason, 2014). Additionally, typical processes of whole Building Energy Model (BEM) generation are subjective, labor intensive, time

intensive, and error prone (O'Donnell, et al., 2013). At this point, it is clear that integrating BIM and BEM generates value in terms of time, cost, and quality since BIM-based building energy models are capable of collecting and also rapidly processing real-time energy performance data. This also provides more accurate and detailed input and output for energy simulation process.

Using the aforementioned energy analysis tools for retrofitting with an optimized investment budget appears to be a viable investment tool. Such procedures can provide substantial savings in terms of energy use, energy cost, and carbon emissions. (Camlibel & Otay, 2011) Not all facility managers, building owners, and other related parties have the ability to access and use a sophisticated optimization software. There are cases in which fast and cost-efficient processes are needed. Heuristic approach can be used to calculate energy, energy cost, and CO<sub>2</sub> savings per invested amount for different energy efficiency measures (EEMs) (retrofit alternatives). Heuristic approach includes the following steps: calculating energy, energy cost, CO<sub>2</sub> savings per investment for each EEM; showing budget amount by drawing a vertical line along the budget amount; selecting EEM with the highest value of saving per USD on the left side of the vertical line; subtracting the selected EEM's investment amount from the given budget; drawing a new vertical line along the new value of the budget amount (Camlibel & Otay, 2011). This process is repeated until the budget no longer supports any other EEM. Thus, the BIM-BEM integration can improve heuristic optimization and selection of energy efficiency measures by providing fast and more accurate input data.

This study shares the energy analysis approach applied to Istanbul Grand Airport Project BIM models. The project encompasses four phases, which includes six runways, three terminals, and an annual 200 million passenger capacity. The first phase of the construction started in 2015. It was planned to make the airport operational in the first half of 2018. This timeline shows that the energy analysis results address the potential future rework that may target to meet or exceed performance guidelines set by building rating systems (e.g., ISI's Envision and the Middle East's ESTIDAMA which include energy efficiency of building envelopes, day-lighting performance, and embodied energy as the crucial part of their evaluation.)

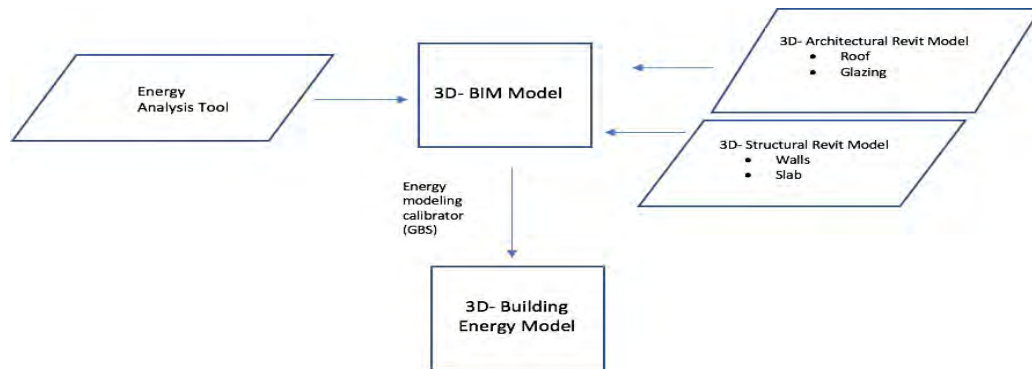

In the literature, it is generally discussed that BIM-based energy modelling utilization leads to sustainable design, and provides easy access to energy analysis results in the early design process. However, to the authors' knowledge, there are no case studies showing that BIM can contribute to sustainability, not only in the design phase, but also throughout the life cycle of the building. Essentially, this study tries to fill the gap in the literature, via proposing BEM generation, by the use of BIM to accelerate the energy retrofitting decision making process.

## **METHODOLOGY**

The case study shows the energy analysis procedure used for Istanbul Grand Airport (IGA) Project BIM models. These models are composed of architectural and structural Revit models. As one of the world's largest aviation projects, the IGA Project encompasses a terminal building with a total floor area of 950,000 m<sup>2</sup>, and pier buildings with a total floor area of 320,000 m<sup>2</sup>. The methodology used in the case study enables a holistic approach on the magnitude of future energy consumption of IGA project. In this respective order, the methodology contains a selection of the most suitable digital tools, an optimization of BIM models, and generation of an energy analysis.

According to Stumpf, Kim, & Jenicek (2009), the energy modeling process can be divided into two sub-processes. The first sub-process is a macro-level energy analysis, which focuses

on comparing building size, shape, and orientation. The second sub-process is a micro-level energy analysis, which considers building details such as wall penetrations and building system details. An energy analysis framework is obtained through the methodology presented below (See Figure 1). It contains data coming from both macro and micro level energy analysis processes.

**Figure 1: Energy Analysis Process Framework**

At the first step of the methodology, the digital tool Insight 360 is chosen for this case study. This tool works as an add-in to Autodesk Revit and integrates existing workflows such as Revit Energy Analysis and Lighting Analysis for Revit. Insight 360 also allows visualization of solar radiation on mass or building element surfaces. Solar analysis includes a new automated workflow for understanding photovoltaic (PV) energy production. Insight 360 also provides a comparison of design scenarios to track performance of the building lifecycle, as well as, measuring the performance against Architecture 2030 and ASHRAE 90.1 benchmarks. The energy analysis results presented in this case study are limited. In essence, only visualization of solar radiation and energy production results are provided.

At the second step, optimization of BIM models, which is mainly dividing and simplifying architectural and structural Revit models, is conducted. Smaller models were extracted out of one master model (See Figure 2). Main purpose of this optimization, which requires discarding some architectural and structural elements, is to achieve the most appropriate model size and complexity for Insight 360, so that the tool can process data smoothly. Such tools have limited capabilities in terms of model size and complexity, making the model shown in Figure 2 infeasible to be analyzed as a whole. Accordingly, five different models with the most basic features (Kim & Anderson, 2011) (See Table 1) were obtained via taking reference of high level zoning plan given in Figure 3. However, it is important to keep in mind that, the number of sub-models should be kept to a minimum. Also, all sub-models should have a fully closed geometry to generate energy analytical models. Overall, the purpose is to eliminate issues including missing elements, elements that are not set to room bounding, gaps in geometry, in-place families, small spaces and surfaces, and columns that cause surfaces to be omitted from the energy model.

**Table 1. List of sub-models**

**Sub-Models**

Terminal 1 (all levels)  
Terminal 2 + Terminal 3 (all levels)  
Pier 1 – Pier 2 (all levels)  
Pier 3- Pier 4 (all levels)  
Pier 5 (all levels)

**Figure 2: Master Model of the Project**

**Figure 3: High Level Zoning of the Project**

Furthermore, the master model is at its real-world coordinates having high accuracy in level and shape to ensure sustaining maximum accuracy in total volume of energy analytical model. As the third step, energy analysis is conducted; and for that purpose, **Generate** command (in Revit 2017) or **Generate Insight** command (Revit 2016) in **Analyze** ribbon (see Figure 4) is used. The process begins with creation of energy analytical model, followed by transmission of the model to the cloud-based Green Building Studio (GBS) server to obtain the results of energy analysis.

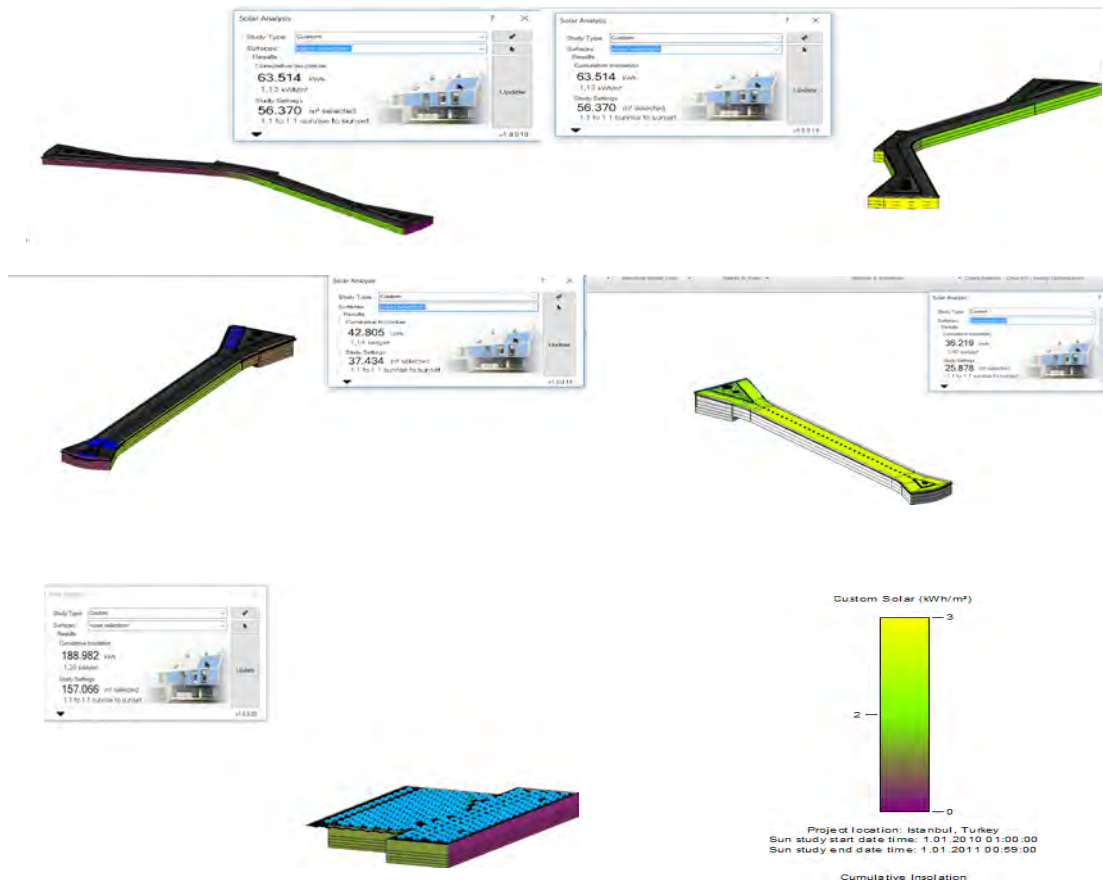

**Figure 4: Analyze Command in Revit 2016**

## RESULTS & DISCUSSIONS

Visualization of solar radiation and energy production results are provided below for each sub-model developed through optimization. The results demonstrate significant total potential in solar energy generation due to the geographic coordinates of the structures, when the retrofitting solutions are applied correctly.

However, the BIM tools used in this study for energy analysis are still under development. Accordingly, it is a significant challenge to optimize models to have accurate flow of data between systems. Since, BIM modeling software market is greatly dominated by only a few companies (e.g. Autodesk Revit), sustainability practitioners are depending upon a limited extend of energy analysis plug-ins; which may otherwise result in compatibility issues.

**Figure 5: Solar Energy Results for Pier 1-2, Pier 3-4, Pier 5, Pier 5 Roof, Terminal Building, Custom Solar Scale on Energy Units (kWh) per Unit Area (m<sup>2</sup>)**

Another problem about this BIM application is associated with the lack of guidelines and standardized workflows for right data retrieval from BIM models. Correspondingly, commercial BIM software technology market should further be evolved; and preparation of detailed BIM guidelines should be encouraged to improve the effectiveness of building retrofitting plans.

Retrofitting of existing buildings, as an evolving field of research, represents vast possibilities in increasing the energy efficiency of buildings. Façade design plays a crucial role in the retrofit of a building, and can offer additional benefits by incorporating possibilities of energy production (Bigaila, Hachem-Vermette, El-Sayed, & Athienitis, 2016).

Correspondingly, building-integrated photovoltaic (BIPV) glazing can be suggested as a retrofit solution for this case study. This is a new approach in which PV modules are integrated into the building envelope materials and components. As such, the PV system is not an added component, but rather a part of the essential building envelope. The electricity generated by the BIPV system can be stored in batteries so that the system can be used as an off-grid system. Alternatively, the system can be interfaced with the utility grid and the electricity generated can be sold back to the grid (Verboon & Laufs, 2013).

BIM implementation in the project gives many opportunities in terms of providing easy access to all project data (or one can say “big data”) – including 3D models at various levels of detail (LODs), 2D drawings, and all supplemental documents- from a single digital platform. Besides,

BIM also allows fast modification or update on data whenever needed while greatly eliminating waste in terms of time and money. As a summary, following points can be listed as benefits of BIM for sustainability;

- Energy modeling (detailed analysis of energy needs of the structure and analysis of renewable energy options such as solar energy),
- Building orientation (providing best building orientation option that leads to minimum energy cost),
- Reducing wasted time and resources for energy analysis (allowing rapid modifications in many design parameters),
- Access to current data for unit energy costs and weather via an internet server.

## CONCLUSIONS

Building energy modeling tools provide an efficient, simple method in predicting the energy use of new and existing buildings. Via a decent optimization procedure and project defaults assumptions, energy analysis of all Terminal and Pier Buildings are conducted. Consequently, Autodesk Insight 360 provides annual and monthly data – both in energy units and in monetary units- of total energy consumption of the analyzed buildings. Annual and monthly monetary and energy equivalents of space heating, space cooling, area lighting, hot water supplies can also be generated graphically, which can enable the users to foresee energy consumption levels of airport buildings in future studies. However, in the context of this paper, solar analysis results are presented to articulate the simplicity in extracting data for retrofitting decision-making process. Since the tool aids in conducting iterative process by means of fast data-input, the facility owners can acknowledge the potential in PV energy production at the operational stage of the airport.

### ABSTRACT

The growth medium of a green roof is likely to affect the chemistry of the rainwater passing through it, which may impact the receiving waters. Currently only limited data exist on the changes in rain chemistry caused by green roofs. The objectives of this project are to determine the differences in concentration of several contaminants in rain and in runoff from a green roof in downtown Syracuse, NY, and to explore reasons for the observed differences. A few samples were collected in 2014 and 2016, but most of the data are from 2017. Collection of precipitation uses funnels, while collection of runoff takes place using a drainpipe that connects to several roof drains. Both types of samples are analyzed by ion chromatography for chloride, sulfate, and nitrate. Preliminary tests show that chloride concentrations in the green roof runoff are generally greater than or equal to those in precipitation. Sulfate in the runoff is greatly enhanced compared with precipitation. Nitrate concentrations do not show a clear pattern. Engineered soil greatly influences the chemistry of the incoming rain, and additional research is needed to better understand this chemistry.

### KEYWORDS

Green Roof, Stormwater, Ion Chromatography, Precipitation Chemistry, Runoff Chemistry

### INTRODUCTION

Widespread urbanization has shown an increase in impermeable surfaces where there was once soil and plants to absorb the precipitation. The lack of area for infiltration can lead to flooding, and in cities with combined sewers, it can lead to combined sewer overflow where raw sewage enters the receiving waters. To reduce flooding and discharge of untreated sewage, green infrastructure such as green roofs can be installed to delay and store rain runoff.

Previous work has shown that rainwater flowing through the growth medium of a green roof (engineered soil) can experience changes in chemistry. For example, Vijayaraghavan et al. (2012) report higher concentrations of nitrate, phosphate, and sulfate in runoff compared to the incident rain using green roof test plots in Singapore. The plots incorporated growth medium with the trade name “universal garden soil” and were planted with sedum. Czemieli Berndtsson (2010) presents a literature review of green roof studies, some of which include chemical analysis of runoff. The data show that levels of nitrogen and phosphorus species in green roof runoff by different authors are quite variable, in part due to different roof characteristics.

The primary objective of this project is to compare the concentrations of chloride ( $\text{Cl}^-$ ), sulfate ( $\text{SO}_4^{2-}$ ), and nitrate ( $\text{NO}_3^-$ ) in fresh precipitation and in rainwater that has passed through a large, extensive green roof. A second objective is to explore the reasons for these changes. Chemicals such as sulfate and nitrate, which contribute to acid deposition, are especially

important. Excess nitrogen in the runoff can have an adverse effect on the receiving waters by enhancing algae growth and eutrophication. The roof used in this study is on the Onondaga County Convention Center (OnCenter) in Syracuse, NY.

## METHODS

The green roof, installed in 2011, is 0.56 hectares with growth medium 7.6 cm deep planted with six types of sedum. There are 25 roof drains, and samples are collected from a pipe connected to eight of these drains. Precipitation is collected on the roof of the Biological Research Laboratories on the Syracuse University campus, about 1.6 km east of the green roof. Sample bottles are secured in a wooden frame with funnels. Field blanks are obtained at each location. All samples are analyzed for chloride, sulfate, and nitrate using an ion chromatograph (IC). No fertilizer or other chemicals have been added to the roof since it was installed in 2011, although characteristics of the growth medium have undoubtedly changed over time. Only limited chemistry data from runoff were obtained prior to 2017.

## RESULTS

Figure 1. a, b, c shows average net concentrations for  $\text{Cl}^-$ ,  $\text{SO}_4^{2-}$ , and  $\text{NO}_3^-$  in the precipitation and green roof runoff. Each bar represents a separate rain event from 2014 to 2017.

## DISCUSSION

Figure 1a shows that chloride concentrations in the runoff are usually equal to or greater than concentrations in the incoming rain. In storms 4/15/2017 and 7/20/2017, the opposite is observed, but the number of samples in these storms is small. The reason for the high chloride concentration in runoff on 6/4/2017 is unknown. This concentration is not likely due to contamination, as all three samples of runoff show similar high concentrations.

Sulfate concentrations shown in Figure 1b are consistently significantly higher in the runoff than in the precipitation. The data support the green roof being a source of sulfate. Investigations of the source of this sulfate are underway.

The nitrate concentrations from the runoff represented in Figure 1c show no dominant pattern when compared to the rain concentrations. About half of the rain events have runoff concentrations greater than precipitation, while the other half of the runoff concentrations are less than the those in precipitation.

The highest nitrate concentration in runoff occurs on 8/3-4/2017. The precipitation data shown in the graph is an average of five samples, one from an event on 8/3 and four from an event on 8/4. The storm on 8/3 had a nitrate concentration of 5.7 mg/L, while the storm on 8/4 had a concentration of 1.4 mg/L. The first storm had an intensity of 15.6 mm/hr and lasted for 10 minutes, a brief but intense cloudburst. In contrast, the second storm the next day had an intensity of 2.4 mm/hr and lasted two hours. The differences in concentrations in the precipitation from these storms is notable.

No runoff from the green roof occurred during the cloudburst on 8/3, as the total rainfall was only 2.6 mm. However, runoff occurred the next day when the total rainfall reached 4.6 mm. The concentration in the runoff averaged 5.0 mg/L, much greater than the concentration in the rain on that day. The runoff on 8/4 most likely included some of the high concentration rain on 8/3. Hence one cannot conclude that the nitrate in the growth medium was responsible for the elevated levels in runoff on 8/4.

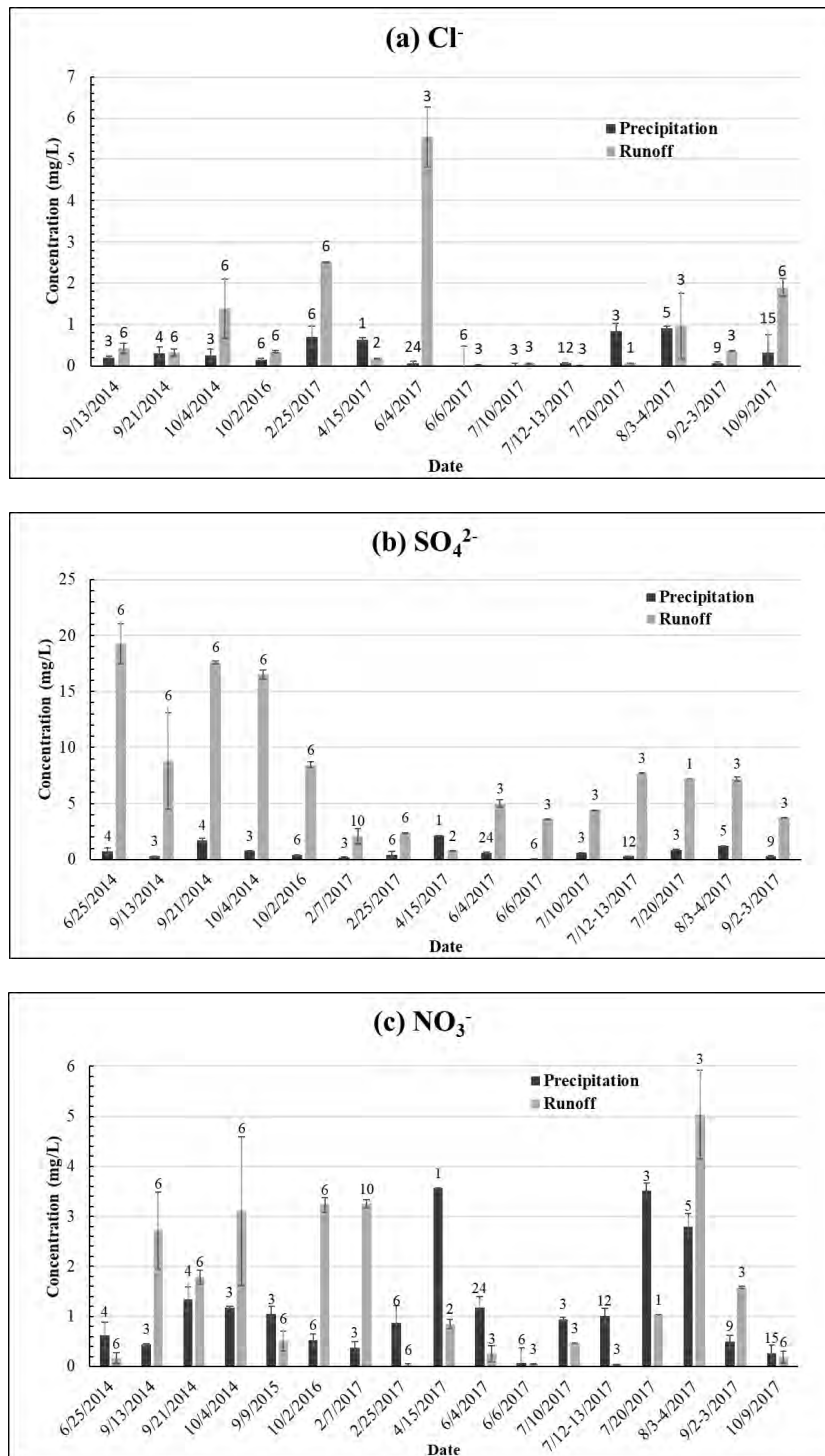

Figure 1. Average concentrations of chloride, sulfate, and nitrate, measured in precipitation and green roof runoff from selected storms. Error bars show one standard deviation from the mean. Each bar represents the average of the indicated number of samples, ranging from 1 to 24.

Johnson and Davidson (2017) note that fertilizer was applied to the green roof at the time of its installation in 2011. It is not known whether the nitrate concentrations in Figure 1c were influenced by this fertilizer. However, it is of interest that events on 6/25/14, 9/9/15, and many events in 2017 had runoff nitrate levels less than those in incoming rain. Rowe (2011) reports high nutrient concentrations in green roofs that have been fertilized. Age of green roof and vegetation type can factor in to the leeching of nitrate into the runoff (Czemiel Berndtsson, 2010).

Comparing patterns for the three analytes in Figure 1 shows that the storm on 4/15/2017 is unique in that concentrations in precipitation exceeded those in runoff for all three analytes. Further investigation of this event is underway.

Data collection is continuing and will expand to include other chemicals in future work. Arrangements are also being made to sample a nearby traditional roof as a control.

## CONCLUSIONS

Concentrations of chloride, sulfate, and nitrate in fresh precipitation and runoff from a green roof in several events show a number of patterns. Concentrations of chloride in the runoff are generally equal to or greater than levels in the incoming rain. The same is true for sulfate. However, concentrations of nitrate showed more complex results: nitrate levels in runoff exceeded levels in rain for roughly half of the events, while the opposite was observed for the other half. One especially intense storm produced the highest levels of nitrate in rain observed throughout the study; runoff from a storm the next day most likely included some of the previous day's rainwater and showed similarly high concentrations. Chemical analysis of rain and runoff will continue in future work.

## ACKNOWLEDGMENT

This work was supported in part by NSF grant #1444755, Urban Resilience to Extremes Sustainability Research Network, by funding from an NSF EMPOWER NRT grant, and by a Syracuse University Water Fellowship. The authors gratefully acknowledge the assistance of the Onondaga County Department of Facilities Management, especially Han Pham and Archie Wixson. The laboratory assistance of Mario Montesdeoca is also appreciated.

### ABSTRACT

The present paper studies the thermal and energy performance and potential adaptive reuse of the lost underground bunkers of Kukës, Albania. The approach is exemplified using a 150-m long cross-section of the underground network selected for the parametric computational simulations. Data regarding local climate, design typology, and building materials is used to generate a finite-element simulation model of the underground tunnels. Different scenarios including insulation of the outer walls, occupancy patterns, and ventilation regimes are tested. The results show that indoor air temperature ranges from 15-18°C during winter and 23- 28°C during summer. During January, the temperatures are higher by 3-5 °C in comparison to the same structure and scenarios located above ground, whilst during July they are 5-8 °C lower. Insulation does not affect the heat flux through the outer walls. The average energy consumption oscillates around 55 KWh.m<sup>-2</sup>.a<sup>-1</sup> for base case and 98-230 KWh.m<sup>-2</sup>.a<sup>-1</sup> for design scenarios. The results establish the same building consumes 44-145% more energy when located above ground as opposed to underground.

### KEYWORDS

Thermal performance simulation, scenarios, energy, underground nuclear bunker, adaptive reuse

### INTRODUCTION

Figure 1. a) Partial section of the underground network of tunnels for Kukës, b) Close-up partial axonometric drawing of the inner construction of the tunnels.

Whilst above ground thermal comfort can be reached only via additional services, earth sheltered buildings are known for their temperature stability (Kajtar et al. 2015) and they gain benefit from the soil's quasi-stationary temperature to achieve energy conservation (Alkaff et al. 2016). Because of the high thermal inertia of the soil, the temperature fluctuations at the

surface of the ground are diminished as the depth of the ground increases (Florides and Kalogirou, 2005): the temperature of the soil changes with amplitude of 0.6 °C in the depth of 8 m and 0.2 °C in the depth of 10 m (Kajtar et al. 2015). After the depth reaches more than 20 m, the temperature becomes practically constant (Popiel et al. 2001). Popiel has concluded with the formula shown in Equation 1, where  $x$  is the depth below the ground surface,  $T$  is the temperature,  $k$  is the heat conductivity of the ground, and  $q$  the heat flux, that the heat flux of the soil is practically constant (2001). Florides depicts that due to the solar radiation and soil's relative capacity there is a 5-hour time lag a day regarding temperature distribution (2005). This explains why after reaching a specific depth the soil's temperature is always higher than the air temperature during winter and lower during summer.

$$q = -k \frac{\partial T}{\partial x} \quad (1) \text{ (Popiel et al. 2001)}$$

This knowledge has been practiced since ancient times: Samos, Greece, Cappadoccia in Turkey, and the Hypogeum belong to the 6th century BC, 1900-1200 BC, and 4000 BC respectively (Nývlt et al. 2016; Debertolis et al. 2015). Living underground has become today a widely spread trend in countries such as China, Japan, and Korea where residents find comfort from the increasingly high economic pressure of living in apartments. In these countries, underground urban planning is a field study of its own (Zhao et al. 2016; Li et al. 2016) and some insist it should be an integral part of any National Regulation Plan (Tan et al., 2018). The studies on the computational evaluation of either thermal or energy performance for such spaces are fewer in number. Zhu has carried out thermal simulations on a sample of atrium plan earth sheltered buildings concluding that the buildings constitute a step forward towards low energy building design (Zhu and Tong, 2017). Another thermal performance simulation and evaluation study has been carried out by Ip, but the building in question has only one wall in contact with the earth (Ip and Miller, 2009). Tan has investigated the thermal comfort conditions in underground spaces in four major Chinese cities characterized by different climate conditions in order to assess the influence of the specific climatic variables (Tan et al. 2018). Tan however also recognizes his study as only qualitative and evaluates a building energy modeling would provide more solid data since qualitative analyzes often depend on real life restrictions (Tan et al. 2018).

In Albania, a special kind of underground shelters can be observed: nuclear bunker tunnels. A similar design typology is the subway, but it differs in many ways such as scenario, and traffic network which greatly influence the thermal and energy performance of the construction. The tunnels of Kukës are part of the ex-secret military establishments of Albania. This network is 2400 m long and composed of 30 galleries. Each gallery is composed of a corridor with a row of rooms on one side; an outer concrete shell envelops rooms and corridors, whilst the indoor walls were built with bricks. The tunnels have corridors which are 270 cm high and 120 cm wide, and rooms of an average of 3.4x3.4m. The network is located from 319 m to 336 m above the sea level (the different levels are connected by staircases), whilst the ground level of the city of Kukës is located 350 m above the sea level (Poliba, 2017; Municipality of Kukës, 1973). The outer walls of the tunnels are composed of 40 cm thick reinforced concrete. The inner walls are composed of bricks and amount to 27 cm thickness. These capillaries, which were constructed in several cities during the communist period and never used to fulfill the purpose for which they were built (refuge in case of war), constitute a large underground network of concrete leftover space. Therefore, the question on the efficiency with which they can fulfill their original purpose i.e. that of sheltering, comes out naturally. This study assesses the thermal performance and evaluates the adaptive reuse efficiency of the underground shelters via computational simulation modelling using the case study of the

tunnel network found in the city of Kukës as a starting point. Whereas previous studies have provided significant insight on different topics related to underground structures, there is a lack of quantitative studies providing close examination of thermal performance and energy consumption evaluation. Thermal and energy performance evaluation has not been explored yet on this typology of shelter in Albania or elsewhere, and the number of similar studies worldwide is limited. Furthermore, this paper suggests and tests alternatives for low energy consumption adaptive reuse functions appropriate for the design typology, and space quality of the tunnels.

## METHODS

Initial simulation models were generated based on collected geometry and construction data. Assumptions were made based on in situ observations and historical documents. The simulations are conducted with Design Builder, a software tool used to perform building energy, lighting, and comfort performance. The software has been developed to simplify the process of building, modelling, and simulation for maximum productivity allowing users to rapidly compare the function and performance of building designs, different scenarios, and deliver results quickly. Meteoronorm software was used to generate the local weather file for the city of Kukës. A 150 m tunnel section that serves as an extension of the existing hospital of the city, directly connected to it by its basement, is used for the simulations. A digital performance simulation model of the underground tunnel section is generated including the modelling, occupancy patterns, air humidity, and ventilation regimes. A set of five sample scenarios are established for the parametric study. The first scenario (S1) corresponds to the existing conditions. A second scenario (S2) is defined involving thermal insulation. Three additional scenarios (S3-S5) address the thermal performance of different potential reuse activities: laboratory (S3), hospital (S4), and museum (S5). Two simultaneous sets of simulations for scenarios S3-S5 are conducted to verify energy reduction potential of underground buildings with comparison to above ground buildings: S3-S5 when the building is located at 325 m above the sea level (the actual level of the tunnels), and S3.2-S5.2 when the building is located at 350 m above the sea level (the level of the city). Table 1 illustrates the data on scenarios S3-S5 and S3.2-S5.2. The thermal transmittance of the materials is as follows: 0.27, and 0.29 for inner and outer walls respectively, whilst without insulation these values are 1.42, and 2.31.

Table 1. Data pertaining to chosen scenarios for the study of activity impact on the underground tunnels' thermal load.

Code	Activity	Schedule	Density (people/m <sup>2</sup> )	Gain (W/m <sup>2</sup> )	Radiant fraction	Heating (20°C)	Cooling (20°C)
S3; S3.2	Laboratory	12/24 h	0.11	8.73	0.2	20	23
S4; S4.2	Hospital	24/24 h	0.10	3.58	0.2	18	25
S5; S5.2	Museum	varying	0.15	3.50	0.2	20	24

## RESULTS

Figure 2. Simulated indoor temperatures (whole building) for S1 (base case without insulation) and S2 (base case with insulation) together with the external temperature data from the weather file. a) 15<sup>th</sup> and 16<sup>th</sup> of January, 2016, b) 15<sup>th</sup> and 16<sup>th</sup> of July, 2016.

Figure 3. Comparison of the simulated indoor temperatures (whole building) of the scenarios together with the external temperature data from the weather file for the 15<sup>th</sup> and 16<sup>th</sup> of January, 2016, a) S3-S5 (underground), b) S3.2-S5.2 (above ground).

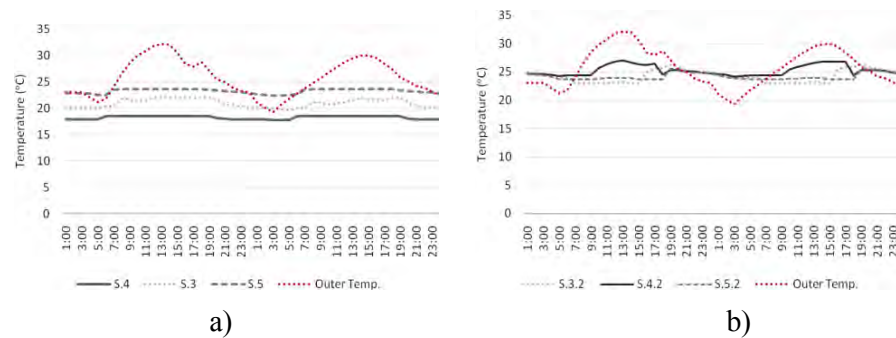

Figure 4. Comparison of the simulated indoor temperatures (whole building) of the scenarios together with the external temperature data from the weather file for the 15<sup>th</sup> and 16<sup>th</sup> of July, 2016, a) S3-S5 (underground), b) S3.2-S5.2 (above ground).

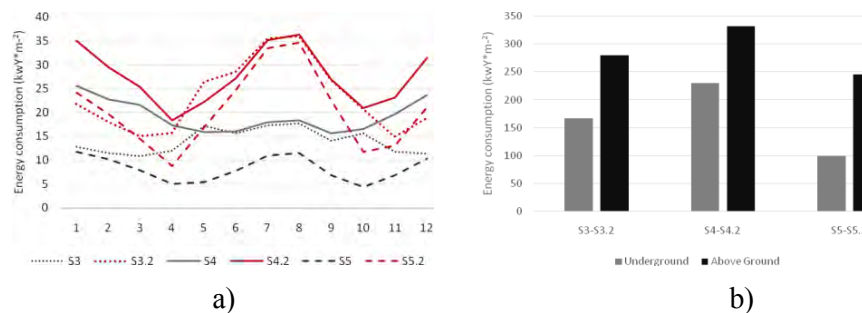

Figure 5. a) Comparison of simulated monthly energy demand ( $\text{kWh}\cdot\text{m}^{-2}$ ) for S3-S5 and S3.2-S5.2, b) Simulated annual energy demand ( $\text{kWh}\cdot\text{m}^{-2}\cdot\text{a}^{-1}$ ) for S1-S5.

Figure 2 illustrates the thermal performance of base case scenarios with and without insulation, S1-S2. Figures 3 and 4 provide an overview of the thermal performance in the selected scenarios (S3-S5; S3.2-S5.2) based on two reference days in January and July. Figure

5 summarizes comparative information regarding undergrounds' monthly energy use for the selected activities (S3-S5; S3.2-S5.2), as well as yearly overall energy consumption for S1-S5.

## DISCUSSIONS

After comparing the theoretical background presented in the *Introduction* section and the results from the graphs in the *Results* section, conclusions are as follows:

- i. The theoretical background assesses the heat flux of the soil in the depth where the tunnels are located, 25 m underground, is almost constant and allows the spaces enveloped in it to remain cool during summer and warm during winter. This fact is proven by the graphs shown in Figure 2 where the graph lines for 10 cm and no thermal insulation temperature performance are overlapping, thus demonstrating the effect of thermal insulation on the thermal performance of the building is negligible. During January, the time lag phenomenon described in the *Introduction* can be observed: the temperature alternates between the earth and the ground, when above ground the temperatures are high, they are lower underground and vice versa. The time lag is of approximately 10 hours. However, this phenomenon cannot be observed during July because the temperatures are constantly high and do not vary.
- ii. Figures 3a and 4a compare the temperature performance of scenarios S3-S5 during two days in January and July. During January, all temperatures show an increment during the day, and cooling down after 18:00. The hospital's temperatures are more constant and 2-3°C lower. The laboratory's and museum's temperatures vary considerably during the 12/24 hours of activity, most likely due to the nature of the activities held which require more physical interaction and movement from the people involved. During July, the temperature variation lines are considerably more constant and closer in value to one another. The average temperatures during July are 23.1°C, 24.2°C, and 23.3°C for S3, S4, and S5 respectively. The average temperatures during January are 21°C, 18.3°C, and 19.1°C for S3, S4, and S5 respectively. Figures 3b and 4b compare the temperature performance of the activity scenarios when located above ground: S3.2-S5.2. During January, the temperatures are lower by 3-5°C in comparison to the same scenarios located underground, whilst during July they are 5-8°C higher.
- iii. The performance of the three scenarios regarding energy consumption varies. The average energy consumption per month is 14, 19.2, and 8.24 kWh m<sup>-2</sup>.a<sup>-1</sup> for S3, S4, and S5 respectively. Regarding yearly energy consumption, the hospital's energy consumption results are 38% higher than the laboratory's, and 135% higher than the museum's. The results establish the same building consumes 44-145% more energy when located above ground as opposed to underground.

## CONCLUSIONS

The case study of underground shelters poses an invitation for different research topics, however, the majority of information on them is provided by theoretical or qualitative studies. This paper is preoccupied with providing quantitative data on underground spaces, specifically nuclear shelters situated in the city of Kukës, Albania. The focus is on indoor thermal performance and energy consumption evaluation conducted via simulation software in order to assess the feasibility of adaptive reuse. Using the example of thermal simulation of a tunnel section, we explore the process and the recent results from the data collection. Hence, a building simulation model can be applied toward the assessment of the buildings'

performance and prediction of the consequences of alternative options for its renovation, reuse, and adaptation. Different scenarios are tested in order to assess the thermal performance of adaptive reuse alternatives for activities of 12/24 h, 24/24 h, and indefinite occupancy hours such as laboratories, hospital extensions, and museums respectively. The study concludes that a preferable scenario for adaptive reuse would be an activity held only 12/24 h, resulting in less energy consumption. In the present specific case, the 150 m section rooms can be proficiently repurposed as laboratory sectors that could serve to the hospital situated above ground. Although simulation and evaluation through software may face limitations due to the inability to make comparison with real life situations, the study represents an effective and well documented first step towards energy efficiency and possible adaptive reuse of abandoned underground or earth sheltered bunkers.

## ACKNOWLEDGEMENT

This research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors.

Special thanks are extended to Artan Hysa, professor at Epoka University, for his assistance during the preliminary phase of this research.

### ABSTRACT

Optimization algorithms play a vital role in the Building Energy Optimization (BEO) technique. Although many algorithms are currently used in BEO, it is difficult to find an algorithm that performs well for all optimization problems. Some algorithms may fail in some cases. This study specifically focuses on failure algorithms in BEO and the possible causes. Several criteria are proposed for identifying failure algorithms. Four optimization problems based on the DOE small and large office buildings are developed. Three commonly used algorithms in BEO, namely, Pattern Search (PS) algorithm, Genetic Algorithm (GA) and Particle Swarm Optimization (PSO) algorithm, are applied to the four problems to investigate possible reasons for their failure. Results indicate that the effectiveness of the three selected algorithms is highly dependent on the optimization problems to be addressed. Besides, the control parameter setting of the PS algorithm appears to be a significant factor that may cause the algorithm to lose effectiveness. However, it does not seem to be the main reason for the failure of the GA and PSO algorithm. In General, the results gained from this study can deepen our understanding of optimization algorithms used in BEO. Besides, understanding the reasons why optimization algorithms are ineffective can help architects, engineers, and consultants select the appropriate optimization algorithms and set their parameters to achieve a better BEO design that is less vulnerable to failure.

### KEYWORDS

Building energy optimization; failure optimization algorithm; cause of failure; algorithm parameter setting

### INTRODUCTION

Building Energy Optimization (BEO) is a booming technique that combines building energy simulation engines with optimization engines. Unlike the conventional “trial-and-error” design methodology, which requires designers to manually adjust the design based on their experience and limited simulations, the BEO technique can automatically generate and simulate new designs utilizing optimization algorithms and performance simulation software and finally achieve the best design based on the predefined design objectives (Si et al. 2016). Therefore, optimization algorithms play a crucial role in the application of the BEO technique.

As shown in some important review works (Machairas et al. 2014; Shi et al. 2016), a quite number of algorithms can be used in BEO, for example, the evolutionary algorithms, direct search algorithms, hybrid algorithms, etc. However, there is in fact no universal algorithm that applies to all optimization problems, which means an algorithm may fail under certain circumstances. Thus, finding the causes for their failure and exploring the circumstances under which an algorithm may become fail can significantly help designers to choose an appropriate algorithm among the available options and help them avoid failure algorithms.

The objective of this research is to study failure optimization algorithms used in BEO and possible failure reasons. The first research task is to develop a set of criteria to recognize whether an optimization algorithm fails for a BEO problem. Then four optimization problems are developed using the DOE small and large office buildings. Three optimization algorithms are selected to investigate the possible factors that may cause them to fail for the four optimization problems.

## METHODS

### Criteria for identifying failure algorithms

Before defining a failure algorithm, we need to distinguish two concepts: a failure algorithm and a failure optimization run. For a specific optimization problem, an optimization algorithm fails on an optimization run does not mean it fails for the optimization problem. The reasons are stochastic optimization algorithms (e.g., GA, PSO, etc.) usually involve random operators in their optimization processes, which will result in different optimization runs when they are run repeatedly. In this case, one specific optimization run cannot reflect the performance of the algorithm. Users need to repeat the optimization test as many times as possible and then analyse all optimization runs. However, for a determined optimization algorithm, it usually has a unique optimization run which can fully reflect the performance behaviour of the algorithm when all relevant parameters and the initial solution remain unchanged. Therefore, in this study, we firstly proposed two criteria, which are the most concerned issues for designers when using optimization techniques, to identify a failure optimization run. Then the failure rate criterion was used to identify a failure algorithm. Note that this paper is particularly focuses on single-objective algorithms because about 60% of the building optimization studies used the single-objective approach (Nguyen et al. 2014). Multi-objective optimization algorithms are not covered.

In general, a successful optimization run should find the optimal solution within the desired accuracy level using a limited amount of time. It requires two criteria that should be met simultaneously, one of which is the quality of the optimal solution obtained in the optimization run should be high enough to meet the users' requirements, and the other is the computing time cannot exceed the time limit. An optimization run that violates any of the above two criteria is considered failure. In this study, to measure the quality of the optimal solution, Equation 1 can be used to calculate the relative distance between the optimal solution found in an optimization run and the true optimum of the optimization problem.

$$\delta = \frac{|f(x') - f(x^*)|}{f(x^*)} \times 100\% \quad (1)$$

where  $f(x')$  is the objective value of the optimal solution found in an optimization run, and  $f(x^*)$  is the objective value of the true optimum, which in some cases can be obtained through brute-force search. If the value of  $\delta$  is larger than that of  $\delta^*$  which is the acceptable accuracy level defined by the designer, then the optimization run is considered failure.

To define a failure optimization algorithm for a given problem, the algorithm needs to repeat the optimization process several times and then those failure runs need to be isolated to calculate the failure rate, which in essence, is the ratio of failure optimization runs to the total runs. Equation 2 provides a formula.

$$\beta = \frac{N_{failure}}{N_{total}} \times 100\% \quad (2)$$

where  $N_{failure}$  is the number of failure runs and  $N_{total}$  is the total number of runs driven by the algorithm. According to the Low Probability Event (LPE) principle (McClelland et al. 1993), which is an important theorem in probability and commonly applied in practical projects and mathematical statistics, an LPE is considered will not occur in the actual environment. In practice, the value of 0.01, 0.05 or 0.1 are commonly used for an LPE which can be denoted by  $\beta^*$ . Users can also set other values according to their specific conditions. Consequently, in this study, an algorithm is considered failure for a given optimization problem when  $\beta > \beta^*$ .

### Description of the standard optimization problem

Table 1. Specifications of optimization variables.

Design variables	Symbol	Unit	Step size	Range	Initial value
Building long axis azimuth	$x_1$	°	5	[0,180]	90
Cooling set-point temperature	$x_2$	°C	0.05	[22,29]	24
Heating set-point temperature	$x_3$	°C	0.05	[15,22]	21
Roof insulation conductivity	$x_4$	W/m·K	0.001	[0.03,0.06]	0.049

North window U-value	$x_{20}$	W/m <sup>2</sup> K	0.05	[1,7]	3.25

Figure. 1 Perspective views of the DOE small and large office buildings.

In this study, four optimization problems with 10 and 20 optimization variables respectively were developed following the models of the DOE small and large office buildings (Deru et al. 2011) in Baltimore, USA. They were all designed to minimize the annual energy consumption of the case buildings. Figure 1 shows the architectural schematic views of the buildings. They

all have one core thermal zone and four perimeter thermal zones on each floor. Table 1 lists the optimization variables involved in the optimization problems as well as their initial values, step sizes and range of variations. Specifically, the value for the lower window position is fixed at 0.9 m, and the windows in the same facade are of equal area. Besides, the first ten variables were used for optimization problems with 10 design variables.

## RESULTS

In this section, three commonly used optimization algorithms in BEO, namely, Pattern Search (PS) algorithm, Genetic Algorithm (GA) and Particle Swarm Optimization (PSO) algorithm were assessed to find out possible factors that may cause the algorithms to fail. As shown in Table 2, four algorithm parameter settings for each algorithm are randomly generated to investigate their impacts on the effectiveness of the selected algorithms. Readers are referred to the manual book (Wetter M, 2011) for more information of the working strategies and the original development of each algorithm. Based on the two criteria proposed above about a failure optimization run, two evaluation approaches are accessible: (1) assessing the quality of the optimal solution obtained when the computing time is restricted; (2) assessing the computing time consumed when the optimization run finds the desired solution. In this study, we chosen the first approach. The maximum number of simulations for each optimization run was restricted at 300, and each optimization process was repeated 10 times to calculate the failure rate. These numbers were chosen to strike a balance between what is preferred and what is practical in terms of computing time. Specifically, the true optimum of the four optimization problems were obtained by brute-force search and were listed in Table 3. Besides, the desired accuracy level  $\delta^*$  of optimal solutions was set at 1%, and the acceptable maximum failure rate  $\beta^*$  was 10%.

Table 2. Algorithm control parameter settings for each algorithm.

Algorithms	Parameters	Test 1	Test 2	Test 3	Test 4
PS	Expansion factor	2	3	4	5
	Contraction factor	0.2	0.4	0.6	0.8
GA	Population size	10	15	20	30
	Number of generations	30	20	15	10
	Elite count	1	2	3	4
	Crossover fraction	0.2	0.4	0.6	0.8
	Mutation rate	0.05	0.1	0.15	0.2
PSO	Population size	10	15	20	30
	Maximum number of iterations	30	20	15	10
	acceleration const 1 (local best influence)	2	3	2	3
	acceleration const 2 (global best influence)	2	2	3	3
	Initial inertia weight	0.9	0.8	0.7	0.6
	Final inertia weight	0.4	0.3	0.2	0.1

For each optimization problem, the quality variation of the optimal solution obtained by each algorithm in each test were illustrated in Figure 2. As shown, each algorithm has 4 consecutive boxplots, corresponding to the 4 tests listed in Table 2. It is noted that all optimization runs used the same initial solution listed in Table 1 to avoid the influence of different initial solutions on the evaluation results.

As shown in Figure 2, for each optimization problem, the average quality of optimal solutions found by the PS algorithm changes violently between different tests, which means the performance of the algorithm is sensitive to its parameter settings. It is further verified when the PS algorithm was use to solve Problem 1, in which it succeed in Test 1 but failed in Tests

2-4. Therefore, inappropriate parameter settings of the PS algorithm may cause it to fail. However, for the same optimization problem, the average quality of optimal solutions searched by the GA and PSO algorithm appears to be more stable between different tests. Thus, the effectiveness of the two algorithms are less sensitive to their parameter settings. Although GA and PSO algorithm failed in all four tests for Problem 1, 2 and 4, we cannot conclude if different parameter settings will cause the two algorithm to lose effective.

Figure. 2 Quality variability of the optimal solutions obtained by each algorithm in each test with different algorithm parameter settings.

Table 3. True optimum of each optimization problem and failure rate of each algorithm for each test.

Index	Optimization problems	True optimum ( $\text{kW} \cdot \text{h}/\text{m}^2 \cdot \text{a}$ )	Algorithms	Failure rate			
				Test 1	Test 2	Test 3	Test 4
Problem 1	Small office and 10 variables	95.532	PS	0	100%	100%	100%
			GA	100%	100%	100%	100%
			PSO	100%	100%	100%	100%
Problem 2	Small office and 20 variables	134.741	PS	100%	100%	100%	100%
			GA	100%	100%	100%	100%
			PSO	100%	100%	100%	100%
Problem 3	Large office and 10 variables	96.066	PS	0	0	0	0
			GA	10%	0	0	0
			PSO	0	0	0	0
Problem 4	Large office and 20 variables	125.355	PS	100%	100%	100%	100%
			GA	100%	100%	100%	100%
			PSO	100%	90%	100%	100%

Table 3 gives the calculated failure rate of the trial optimizations (each statistic relating 10 repeated optimization runs). It shows that for Problem 1, the PS algorithm performed well for Test 1 with a failure rate of 0, but failed for Tests 2-4 with a failure rate of 100%. The quality of the optimal solutions obtained by GA and PSO in the four tests were all beyond the desired accuracy level of Problem 1, and therefore, their failure rates were all 100%. For Problems 3 and 4, all the three algorithms failed to find desired solutions in all tests with a failure rate larger than the acceptable maximum failure rate (i.e., 10%). However, when applying the three algorithms to Problem 2, all of them could consistently find desired optimal solutions with a failure rate of no more than 10% even when they used different parameter settings. Thus, the effectiveness of the three selected algorithms highly depends on the optimization problems solved. In this study, some properties involved in the Problems 1, 2 and 4 seem to dominate the failure of the three selected algorithms.

## CONCLUSIONS

Optimization algorithms play a critical role in determining the effectiveness and efficiency of BEO techniques. In this study, the criteria for helping users to detect failure optimization algorithms used for BEO problems are proposed. Four optimization problems were developed to find out possible factors that may cause three commonly used algorithms to fail. The numerical results demonstrate the following failure mechanisms of the selected algorithms: (1) algorithm control parameter setting is an important factor that may cause the PS algorithm to fail but it does not seem to be a key factor that may cause the failure of the GA and PSO algorithm. (2) Some inherent properties of optimization problems may cause the three algorithms to fail because their performance appeared to be highly dependent on the optimization problems addressed. Future research is required to examine the impacts of different properties involved in a BEO problem on the performance behaviour of different optimization algorithms.

### ABSTRACT

The objectives of the present review are to: 1) summarize the existing knowledge on the mechanisms of the corrosion, identify and analyze the major factors affecting the corrosion of copper and silver; 2) compare various measurement techniques for the study of atmospheric corrosion and models of corrosion; 3) identify knowledge gaps for atmospheric corrosion; 4) recommend “realistic worst case” pollution levels for laboratory testing of humidity and temperature effects on corrosion and assessment of datacom equipment reliability in data centers. This review focuses on the five pollutants: SO<sub>2</sub>, NO<sub>2</sub>, H<sub>2</sub>S, O<sub>3</sub> and Cl<sub>2</sub>. Results of the review include: the pollution levels and thermal environmental conditions in data centers; fundamental mechanisms of corrosion; current knowledge of the major factors affecting the corrosion rates of copper and silver; the techniques (QCM, Coulometric Reduction, SEM, XPS, FTIR and EIS) for the measurement of corrosion levels. It was found that the “realistic worst-case” concentrations for H<sub>2</sub>S, NO<sub>2</sub>, SO<sub>2</sub>, Cl<sub>2</sub> and O<sub>3</sub> are 10 ppb, 80 ppb, 40 ppb, 2 ppb and 60 ppb, respectively. Different levels and combinations of contaminants, temperature, relative humidity and air velocity cause different corrosion on the metal. Chloride, Nitrogen dioxide and Sulfur dioxide are the common corrosive gases for the datacom equipment. Hydrogen sulfides and ozone are very important gaseous contamination in data center environment. Each of them alone can damage the equipment, and their synergistic effects with the other compounds and humidity can cause significantly more damages, but a mechanistic model is lacking for predicting the synergistic effects and better design of the thermal environment to ensure equipment reliability while improve the energy efficiency through the use of outdoor air for free cooling.

### KEYWORDS

Atmospheric corrosion, copper, silver, SO<sub>2</sub>, NO<sub>2</sub>, H<sub>2</sub>S, O<sub>3</sub> and Cl<sub>2</sub>

### INTRODUCTION

Data centers have the highest energy usage intensity among all building types and consume increasingly more energy due to the significant increase in the number of data centers worldwide. In an effort to reduce energy consumption, an increasing number of data centers have adopted air-side economizers to enable “free-cooling”. However, gaseous and particulate contaminants can enter data center when using air-side economizers, which may cause environment-related IT and Datacom equipment failures. Due to lack of data on the severity of the corrosion effects under realistic concentration levels and thermal environmental condition, gaseous contamination limits for the reliable operation of electronic equipment cannot be specified presently in terms of the concentration of gaseous contaminants in the air. ITEs can operate in a wide range of thermal environmental conditions including relative humidity levels up to 80% according to the current standards (ASHRAE, 2012c). There is clearly a need to determine the allowable gaseous concentration limits for the data center environment, especially under higher relative humidity conditions.

The objectives of the present review are to summarize the existing knowledge about the mechanisms of the corrosion, compare various measurement techniques for the study of atmospheric corrosion, identify knowledge gaps for atmospheric corrosion and recommend the “realistic worst case” pollutant levels and thermal environmental conditions for corrosion testing and assessment for data center applications.

### MECHANISM OF ATMOSPHERIC CORROSION

Atmospheric corrosion is one kind of electrochemical corrosion. It occurs at the metal-solution interface with the creation of cathodic and anodic sides of the metal surface. The anode and cathode reactions in atmospheric corrosion are shown in Equation (1) and (2):

Figure 1 shows various processes involved in the atmospheric corrosion of copper based on the existing finding from the literature (T. Aastrup, 2000).

Figure 1 A schematic description of the atmospheric corrosion of copper

In the case of corrosion of ITEs, because the air is strictly controlled to have a dew point lower than the surface temperature of ITEs components to avoid apparent condensation, the aqueous layer above is likely to be only a thin layer or multi-layer of H<sub>2</sub>O molecules adsorbed on the surface. Without the presence of contaminants, O<sub>2</sub> can diffuse into the aqueous layer and react with the pure copper to form a layer of copper oxide, a deposition layer that would protect the copper from corrosion. However, the gaseous pollutants, if present, can be dissolved into the adsorbed water molecules and react with O<sub>2</sub> to form H<sub>2</sub>SO<sub>4</sub>, which then reacts with copper to form copper sulfates. H<sub>2</sub>S can also react directly with copper and O<sub>2</sub> to form copper sulfides (Processes 1 through 4 above).

When chlorine dissolves in the aqueous adsorption layer (adlayer), it resolves to the chloride ions. And these ions can react with the copper, which causes the copper dissolves into the liquid regime. Sulfur dioxide react with ozone in the liquid regime and ozone oxidizes the sulfur dioxide to H<sub>2</sub>SO<sub>4</sub>. Then H<sub>2</sub>SO<sub>4</sub> combines with copper to generate the CuSO<sub>4</sub>. NO<sub>2</sub> dissolves in the liquid regime and create HNO<sub>2</sub>. And it has a reaction between HNO<sub>2</sub> and Cu to get the products of Cu<sub>2</sub>O and HNO<sub>2</sub>(gas). NO<sub>2</sub> also generates NO<sub>2</sub><sup>-</sup> and NO<sub>3</sub><sup>-</sup> after dissolving in the liquid. (Processes 5 to 10 above). While the reaction processes can be identified qualitatively, data are lacking on the reaction rate constants for the various processes identified above, and the synergistic effects of the various compounds under different relative humidity and temperature conditions cannot be readily determined from the existing literature.

### FACTORS AFFECTING THE CORROSION RATES OF COPPER AND SILVER

#### Relative humidity

Primary, secondary and tertiary values of Critical Relative Humidity have been defined as the values of relative humidity below which no corrosion of the metal in question takes place, at which corrosion occurs rapidly, and above which further acceleration of corrosion can be

observed (if exists). The primary value of critical RH for uncorroded metals seems to be virtually independent of type of metals, which depends on the type of pollutants and moisture content (and hence the temperature for the given relative humidity level) in the atmosphere (Vernon, 1935). But the secondary and tertiary (if exists) values vary quite widely, depending on the presence and levels of gaseous pollutants and their potential synergistic effects as well as the metal type (Syed, 2006).

#### **Air temperature**

For a given moisture content (or specific humidity) in the moist air mixture, an increase in temperature reduces the level of relative humidity, resulting less water molecules being adsorbed on the material surface, and hence leads to a less amount of soluble pollutant's deposition on the surface and would likely reduce the corrosion effect (Mohan, 1991). However, on the other hand, a higher temperature tends to increase the reactivity of the ionization processes involved in the corrosion, and hence could enhance the corrosion effect (Franey, 1985). Therefore, the tradeoff between these two opposite effects needs to be evaluated for specific pollutant or pollutant mixture.

#### **Sulfur dioxide**

Sulfur dioxide is the most common corrosive gas for the Datacom equipment. Combustion of all fossil fuels can form the sulfur dioxide. Copper exposed to 80% RH, and 200 ppb SO<sub>2</sub> for approximately 1000 minutes formed copper sulfite, probably as a CuSO<sub>3</sub>-xH<sub>2</sub>O-like species, and cuprous (Cu<sub>2</sub>O-like) oxide as major corrosion products (T. Aastrup, 2000). Similar results were also obtained by Erikson (1993).

#### **Nitrogen Dioxide**

Nitrogen dioxide source is the high-temperature combustion and biomass burning. Natural phenomenon like lightening also forms NO<sub>2</sub>. According to Eriksson (1993), NO<sub>2</sub> has very small corrosive effects alone even in the ppm range. Muller (1991) also found that nitrogen dioxide had little influence on the corrosion rate of silver. The data reviewed above indicates that the NO<sub>2</sub> alone is not a significant factor for corrosion, but it can accelerate corrosion through synergistic effect with SO<sub>2</sub>. Data on its possible synergistic effect with other gases of interests such as O<sub>3</sub>, H<sub>2</sub>S, and Cl<sub>2</sub> under different humidity and temperature conditions are lacking.

#### **Hydrogen sulfide**

Hydrogen sulfides is the most important gaseous contamination in the data center. It can cause the serious corrosion on the circuit board. Hydrogen sulfide is formed by the fossil fuel processing and combustion and natural processes (decay of vegetation in soils and wetlands, excess sulfur emission from vegetation and the like). There are two common modes of hardware which will be damaged if they are exposed to the sulfur-bearing gases (H<sub>2</sub>S, SO<sub>2</sub>): printed circuit boards (PCBs) and miniature surface-mount technology (SMT) resistors. Trana (2003) found that after the copper was exposed in this condition, copper sulfide was formed. Exposure to a higher concentration of H<sub>2</sub>S resulted in a faster and larger increase of the thickness of Cu<sub>2</sub>S, as expected. The data also show that there appears to be a maximum thickness of Cu<sub>2</sub>S of 8-10  $\mu$ m, beyond which further increase of exposure time had little impact on the thickness. It is possible that at this thickness, the Cu<sub>2</sub>S layer became a significant resistance to the diffusion of ions between the adsorbed moisture layer and the pure copper, and hence slowed down the electrochemical process that was responsible for the corrosion. It is noted that even at 10 ppb (the proposed realistic worst-case level), 0.1  $\mu$ m of corrosion layer was measured after 3 days of exposure (T.T.M.Trana, 2003).

#### **Ozone**

Natural and anthropogenic electrical discharge is the source of the ozone. It can increase the corrosive effect for the copper and silver (T. Aastrup, 2000). Ozone also enhanced the copper sulphadation when copper was exposed in SO<sub>2</sub> with ozone (T. E. Graedel, 11 May 1984).

#### **Chloride**

Chloride has limited corrosive ability to copper or silver. But it has a large influence on these metals when it combines with the hydrogen sulfide. In the study by Muller (1991), the copper and silver were exposed to 1.9 ppb of  $\text{Cl}_2$  at  $22^\circ\text{C}$  and  $50 \pm 5\%$  RH for one month. The results show that chloride alone had mild corrosion effect, similar to that of  $\text{SO}_2$  tested, but significantly weaker than that of  $\text{H}_2\text{S}$ . Data are lacking on the synergistic effects of  $\text{Cl}_2$  with other gasses, and for different RH and temperature conditions. When copper is exposed in  $\text{H}_2\text{S}$ ,  $\text{Cl}_2$  and  $\text{NO}_2$ , the role of  $\text{Cl}_2$  is to remove the  $\text{Cu}_2\text{O}$  then other pollutants can attack Cu directly (Abbott, 1988).

### Synergistic effect

Figure 2 shows the corrosion thickness as a function of pollutant exposure amount (concentration times duration) found by previous researchers. The combined effects of different pollutants and relative humidity are very complex, and not yet well understood. Data is especially lacking under field concentration levels which are typically much lower than those used in the laboratory studies.

Figure 2 Summary Literature Corrosion Results

Chloride, Nitrogen dioxide and Sulfur dioxide are the common corrosive gases for the Datacom equipment. Each of them alone can cause only a small amount of corrosion on the metallic surfaces, even though some corrosion products can be detected on the surfaces of the materials. However, their co-existence can cause significant corrosion to ITEs due to synergistic effects among them Muller (1991).  $\text{Cl}_2$ ,  $\text{H}_2\text{S}$ ,  $\text{NO}_2$  and  $\text{SO}_2$  can all cause significant damages to silver

surface. But for coppers,  $\text{H}_2\text{S}$  and  $\text{Cl}_2$  can cause the most damage. Hydrogen sulfides and ozone are very important gaseous contamination in data center environment. Each of them alone can damage the equipment, and their synergistic effects with the other compounds can cause even more damages (T. Aastrup, 2000). The catalytic mechanism can increase the reaction speed but cannot produce additional products. It is necessary to consider the synergistic effect to assess the risk of ITE failure in a polluted environment. Such studies are lacking and need to be pursued in order to develop a reliable method for failure predictions.

### MODELING OF ATMOSPHERIC CORROSION

In the data center, gaseous contaminations can include  $\text{SO}_2$ ,  $\text{H}_2\text{S}$ ,  $\text{NO}_2$ ,  $\text{Cl}_2$ , and  $\text{H}_2\text{S}$ . They can corrode the metallic materials and damage the circuit boards, connectors and various other electronic components. From the multi-regime perspective on atmospheric corrosion chemistry (Graedel, 1996), six regimes can be identified (Figure 3-1): G (gas), I (interface), L (liquid), D (deposition layer), E (electrode regime) and S (solid). Study of different layers requires knowledge of different science fields: gas layer – atmospheric chemistry; interface layer – convective and diffusive mass transfer and interface thermodynamics; liquid layer – freshwater, marine, and brine chemistry; deposition layer – colloid chemistry, surface science, and mineralogy; electrodic layer – electrochemistry; and solid layer – solid-state chemistry.

In this model, for the gas regime, pollutant gases by convection or detrainment from interface get into this regime. Then some of the gases deposit on the interface. Some species have chemical interaction with each other. When they arrive at the interface, some of them will volatilize into the gas regime and some enter into the liquid regime. In the interface regime, there are some chemical transformations among different

species. In the liquid regime, the species not only can reach the deposition regime but also can directly reach the electrodic regime and the solid regime. Chemical transformation can take

place at each regime. For the species in the solid regime, they react with species which come from the liquid regime and electrodic regime. The electrodic regime is where electrochemical reaction takes place. Copper loses its electrons and becomes the copper ions which get into the electrodic regime. Oxygen which is in the liquid regime reacts with the copper ions to generate the depositions. The circle and square symbols represent different species. When the corrosion products are generated over the surface, they will become more resistant to the corrosion process. The research of T.T.M.Tran (2003) shows that  $\text{Cu}_2\text{S}$  is an important resistance of diffusion of the ions between the liquid regime and the solid regime.

### MEASUREMENT TECHNIQUES

In order to analyze the corrosion, there are many techniques for monitoring the mass change and for analyzing the geography of surface and surface compositions. Quartz crystal microbalance (QCM) is a technique to detect the mass change of the materials using the piezoelectric effect. In scanning electron microscopy (SEM), the information of topography and composition on the surface can be gained. X-ray photoelectron spectroscopy (XPS) is for the solid surface. It can be applied for the oxide thickness measurements. It can identify all elements except for hydrogen. In Fourier transform infrared spectroscopy (FTIR), it is useful for identifying the “chemical family” of a substance. An electrochemical impedance spectroscopy (EIS) is very useful for detecting the atmospheric corrosion. It measures the corrosion rate by estimating the polarization resistance, which is based on the theory of AC impedance. This technique is useful on high resistance materials and non-destructive. Coulometric Reduction is an electrochemical-based technique. This technique measures the thickness of the film by monitoring the quantity of electricity which is forming during the chemical reaction between the electrolyte and the corrosion products.

### RECOMMADATION FOR THE “REALISTIC WORST-CASE CONCENTRATION LEVELS”

Table 1. Summary of Pollutant Concentrations and Recommended Limits by IEC (2002), Telcordia (2006), ISA(1985) and One Manufacturer’s Internal Standards

Gas	$\text{H}_2\text{S}$		$\text{SO}_2$		$\text{Cl}_2$		$\text{NO}_2$		$\text{O}_3$	
	Max	Min	Max	Min	Max	Min	Max	Min	Max	Min
Measurement (ppb)	8310008	0.101	87	0	0.58	0	152	0	174	0
Limits (ppb)	40	2	50	10	35	1	700	50	123	2

Table 1 shows the measurement data of outdoor pollutant levels and the concentration limits recommended for IT equipment protection against corrosion. The current guideline gives the recommended temperature and relative humidity envelope: the dew point is from  $-9\text{ }^\circ\text{C}$  to  $15\text{ }^\circ\text{C}$ ; The dry-bulb temperature is from  $18\text{ }^\circ\text{C}$  to  $27\text{ }^\circ\text{C}$  and the relative humidity is less than 60%. We propose the following as the “realistic worst- case concentration levels” for the MFG testing (Table 2)

Table 2. Proposed “Realistic Worst Case” Concentrations for Mixed Flow Gas (MFG) Testing

Pollutant	$\text{H}_2\text{S}$	$\text{NO}_2$	$\text{SO}_2$	$\text{Cl}_2$	$\text{O}_3$
Concentration (ppb)	10	80	40	2	60

The values in the table are consistent with the guideline limits for G2 (moderate) levels of corrosion per the ANSI/ISA Standard 71.04-2013.

## SUMMARY AND CONCLUSIONS

It was found that the “realistic worst-case” concentrations for H<sub>2</sub>S, NO<sub>2</sub>, SO<sub>2</sub>, Cl<sub>2</sub> and O<sub>3</sub> are 10 ppb, 80 ppb, 40 ppb, 2 ppb and 60 ppb, respectively. Chloride, Nitrogen dioxide and Sulfur dioxide are the common corrosive gases for the datacom equipment. Hydrogen sulfides and ozone are very important gaseous contamination in data center environment. But the lack of knowledge is about the synergistic effect at different thermal environmental conditions. There is lacking for a mechanistic model to predict the synergistic effects combining with various thermal environment.

### **ABSTRACT**

Multiobjective optimization is widely used in building physics but it has to face construction and regulation constraints to elaborate feasible solutions. This paper investigate how to integrate constraints in genetic optimization carried out with NSGA2 algorithm: it studies the implementation of constraints in the decision space and its impact on convergence speed and diversity in the optimization. The study was carried out on a 8 apartments building with three objective function to optimize: energy demand, comfort of the tenants and economic cost. As a result, convergence speed was improved and expert knowledge was included inside the decision space in a comprehensive way.

### **KEYWORDS**

Multiobjective optimization, retrofit, building stocks, decision space

### **INTRODUCTION**

In France, new buildings represent 1% of constructions each year. Decreasing the energy demand of the entire building stock will only be achieved if existing building are refurbished. On this topic social housing tenants have specific constraints and opportunities, and build their refurbishment strategies based on expert judgment. Experts try to balance constraints such as environmental impact, energy consumption, comfort of tenants to end up on a good solution and it is not possible to confirm that they are objectively the best solutions. Multi-objective optimization is an appropriate approach to efficiently suggest optimal solutions, so the expert could focus on picking a solution in the optimal ones. This work has been carried out in the scope of Reha-Parcs project which aim to apply multi-objective optimization on building stocks constituted of approximately 100 buildings owned by the same entity. Optimal solutions may then feed a decision-making tool for managers to pick the best one according to subjective needs like local policy, and funding.

Multi-objective optimization has been carried out on the design stage of new buildings to improve the shape and windows with respect to the energy demand and comfort (Tuhus-Dubrow and Krarti 2010; Diakaki, Grigoroudis, and Kolokotsa 2013). Other work addresses the optimization of HVAC Systems in addition to the building envelope (Machairas, Tsangrassoulis, and Axarli 2014).

In multi-objective optimization, the formulation of the problem has a significant role in the success of the process, in order to get solutions that fit with construction and regulation constraints. The implementation of these constraints is mostly done at the optimization level by a penalty function (Coello Coello 2002). This approach limits the number of valid individuals in the population and consequently limits the diversity of the solutions. This seems to imply more generations to be computed in order to achieve the same diversity. This can be

time consuming depending on the computational cost of the evaluation function, especially on multiple buildings, as it limited previous works (Rivallain 2013)

A novel approach is to integrate constraints directly into the decision space, and this is the main focus in this paper. The aim of the study is to determine the impact of the integration of constraints in the decision space in term of convergence speed and diversity of the optimization.

## METHODS

Optimization involve multiple parts: in this section will be detailed the evaluation function used to affect a fitness value to each retrofit strategy, the algorithm that has been chosen to carry out the optimization and the decision space of the optimization.

To evaluate the energy efficiency of a retrofit strategy, a test building has been modelled. This building is constituted of 4 floors and 8 apartments. Each apartment is 65m<sup>2</sup> large and is 2,3m high. In the model, each of those apartments is a thermal zone. The building is modelled in Modelica language using models issued from the *BuildSysPro* library, developed by EDF (Plessis et al. 2014). The model features an ideal heating generator and will be upgraded in future work with realistic systems. A TMY file is used to simulate the weather of the city of Nice (France). The objective function of the simulation are the energy needs of the building and summer comfort of the inhabitants that is presented in degrees.hours above an adaptive comfort temperature. The adaptive comfort model chosen is the revised standard 55 of ASHRAE (De Dear and Brager, 2002).

The last objective function is the economic cost of retrofit strategies. It is calculated with expert data provided in Reha-Parcs project: material price is a function of its thickness, then labour time cost is included and added to it.

First of all, the choice of an appropriate algorithm has been made with respect to the discrete nature of the problem: in order to keep only possible strategies. Indeed we had to comply with commercial solutions (eg. insulation is available for only selected thickness). In a discrete decision space, genetic programming suits better to the problem (Evins 2013). Moreover, genetic algorithm are widely used in building physics, especially NSGA2 (Deb et al. 2000) as it has proven to be both stable and efficient. In this paper, we used the implementation of NSGA2 provided in Python library DEAP (Fortin et al. 2012). The parameters used are the following:

Table 1: Settings of NSGA2 algorithm

Number of individuals	96
Number of generations	50
Probability of crossing	0,8
Probability of mutation	0,2

Those parameters were selected after a literature study (Rosenthal and Borschbach). They enable to have a good exploration of the decision space with mutation while the convergence speed towards Pareto front is not slowed down. The number of individuals has been selected to be 96 for a good diversity and to suit the 48 cores available for parallel computation.

In this paper, the main focus is on the decision space. In our case, the decision space is constituted of a series of retrofit possibilities. Those retrofit possibilities are considered for the

envelope: outer walls, top floor ceiling, bottom floor and windows. The comparison is made between a decision space that includes every retrofit possibility broken down into elementary tasks and a decision space composed of aggregated task for walls and windows operations. Both of them are described below.

### Standard decision Space

The outer vertical walls, ceiling and floor have the same structure, which is 20cm of reinforced concrete. Vertical walls, ceiling and floor are independent from each other in the optimization. The insulation proposed features one of the following component:

Table 2: Insulation possibilities for outer walls in the optimization

Insulation material	Commercially available thickness (in cm)
Polyurethane	2, 4, 6, 8, 10, 12, 14, 16, 18, 20
Glasswool	6, 8, 10, 12, 14, 16, 18, 20
Polystyrene	6, 8, 10, 12, 14, 16

Another parameter of the optimization is the windows: the U coefficient for each type of window is the value that changes. Commercially available windows used in refurbishment in France where again provided by expert data within Reha-Parcs project, and are as follow:

Table 3: windows possibilities in the optimization

Windows U values	0.8, 1, 1.2, 1.4, 2
------------------	---------------------

As a result, this decision space provides 109760 possibilities of retrofit that could be applied on the building.

### Constrained decision Space

The second decision space differs from the first one as windows and outer vertical walls are combined: in this problem, one gene of each individual corresponds to a facade solution which includes one type of window and one type of insulation of the vertical walls.

In order to fit construction constraints, some solutions are not possible: these solutions involve high performance wall with low performance windows or high performance windows with low performance walls. In this problem, 22 combination are forbidden. Should an individual propose on a forbidden solution, it will be mutated until it is an allowed combination. In this way, optimization avoids a costly evaluation function but can slow the convergence of the optimization. Constraints slightly reduce the decision space to 92512 possibilities offered to elaborate retrofit strategies.

## RESULTS

In order to benchmark convergence speed of the optimization, we chose the Hypervolume criteria (Zitzler et al. 2002). Hypervolume is computed with a reference point chosen outside the objective space of both optimizations: depending on the shape of pareto front, the reference point can be selected from Nadir point to 150% of the values of Nadir point (Ishibuchi et al. 2017). Here, according to Ishibuchi and the shape of our Pareto fronts, the reference point should be between 120% and 150% of Nadir point's values. Whatever the value for the reference point results remain identical, hence figures for a reference point at 130% of Nadir point will be presented. Same reference point has been selected for both of hypervolumes computation.

Figure 1: Convergence performance of each decision space

This figure shows a quickest convergence of the optimization when carried out with the constrained decision space. With this decision space, the best Pareto front is reached from generation 6 while with the first and unconstrained decision space, best solutions are found at generation 15. Moreover, the figure shows that with the unconstrained decision space, optimization does not reach global optimum before generation 15, while constrained decision space does reach it as soon as generation 5.

Pursuing the optimization until 50<sup>th</sup> generation shows that hypervolume does not vary significantly after generation 15, that is why only the first 20 generations are showed in Figure 1. It decreases for some generations due to mutations of individuals and get back to prior levels after two generations of selection.

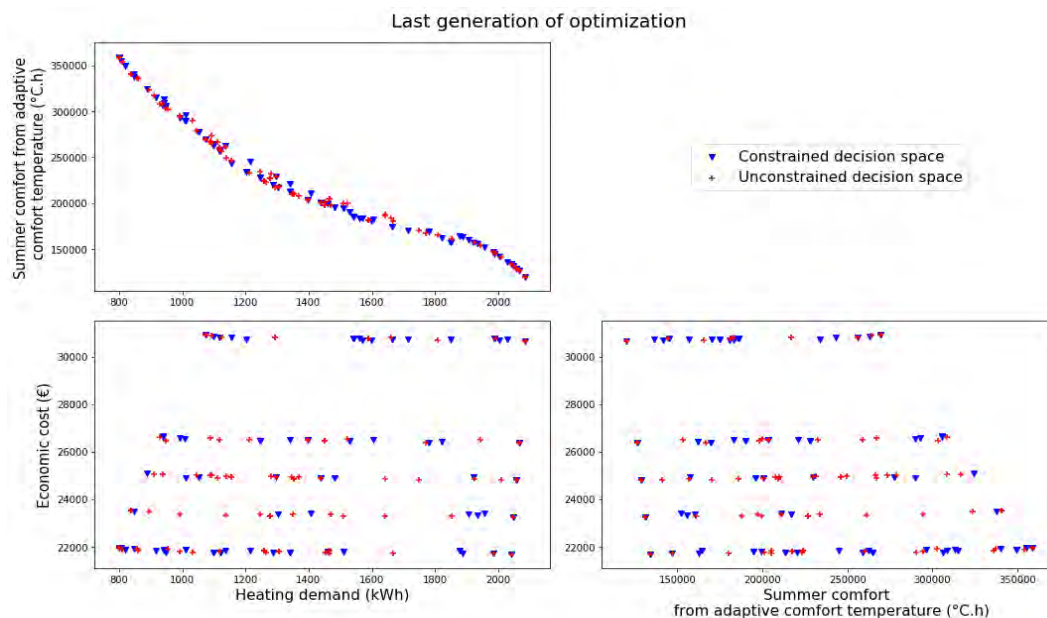

Figure 2: Pairwise plotting of last generation of optimization

Diversity of individuals is ensured with NSGA2's selection process. The diversity of proposed solutions can be checked by plotting Pareto fronts: Figure 2 shows Pareto fronts for all of the 3 objectives. A wide spread of the solution can be noticed and can sometimes be counter-intuitive regarding the performance of some of them. However, NSGA2 tends to keep only strictly non dominated solutions since it is an elitist algorithm.

## DISCUSSIONS

Results support the integration of constraints in the decision space on a test case rather small with a decision space composed of around 100 000 possible combinations. It shows that optimization could be stopped 7 generations earlier with the same results if constraints are implemented in decision space, saving in our case 672 thermal simulations, which are the more costly part of the optimization calculation-wise.

This approach avoid implementing constraints by penalty function or by "death penalty" (Coello Coello 2002), but still enable to incorporate expert knowledge in the optimization problem. Moreover, it shows that adding expert knowledge in the algorithm can speed up the elaboration of retrofit strategies on this multi-family dwellings. Those results are promising since regulation and new construction solutions brought to market are generating more and more constraints, and we can implement them in a comprehensive way. Indeed it will help bringing multi-objective optimization to engineering by keeping the link between optimization constraints and practical solutions. In addition as a minor side effect, implementing constraints in the decision space saves time in post-processing to pick possible solutions and preventively clears out unrealistic solutions.

As optimization problem are quite specific, further studies will have to determine whether the impact is the same with more complex problems. First of all, the combinatorial will get bigger with the implementation of new possible retrofit tasks in the decision space. Secondly, the aim is to turn building model into a small building stock model of around 15 buildings with different shape and construction type. Finally, the application of such constraints should be verified with more than 3 objectives as NSGA2 algorithm is less efficient with more objectives (Campos Ciro et al. 2016).

## CONCLUSIONS

This paper presents a method to integrate constraints in a problem of multi-objective optimization of building retrofit. A case test was studied in order to compare the performances of this approach: as a result, 25% less evaluation were needed during the optimization process in order to converge to Pareto front of optimal solutions. Some solutions proposed by the algorithm can be counter intuitive because of its performance on one objective but are still non-dominated on other objective, which illustrates that diversity is kept in the set of possible solutions.

Multi-objective optimization is a growing field when it comes to retrofitting buildings, and will get more important to develop strategies for energy conservation for buildings and building stocks. That is why we handled constraints here with a simple description that keeps the link between the decision space and the actual construction work. This method would be appropriate for an integration in an engineering tool featuring interactive decision-aid for the elaboration of optimal retrofit strategies developped by (Delhomme et al. 2017). This tool will enable designers to parse through optimal solutions for energy retrofit and to save time on

defining building stock-wide retrofit strategies and spend more time on non objective criteria such as the acceptability by users and urban integration of retrofit strategies.

## ACKNOWLEDGEMENT

The authors would like to acknowledge French National Research Agency (ANR) for its funding within ANR-15-CE22-0011 Reha-Parcs project.

### **ABSTRACT**

Buildings in the Northeast U.S. with large interior open spaces and high ceilings require substantial amounts of energy to heat and cool the spaces. The objectives of this experiment are to model the heat flux across different layers of a green roof and to estimate the thermal resistance of the layers. The project will examine conditions in winter and summer, considering air temperature and snow cover on the roof. The scope of this study includes measurements of the transfer of energy through the green roof on the Onondaga County Convention Center in Syracuse, NY. The methods include collection of data from Campbell Scientific temperature probes at six heights through the roof layers, ranging from the Convention Center ceiling to the ambient air above the roof. The temperature data are stored in CR-1000 data loggers. Under certain conditions, the green roof is expected to be an effective barrier to energy flow across the roof. The implications of this work are a better understanding of how green roofs function as a barrier to energy loss from the building in winter and a barrier to energy gain from direct sunlight in the summer. This, in turn, can assist designers of green roofs in a variety of climates.

### **KEYWORDS**

Green Roof, Energy Flow, Heating and Cooling, R-values

### **INTRODUCTION**

Green roofs are sometimes used to reduce the amount of flooding and combined sewer overflow in a city caused by lack of surface area where rainwater can infiltrate into the soil. However, they can also have other benefits, such as reducing the heat loss during winter and reducing heat gain in summer, leading to reductions in energy used for heating and cooling.

For example, Jaffal et al. (2012) report a 6% reduction in annual energy demand in a simulation study with a single-family house when a green roof is added. Another simulation study by Zhang et al. (2017) shows the potential temperature reduction of the external surface of a building and subsequent energy savings with a green roof. Dahanayake and Chow (2018) have determined that green roofs and green walls reduce the surface temperature of buildings, therefore controlling the cooling load to maintain indoor temperatures.

The overall goal of this study is to determine the heat flux through the Onondaga County Convention Center green roof in different seasons, and to calculate the thermal

resistance of the roof layers. Previous work on heat flux through this roof was based on a smaller dataset and produced preliminary findings for 2014-15 (Squier and Davidson, 2016).

This study looks at temperatures in different layers of the Onondaga County Convention Center green roof from December 2016 through February 2018. Heat flux was calculated for December 2016 until June 2017. Times in winter were chosen when there was sufficient snowpack to insulate the surface from variable air temperature, creating quasi steady state conditions in which the thermal resistance (R-values) were calculated.

## METHODS

During construction of the roof, Campbell Scientific T109 temperature probes were placed in 4 roof layers (A, B, C, G); this was accomplished at 5 widely separated stations on the roof. Three more probes were affixed to the ceiling below at Y (**Figure 1**).

**Figure 1:** Layers of the roof and locations of the temperature sensors.

Because of possible malfunctioning probes, duplicate temperature sensors were placed in a number of roof layers. When analyzing the temperature data, some values from probes at stations 3 and 4 were flagged due to inconsistent temperatures for short time periods; the problematic data represent only a small fraction of the data from these sensors. Nevertheless, it was decided to exclude values from stations 3 and 4 in calculating average temperatures and R-values. Thus, data from only stations 1, 2, and 5 were used in the current study.

R-values were calculated over a period of high snow depth, 400-600 mm, which occurred over March 15-19, 2017 (**Figure 2**).

**Figure 2:** Air Temperature and Snow Depth as reported by the National Weather Service. The y-axis on the left side of both graphs corresponds to March 15, 2017.

The snow depth on the roof was assumed to be the same as the data collected by the National Weather Service station in Dewitt, NY, 4.1 km from the test site. This snow depth is consistent with the height of snow used by Squier and Davidson (2016) to calculate the R-values.

Fourier's equation was used for the steady state calculation of flux and resistance:

$$q = \frac{1}{R} \Delta T \quad (1)$$

where  $q$  is heat flux through the layers ( $\text{W m}^{-2}$ ),  $R$  is the thermal resistance of the layers between the sensors ( $\text{m}^2 \text{K W}^{-1}$ ), and  $\Delta T$  is the difference in temperatures (degrees K) between the layers of the roof, calculated using the data from the temperature sensors. The R-values reported by the manufacturer are in **Table 1**. Additionally, the values calculated by Squier and Davidson (2016) based on limited data are in **Table 2**.

**Table 1:** Layers of the roof and their respective thickness and thermal resistance values as reported by the manufacturer.

Layer	Thickness (cm)	Material R-Values ( $\text{m}^2 \text{K W}^{-1}$ )
Growth Medium	3.81	0.211
Drainage Mat	0.63	n/a
Waterproof Membrane	0.12	0.028
Gypsum Board 2	1.59	0.118
Grounding Screen	0.102	0
Extruded Polystyrene Insulation	7.62	2.64
Gypsum Board 1	1.27	0.079

**Table 2:** R-values calculated by Squier and Davidson (2016) at stations 1, 3, 4, and 5 from February 1-14, 2015.

	5	1	4	3
B-C (Gypsum Board 2)	0.245	0.170	0.180	0.268
C-G (Waterproof Membrane and Growth Medium)	0.216	0.306	0.218	0.241
Overall, A-G	3.100	3.116	3.038	3.149

## RESULTS AND DISCUSSION

Using Fourier's equation, the R-values across the roof layers for March 15-19, 2017 are given in **Table 3**. Based on the difference in temperature between layers B and C in both **Table 2** and **Table 3**, the R-values at station 5 are higher than the R-values at station 1. Conversely, over C-G, values at station 5 are less than the values at station 1. Values for stations 3 and 4 as presented by Squier and Davidson (2016) could not be compared for March 2017 due to malfunctioning sensors. It should be noted that station 2 reported average values in between the values of stations 1 and 5 in **Table 3**.

**Table 3:** R-values calculated at stations 1, 2, and 5 from March 15-19, 2017.

	5	1	2
B-C	0.246	0.139	0.174
C-G	0.214	0.327	0.278
Overall, A-G	3.100	3.106	3.092

The relationships between R-values shown in **Tables 2 and 3** are consistent. The values across different stations may be explained by the placement of sensors within the layers at each station. It is possible that some sensors rest slightly higher or lower than others at different stations, which would account for these deviations.

**Figure 3** shows the temperature data for the G layer at the three stations used in this experiment from December 1, 2016 until March 31, 2017. The effect of the mid-March snowpack was to insulate the soil so that the temperature of the G layer hovered around 0° C throughout the period, despite wide variations in air temperature as shown in **Figure 2**.

**Figure 3:** G-layer temperatures from three stations during Dec. 1, 2016 - March 31, 2017.

**Figure 4** shows the temperatures in the different layers of the roof during 20 days of typical weather in the summer. Values shown are the averages at stations 1, 2, and 5. The temperatures at sensors G, C, and B follow the curve of the air temperature and frequently exceed the air temperature due to direct sunlight reaching the roof. The peaks at G, C, and B occur slightly later each day than the peak in air temperature, due to the time for heat conduction through the roof. Temperatures at A and Y are much lower than the air temperature and the other sensors in the roof because the Center is air conditioned. The greatest difference in temperature between adjacent sensors occurs between A and B.

**Figure 4:** Temperature of each layer of the roof during July 4-24, 2017

**Figure 5** shows the temperatures in the different layers of the roof during a 20-day period with typical winter weather. According to the National Weather Service there was no snow until January 24. There was significant snowpack (~100 mm) from January 24-27. From January 28-29, there is no snow on the roof, which corresponds to the small increase in temperature in the roof layers on January 28. Finally, there is significant snowpack again from January 31-February 9. The temperatures at Y and A reflect the heated interior of the building. The greatest difference in temperature between adjacent sensors again occurs over the insulation layer from sensor A to sensor B. Sensor G is closest to the air, followed by sensors C and B. The temperature at B is higher than at C, which is higher than at G, consistent with distance from the heated interior. Around January 23, there is an increase in air temperature, and the temperatures at sensors G, C, and B increase and are nearly the same over this period.

**Figure 5:** Temperature of each layer of the roof during January 20 - February 9, 2018.

The heat flux from A to B shows the transfer of energy across the insulation layer. **Figure 6** shows this heat flux over six months. During the winter months, there is generally a positive flux of heat escaping the building through the roof. During the summer months, the flux is negative, indicating heat entering the building. The heat flux from March 15-19 (shown by dashed lines) is positive as expected, and this time period corresponds to the period of high snowpack on the roof, as shown in Figure 2.

**Figure 6:** The heat flux through the insulation layer during Dec. 1, 2016 - June 30, 2017.

## CONCLUSION

Temperatures have been measured from December 2016 to February 2018 in layers of a green roof on the Onondaga County Convention Center. The inside temperature at the ceiling, and temperatures in the lowest roof layers below the insulation, remain around 20° C in both winter and summer. The greatest difference in temperature between adjacent sensors occurs across the insulation layer (A to B). The temperatures at the top of the insulation (B), at the upper gypsum board (C), and in the growth medium (G) are closer to the air temperature. During the winter, and when there is significant snowpack on the roof, the temperature in these upper layers remains at 0-5° C despite much colder air temperatures. The insulation layer provides the main barrier to heat escaping the building during cold conditions. During the summer, the temperatures in the top layers of the roof tend to be higher than the air temperature, due to the impact of direct sunlight impinging on the roof surface.

The calculated R-values of the green roof are consistent with previously calculated R-values based on limited data. The values from stations 1, 2, and 5 show distinct differences that may be due to the precise placement of the sensors within the various roof layers. For example, the R-values overall from A to G are nearly identical at all three stations, but the R-values between sensors B and C at stations 1 and 2 are much smaller than at station 5. This indicates that sensors B and C are probably closer together at stations 1 and 2 than originally thought, providing more information on the build of the roof. Additional data collection and analysis is underway, both at the green roof and at a traditional roof nearby.

## ACKNOWLEDGMENT

This work is supported in part by the National Science Foundation under grant number SES-1444755, Urban Resilience to Extreme Weather-Related Events Sustainability Research Network (URE<sub>x</sub> SRN). The authors acknowledge the assistance of the Onondaga County Department of Facilities Management for enabling this work on the green roof. The assistance of several other members of the Green Roof Research Group at Syracuse University is greatly appreciated.

### **ABSTRACT**

Understanding the dynamic response of a building is essential in the design of sustainable energy-efficient buildings. Using data from over 10,000 smart thermostats, this study identifies patterns in the dynamic thermal response of residential buildings in Canada and the United States (US). The data set consists of one year of measurements recorded at 5-minute intervals for the indoor and outdoor air temperature as well as HVAC equipment run times.

This study focuses on identifying effective values of time constants for the houses by applying the following procedure. First, periods complying with the following basic criteria are identified: a) the house is under free-floating conditions (i.e. when the HVAC system is switched off) for more than three hours and b) the outdoor temperature remains approximately constant (the outdoor temperature change is smaller than or equal to 2°C). Second, for each identified period, time constant values are determined by tracking the temperature responses of the house. These values are determined assuming the characteristic exponential decay of a first-order resistance-capacitance (RC) thermal model. Finally, a statistical analysis is applied to identify a typical range of effective time constant values according to month.

Consequently, calculations show significant differences between estimated values for the summer and winter months, which may be attributed to occupant behaviour. In winter, the majority of time constants range from 15 to 55 hours. In summer, most of time constants vary between less than 1 hour and 18 hours due to occupants opening windows. In addition, the dependence of the time constant on the age of the home is investigated.

### **KEYWORDS**

Time constant estimation; pattern recognition; dynamic thermal response; residential building; statistical analysis.

### **INTRODUCTION**

In support of sustainable development and energy efficiency, effective energy management in buildings is increasingly recognized as a priority. In Canada and the US, the building sector accounts for approximately 28% and 40% of the national energy consumption, respectively. The residential sector is a major contributor to the energy use of both the Canadian and American building sectors, making up 62% and 53% of their total energy consumption, respectively. Moreover, in both countries, more than 40% of the total energy demand in a residential building is used to heat and cool the occupied spaces (Office of Energy Efficiency, 2016; U.S. Energy Information Administration, 2009, 2018).

With the increased adoption of the Internet-of-Things (IoT) such as smart thermostats, numerous homeowners are outfitting their residences with home automation and data acquisition systems. A recent study predicted that, by 2025, IoT applications would offer a potential economic impact of \$200-300 billion a year in relation to the residential sector (Manyika et al., 2015). In the building and urban environment, big data sources are becoming increasingly more prominent and the release of certain anonymized data sets for data science could progressively become the norm. As a result, the building industry will face a critical dilemma: how will performance data from potentially thousands—or even millions—of buildings be reasonably integrated into design and energy management? This unprecedented level of access to raw data will promote the potential of machine learning, visual analytics, and data-driven statistical modelling techniques in estimating the building's dynamic thermal response (Miller, Nagy, & Schlueter, 2017). Grey-box model approaches use operational data from numerous real buildings to calibrate a simplified physical model, in the effort of providing good approximation of a building's thermal response (Vivian, Zarrella, Emmi, & De Carli, 2017).

In this study, the operational data of real homes are analyzed to recognize patterns in their dynamic thermal response. This paper focuses on proposing a method of estimating the typical thermal time constant values for residential buildings located in Canada and the US. The estimation is based on temperature measurements and equipment runtimes acquired from smart thermostats. When limited information is available, the knowledge provided in this paper can: i) assist in the generation of simple grey-box models that could guide the preliminary design of new residential buildings (Vivian et al., 2017), and ii) assist in the development and adoption of effective load management strategies for existing buildings.

## **METHODOLOGY**

### **Data Collection**

Ecobee, a Canadian home automation company, has established the Donate Your Data (DYD) program for its smart thermostat users to donate measured time series data to science. The meta-data from this program are user-reported, anonymized and include details such as the geographic location, age of home, total floor area, style of home, and number of occupants. Recorded at 5-minute intervals, the Ecobee thermostats collect measurements for temperature, humidity, occupancy detection, and HVAC equipment runtimes. For the building time constant estimation, over 10,000 residential buildings were monitored between March 2016 and February 2017. The Ecobee smart thermostats control the HVAC system based on the indoor control temperature, which is an average temperature of the building based on readings from the thermostat and any additional remote sensors present.

### **Building Time Constant Estimation**

Diurnal and seasonal variations in outdoor temperature, solar energy and occupant behaviour account for the main thermal losses and gains between the building and its surroundings. The time constant is a measure that characterizes a building's ability to retain heat. With no influence from a heating or cooling system, theoretically, the thermal time constant provides an indication of how fast the building will take to achieve a new thermal equilibrium in response to changes in its internal and external thermal conditions. As demonstrated in Figure 1, the time constant can be found by applying a step input to the building and then recording the time the building takes to realize 63.2% of the final value in the step change (Equation 1).

The first step in estimating the time constant of a building is the identification of suitable time periods for analysis. In this study, these analysis periods are selected according to following

basic criteria: a) the house is under free-floating conditions (i.e. when the HVAC system is switched off) for more than three hours, and b) the outdoor temperature remains approximately constant (the outdoor temperature change is smaller than or equal to 2°C). The measured time series data for HVAC equipment runtimes and the outdoor temperature are used to determine if the criteria are met during each analysis period.

Figure 1: The time constant,  $\tau$ , is the time needed for the building to realize 63% of the final value of an applied step change.

The second step is the determination of a time constant for each identified analysis period by treating the thermal space of every home as a first-order resistance-capacitance (RC) model (Vivian et al., 2017). While this is a relatively simple model, it provides a useful characterization of the dynamic behaviour of the house. Assuming the characteristic exponential decay of a first order system:

$$T(t) = T_f + (T_i - T_f)e^{-t/\tau_{bldg}} \quad (1)$$

where  $t$  represents time elapsed in hours,  $T_i$  represents the initial indoor temperature,  $T_f$  represents the long-term final temperature of the indoor space in free-floating conditions, and  $\tau_{bldg}$  represents the estimated time constant value.

Considering plausible physical constraints and using the least squares method, the following parameters of a regression function are calculated according to Equation 1 and the recorded indoor temperature measurements  $T(t)$ : a) the long-term final indoor temperature b) the change in indoor temperature ( $T_i - T_f$ ), and c) the time constant value to be estimated. The time constant values were estimated with the use of the programming language Python. Next, these estimated values are then filtered, retaining only those whose corresponding R-squared values are 0.7 or higher. The R-squared value of 0.7 was visually determined to be the minimum acceptable value representing an accurate fit of the regression line to the observed data.

### Identification of Typical Building Time Constant Values

In the previous step, multiple time constants are found for each building and organized according to month for analysis purposes. For each residence, a monthly average of the estimated time constant values can be obtained by weighing these estimated values by their corresponding R-squared values from the previous step. Statistical learning methods, particularly visual analytics, are then used to identify typical time constant values among the weighted averages. Histograms, kernel density estimations (KDE) (a method to estimate frequency distributions), and other statistical analysis tools are used to identify patterns in the

distribution of time constant averages. Furthermore, possible correlations between the time constant averages and the age of the home have been investigated.

## RESULTS

Figure 2 and 3 show typical results obtained for the time constants for the months of August and February, respectively. The time constants are plotted versus the age of the home.

Figure 2: For August 2016, KDEs representing the building age distribution (right), time constant distribution (top), and their relationship to each other (center).

Figure 3: For February 2017, KDEs representing the building age distribution (right), time constant distribution (top), and their relationship to each other (center).

The patterns observed in August and February are very similar to time constant distributions seen throughout the rest of the warmer months and colder months, respectively. For the warmer months, specifically June through September, most of time constants fall within a range of less than 1 hour to 18 hours as seen in Figure 2. The colder months, meaning October through May, have most of their time constants varying between approximately 15 to 55 hours as demonstrated in Figure 3. As seen in both Figure 2 and Figure 3, the greater part of the buildings observed are between 0 and 35 years old.

## DISCUSSION

Comparing Figure 2 and Figure 3, the warmer and colder months show significant differences between their resulting time constant averages; for the same group of homes, the warmer months have time constants that are much lower in value. The occurrence of different time constants for one building at different times of the year is an interesting phenomenon. In principle, the time constant should only depend on the materials and physical configuration of the house, which should not be expected to change. This decrease in value for the time constant averages may be linked to occupant behaviour. During the warmer months, it is reasonable to expect occupants to have their windows open and leave them open for longer periods of time due to more favorable weather conditions; open windows decrease a building's ability to resist changes in external thermal conditions thus reducing the effective resistance. Moreover, there is also a trend observed shared by both the warmer and colder months: the variance of time constants narrows with an increase in the age of home. The broad range of values for younger buildings and the narrow range of low values for older buildings suggest the introduction of a larger variety of construction methods and materials—some more energy efficient than others—over the last 120 years.

Understanding a building's natural dynamic thermal response is crucial to the design of heating, ventilation, and air conditioning (HVAC) systems, the maintenance of a comfortable environment for occupants, and the management of their electrical load profile (Palensky & Dietrich, 2011). In future studies, the proposed method will be extended to a larger data set of approximately 27,000 smart thermostats in North America to examine the relationship of the time constant to other variables. The variables to be considered include type of home (e.g. semi-detached, row house, condominium), geographical location and floor area. Considering that the age of home is user-reported, it would be interesting to see if the relationship observed between the time constant and the age of home persists in a larger sample of homes. Other considerations taken into account to select the periods of interest will include the effects of weather conditions, solar gains and occupancy which are currently not being tracked.

As we seek increasingly low-energy solutions for buildings, HVAC systems are being designed as more responsive to changes in a building's internal (e.g. occupants, appliances) and external thermal conditions (e.g. temperature, humidity, solar gain). The most commonly used software tools for building performance simulation (e.g. EnergyPlus or TRNSYS) require extensive computational power and a large number of assumptions about the building's geometry, its characteristic physical properties, its environment and its occupancy (Zawada, 2017). In addition, many of these inputs end up being assumptions based on the experience and intuition of professional experts. As a result, simple, reliable building models (e.g. grey-box models) have been receiving more attention of late, because there is often a need to model building performance when the required inputs are limited (e.g. only age, location and building type) and the energy modelers are less experienced. When limited building information is available, the knowledge acquired from this study will be used to facilitate preliminary estimations of dynamic parameters (such as RC values) in the rapid generation of control-oriented models.

## CONCLUSIONS

This study presents a statistical methodology for the identification of typical time constant values of residential buildings for the heating, cooling and intermediate shoulder seasons (i.e. when houses are typically in passive mode with open windows). Preliminary results for different times of the year have been presented. Based on a simple physical model and measurement data from smart thermostats in North America, the proposed method for making preliminary estimations of the time constant offers benefits for researchers, home automation companies, utilities and homeowners who seek to reduce energy costs while maintaining occupant comfort. The advantages include facilitating the creation of simpler models for testing and control scenarios, providing a better understanding of consumer behaviour and needs, and promoting energy conservation and efficiency. A major result of the present study is the observation that time constants vary seasonally: from less than 1 hour to 18 hours during summer, to 15 to 55 hours during winter. This result is most likely due to open windows that directly couple the interior of a house to the exterior environment through a high effective thermal conductance. Future studies will focus on extending the proposed method to a larger data set and examining the relationship of the time constant values to other variables including type of home, geographical location and floor area.

## ACKNOWLEDGEMENT

The financial support of both the NSERC Discovery Grant Program and the NSERC/Hydro Québec Industrial Research Chair held by Dr. Athienitis are gratefully acknowledged. The authors thank Ecobee, a Canadian home automation company, for kindly providing the data used in this study. The authors would like to thank Vasken Dermardiros and the internal reviewers at CanmetENERGY-Varennnes for their valuable comments.

### ABSTRACT

In view of growing concerns on climate change and temperature extremes, there is a need to explore novel methods that provide thermal comfort in architecture. Latent heat thermal energy storage with phase change materials (PCM) has been widely researched in last decades in the field of energy technology and proved beneficial for reduction and shifting of the thermal loads and improving the overall thermal storage capacity of building components. Although a variety of PCM containments have been investigated for indoor cooling applications, the examples of exposed, design-oriented macro-encapsulations are rare.

This paper presents a study of visible, suspended ceiling encapsulations for passive cooling, made of glass and novel bio-based PCM. The aim is to provide an overview of correlations between basic containment geometries and their thermal behavior that serves as a base for the further design of custom-made PCM macro-encapsulations. An experimental set-up of test boxes is developed for thermal cycling and a comparative analysis of the thermal performance of varied PCM encapsulation geometries. The study concludes that the containments with the large exchange surface and the small thickness offer an optimal material distribution for the temperature reduction in the box. Based on experimental results, suggestions are made on further formal strategies for the design of cooling elements for local thermal regulation.

### KEYWORDS

Phase change materials, passive cooling, containment geometry, thermal cycling, glass macro-encapsulation

### INTRODUCTION

Contemporary buildings increasingly rely on centralized mechanical systems for the indoor climate control, due to the low thermal inertia and high energy gains in buildings. A promising renewable energy alternative that could decrease the dependency on high-energy consuming technologies and improve the thermal stability of buildings is the latent thermal energy storage with PCM (Kośny, 2015; Zalba et al., 2003).

Current advancements in materials science and the growing interest of designers in a material-driven performance are opening a possibility for architectural elements to take a more active role in managing thermal environments (Addington and Schodek 2005; Bechtold and Weaver 2017). PCM belong to the novel class of property-changing materials with an inherent capacity for thermoregulation, as they can dynamically exchange the energy with surroundings while changing the phase at a desirable temperature. Although the primary goal of the implementation of PCM is to achieve energy savings in buildings, PCM present yet unrealized potential for architectural design and an opportunity for new design methodologies based on their thermodynamic behavior.

PCM are substances capable to absorb, store and release a large amount of energy in the form of latent heat during melting and solidification at a certain, predictable temperature. PCM act as latent thermal energy storage due to their large phase change enthalpy or latent heat of fusion. Unlike the sensible heat storage, where the added heat results in the temperature increase of the storage medium, the latent heat storage medium remains at almost constant temperature throughout the solid-liquid phase transition. The added heat is gradually absorbed by the material till the melting is complete and released when the surrounding temperature drops, and the material starts to solidify (Mehling and Cabeza, 2008). In that way, PCM operate in thermal cycles responding to local temperature fluctuations and can be used repeatedly without material degradation.

In passive or free cooling applications, PCM takes advantage of diurnal temperature differences, releasing the coldness stored during the night when, during the day, the indoor temperature rises above the comfort zone (Raj and Velraj, 2010). Currently available PCM products for passive cooling span from micro-encapsulations integrated in different building materials to macro-encapsulated elements placed behind the suspended ceiling. However, for PCM to function efficiently and regenerate during the night, a direct contact with the cold air (heat sink) is of advantage. This study therefore proposes visible suspended glass encapsulations that support recharging of the PCM by night ventilation. Since PCM has a low thermal conductivity, the containment geometry plays an important role for managing the heat transfer between the PCM and surroundings. Thus, coupling the basic encapsulation geometries with their thermal behavior in this paper aims to widen the range of PCM encapsulations and outline their use within the design realm.

## METHODS

To evaluate the impact of varied PCM encapsulations on the indoor temperature, an experimental set-up for thermal cycling with test boxes was developed. Previous experiments that used test boxes to access the thermal performance of the composite PCM wall are described in literature (Kuznik and Virgone, 2009). Similarly, in this study two identical boxes – a test box containing the PCM sample and an empty reference box – were placed next to each other in a controlled indoor environment and exposed to thermal excitation. Boxes were made of plywood 18mm, covered with 30mm insulation panels, with the glazed front that allowed irradiation by two halogen 750W lamps placed in the front (Fig. 1).

Figure 1. Experimental set-up for thermal cycling. a) Test boxes, b) Tubular encapsulations.

The temperature differences were observed during two subsequent heating (3h) and cooling (6h) cycles of total duration of 18h. During heating cycle, the temperature in the boxes

oscillated from 17°C to 30°C, with a resulting heat rate slightly above of the average due to the direct solar irradiation of buildings in the summer. The cooling cycle corresponded to the effect of night cooling needed for the PCM regeneration. The instrumental set-up consisted of two 176T2 dataloggers with four Pt-100 glass-coated probes of the class A precision, measuring air, PCM and the room temperature in the interval of 1 minute. Thermal camera was attached at the bottom of the box, capturing surface temperatures every 30 minutes. A reflective shield protected air probes from the direct irradiation. Before commencing measurements, several calibration cycles with different positions of probes were done and showed no temperature gradients in the box, and the temperature differences within tolerance values (0.2°C).

Table 1. Physical properties of bio-based PCM from the data sheet of the producer.

Property	Values
Melting / crystallization temperature	21°C / 19°C
Latent heat	190 KJ/kg
Specific heat capacity solid / liquid	2.1 kJ/(kg·°C) / 2.3 kJ/(kg·°C)
Thermal conductivity solid / liquid	0.18 W/(m·°C) / 0.15 W/(m·°C)
Density solid / liquid	891 kg/m <sup>3</sup> / 850 kg/m <sup>3</sup>

The material used in the study belongs to the novel bio-based category of PCM, with a low melting temperature suitable for indoor applications (Tab. 1). The choice of the containment geometries was made according to the standard typologies described in the literature (Mehling and Cabeza, 2008; VDI, 2016). A total volume of 500ml of PCM was used in each measurement, either in a single containment or divided into five smaller units of 100ml. Encapsulations were made of borosilicate or soda-lime glass of approx. thickness 2mm in following formats: spherical containments used standard laboratory 500ml and 100ml glass flasks; multiple tubular used standard 100ml test tubes; 500ml tube was produced by lampworking technique; flat container was produced by modifying a standard petri dish ø 180mm.

Figure 2. Ground plan of the box with containment geometries showing surface area and max. thickness. a) Sphere 500ml, b) Multiple spheres 5x100ml, c) Tube 500ml, d) Multiple tubes 5x100ml, e) Flat plate containment 500ml.

## RESULTS

The graphs show a characteristic latent heat thermal storage effect with a temperature plateau during the melting phase of the material (Fig. 3). All encapsulations except the 500ml spherical and flat containments allowed the full melting of the PCM. The multiple tubular geometry caused the biggest temperature differences between the test boxes (Tab. 2 and Fig. 3) and allowed the largest portion of the material to recharge during the cooling cycle in comparison to other containments (Fig. 4).

## Tables and illustrations

## DISCUSSIONS

Multiple containments improved the cooling effect of the single ones by 40%. The results point out to benefits of increasing and differentiating surfaces that enclose a certain volume. Although the exhibited differences of the cooling potential between PCM containments are small, it is expected that they gain on importance in the design of larger ceiling systems. Measurements in real conditions with actual thermal loads, building materials and occupant behaviour are, however, necessary to validate these findings. Regarding the orientation of encapsulations, the experiments assumed the horizontal position of tubes and flat containers optimal for the uniform temperature distribution and steadily moving melting fronts (Khan et. al, 2016).

Figure 4. Thermographic images showing surface temperature at the beginning and the end of the heating and cooling cycle: a) 0h, b) 3h, c) 12h.

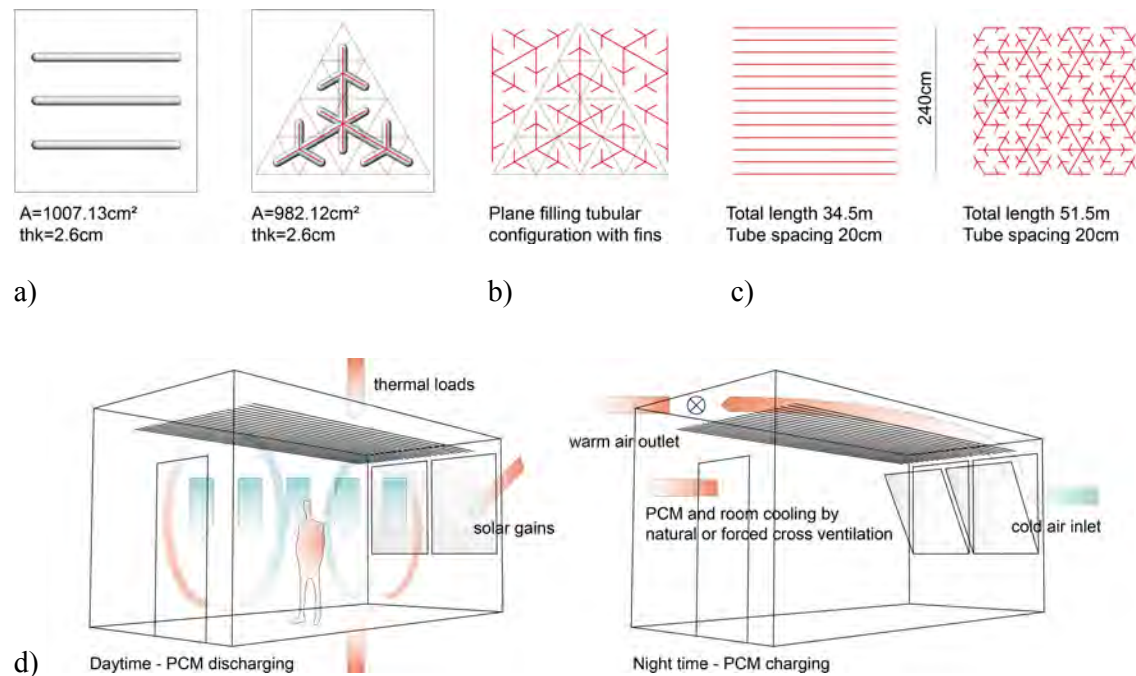

Figure 5. a) Linear and plane filling tubular elements of 2.6cm thickness and 500ml volume in the test box, b) Plane filling configuration principle, c) Difference between linear and plane filling patterns in material distribution in larger space, d) Diagram of the operating principle of the PCM cooling ceiling made of suspended glass elements.

A further increase of the surface area of tubular encapsulations could be achieved by introducing elements with fins (Fig. 5a), and by formal strategies for connecting elements into larger systems, such as plane or space filling tree configurations (Fig. 5b). Compared to linear configurations (VDI, 2016), these branching structures could provide a large and uniform material distribution with an increased element spacing (Fig. 5c) necessary for recharging the material during the night by convection and conduction (Fig. 5d).

## CONCLUSIONS

This work presented investigation of thermal performance of spherical, tubular and flat plate glass encapsulations containing novel bio-based PCM. An experimental set-up of the test box was developed for the comparative analyses of the impact of the encapsulation geometry on the indoor temperature in the test box. Single and multiple units of an equal volume, but varying surface and thickness were tested, and the effect of the increased surface and reduced thickness on temperature reduction was observed. Temperature measurements reflected the differences in the volume-surface ratio of containments and showed the biggest reduction of 2°C in the box with multiple tubular PCM encapsulations. The paper concludes that new design and recharging opportunities for cooling ceilings could be afforded by the exposed glass encapsulations and suggests further formal strategies for increasing the surface area while keeping the thickness, volume and spacing of the encapsulation elements at optimum. These findings on cooling effects of glass encapsulations can inform the concept phase of the design of more elaborate custom-made ceiling elements for local thermal regulation.

## ACKNOWLEDGEMENT

The project has received funding from the European Union's Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grant agreement No. 642328.

### **ABSTRACT**

Interstitial condensation and water accumulation risk in building envelopes could be assessed with methods and models based on moisture migration through porous media coupled to heat transfer. One of the difficulties in evaluating the boundary conditions for the heat and mass transfer model is the choice of an appropriate weather file. The most advanced models, described by the standard EN 15026:2007, require the hourly values of rain, wind, radiation, temperature and relative humidity to compute the water content in the porous materials.

In this contribution, the method described by the standard EN ISO 15927-4:2005, typically used to design Moisture Reference Years (MRY), has been extended to the design of 34 typologies of representative weather files. The generation criteria have been based on the assumption that the simulation results are influenced by rain deposition on the considered wall. The procedure has been followed considering 5 different wall exposures that lead to different MRYS. The years of the climate of Turin (Italy) between 2002 and 2016 have been considered for the generation of the reference years.

Finally, the annual mean moisture contents for two common wall types have been calculated using the obtained MRYS and compared to the annual mean moisture contents obtained with the measured weather data, and the effects of the selection of the weather parameters is presented.

### **KEYWORDS**

Building enclosures, condensation risk assessment, moisture accumulation, reference year, weather file, Moisture Reference Years.

### **INTRODUCTION**

The building envelope design process requires the risk assessment for condensation and moisture accumulation of all the enclosures and their intersections to avoid mould growth conditions and material damage due to prolonged moisture exposure. Up to now, several evaluation methods, simplified and advanced, have been developed. The simplified and most used methods are based on stationary models, they consider monthly mean weather data and are not intended to simulate the real phenomena of the heat and moisture transfer (for example the Dew-Point method or the Glaser method). When more accurate methods are needed (and a simulation of the real physical phenomena is required) it is possible to use advanced models. These models are based on transient state heat, air and moisture transfer equations and require a deep knowledge of the material properties, with weather data files that have to include additional hourly normal rain, wind and solar radiation descriptions.

The standard EN 15026:2007 describes the commonly accepted models used for the advanced moisture accumulation and interstitial condensation risk assessment and refers to the EN ISO 15927-4:2005 for the boundary conditions; this standard describes a method intended to produce hourly data for assessing the annual energy use for heating and cooling. In this paper,

following the previous works of the authors (for example Riva et al. 2010, Riva et al. 2012 and Murano et al. 2016), a modification to the standard method of reference years generation is presented. It has to be noted that the methodology produces reference years and not extreme weather years. Reference years could be used only for moisture accumulation and interstitial condensation risk assessment; if water condensation in building components is not acceptable, even for short periods, other methods are available for the generation of extreme weather years. Various approaches have been investigated in the literature. Cornick et al. (2003) have selected Reference Years using a Moisture Index approach developed for Moisture Management of Exterior Wall Systems (MMEWS). The index comprises wetting function and drying function. In this approach wet and dry years are defined as those years that deviate more than one standard deviation from the mean value on long-term. MEWS is a building-independent method. The wet year is defined as the year with highest moisture index, the dry year as the year with lowest moisture index, and the average year as the year closest to the mean Moisture Index. MEWS can be assembled for problems such as long-term performance or limit-state design. There isn't a definitive method for selecting MRY's but different sets of MRYs should be produced to evaluate different problems.

Salonvaara et al. (2010) have developed a new method that provides an approach for selecting the most critical years in terms of hygrothermal performance. Performance data is analysed using various methods to provide a ranking of the weather years in terms of severity. Damage functions (time of wetness, mould growth index, and maximum moisture content) are used to quantify the moisture related performance of the building envelope. The analysis has included 30 years of hourly weather data for 12 locations in the U.S. and Canada.

Schönerl and Zirkelbach (2016) for the selection of the months of the reference years for the hygrothermal assessment (HRY) have used median, mean, minimum, maximum value, the 25%, and the 75% quartile of air temperature and normal rain. The results of HRY was compared with the standard methodology of EN ISO 15927-4 and with measured data on long-term. The simulations have shown that the mean water content based on the HRY was slightly higher than the one based on the measured data.

Considering the effect of climatic variability on the performance of the building envelope, Zhou et al. (2016) have developed a Climatic Index that considered wind-driven rain load and potential evaporation. This index was suitable for the evaluation of the level of moisture damage risk of wall assemblies where typical moisture problems are mainly caused by rainwater uptake or ingress. The combination of Climatic Index and RHT Index has allowed the creation of MRYs that have 10% level of failure.

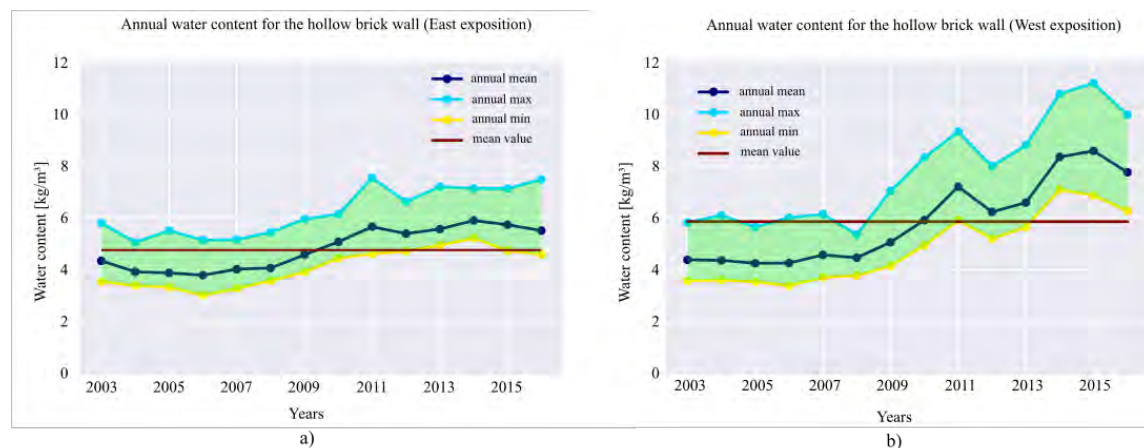

Figure 1. Annual mean water contents of the hollow brick wall for the measured weather files simulations for the East exposition (a) and the West exposition (b).

## METHOD

The EN 15026 (European Committee for Standardization, 2007) refers to EN ISO 15927-4:2005 (International Organization for Standardization, 2005) for the creation of Moisture Reference Years. This method is intended for the creation of typical meteorological years and it is based on the Finkelstein-Schafer (FS) statistic method (Finkelstein and Schafer, 1971). In this research some modifications are introduced to extend the procedure to moisture migration related applications. From the observation that the total moisture content of a simulated wall depends also on the exposure of the wall itself (Figure 1) other rain related climate parameters (normal rain, driving rain) are alternatively considered to select the representative months of the reference year from the historical measured data, in addition to the standard ones (temperature, relative humidity, irradiation, wind speed). Then, the validity of the reference years generated for every combination is evaluated on two wall build-ups with a comparison in terms of the moisture contents against the historical years. The revised procedure for the generation of reference years is shown below. Let  $p$  be the generic measured parameter of the historical years required for the hygrothermal simulations. First, from at least 10 years of hourly values of  $p$ , for every day  $i$ , the daily mean  $\bar{p}_i$  is calculated; then, for each calendar month ( $m$ ), the values  $\bar{p}_i$  are ordered in ascending order and 12 arrays for the whole data set are obtained. The cumulative distribution function  $\Phi(p, m, i)$ , associated to every  $\bar{p}_i$  over all the years in the data set, is calculated using the Eq. (1), with  $i$  the considered day in the month, from 1 to  $N$ , and  $N$  the sum of the number of days in any calendar month,  $K(i)$  is the position (“rank”) in the ordered list of  $\bar{p}_i$  of the month  $m$ ;

$$\Phi(p, m, i) = \frac{K(\bar{p}_i)}{N+1} \quad (1)$$

For each year  $y$  of the data set, the cumulative distribution function of the daily means within each calendar month (using Eq. (2)),  $F(p, y, m, i)$ , is obtained by sorting all the values for the month  $m$  and the year  $y$ , in increasing order. 12 arrays are obtained for every year.  $J(i)$  is the “rank” of the value of the daily mean  $\bar{p}_i$  for the month  $m$  and the year  $y$ ,  $n$  is the number of days in the month  $m$ ;

$$F(p, y, m, i) = \frac{J(\bar{p}_i)}{n+1} \quad (2)$$

For each calendar month, for each year of the data set, the Finkelstein-Schafer statistic,  $F_S(p, y, m)$ , is calculated using Eq. (3):

$$F_S(p, y, m) = \sum_{i=1}^n |F(p, y, m, i) - \Phi(p, y, m, i)| \quad (3)$$

For each calendar month with the same  $m$  from all the years, the rank  $R$  is calculated for each value. Differently from the standard method, in this work the ranking is performed ordering the values ascending by the  $F_S$ , calculated from the multiyear record for the parameters selected among temperature ( $T$ ), solar irradiance ( $I$ ) and relative humidity ( $RHU$ ) the driving rain ( $RDW$ ) obtained from the wind normal to the considered wall direction and from normal rain ( $RIH$ ), the wind speed ( $WS$ ) and the normal rain ( $RIH$ ); for each calendar month and for each year, the separated ranks ( $R$ ) are summed for the climate parameters selected for the formation of MRY (the parameter selection used in this work is shown in Table I) and the total ranking  $R_{\text{tot}}(y, m)$  is obtained; the month with the lowest  $R_{\text{tot}}(y, m)$  is selected as the “best” month to be included in the Moisture Reference Years;

Once the months are selected, the weather file is completed substituting the unrealistic leaps between the values of adjacent months with a linear interpolation.

The validation of the proposed MRYs is carried out by comparing the hygrothermal behaviour of building components simulated with the new MRY, with the behaviour obtained with the weather conditions over the long term from the measured weather file. 34 MRYs weather files have been generated with 16 different criteria. The historic weather data series, from 2002 to 2016, are provided by the Regional Agency for the Protection of the Environment (ARPA) of the Piedmont Region (Italy).

The evaluation of the obtained reference years has been performed comparing the hygrothermal simulation results of two different building envelopes, a hollow brick wall and a timber wall. The simulations have been performed with the software WUFI Pro, based on the model presented in Künzle et al. (1996). The comparison is held evaluating the monthly mean moisture content and comparing it to the one evaluated with the historical data set.

## RESULTS

The reference years from number 1 to number 24 have been simulated considering the design orientation (for example the reference year 1, designed considering the rain deposition on vertical wall facing South has been used for the simulation of the wall build-up facing South), while the reference years from number 25 to 34 have been used for the simulations for the five expositions considered (since normal rain has a general effect on all the expositions). The walls passed the moisture accumulation assessment and the condensation risk assessment for every MRY considered and for the historical data set. For this reason the annual mean results (Figure 1) have been compared in terms of relative standard deviation from the annual mean values obtained by the measured weather data (Figure 2). The Timber wall results show better representative MRY, with lower values of the relative standard deviation, with respect to the Hollow brick wall results.

Figure 2. Relative standard deviations of the moisture contents between the simulation of the historical years and every reference year described in Table 1.

The results present exposition specific trends. For the Timber wall, the ID 34 (based on *RIH*) better represents the South, East and North expositions, while the West exposition is better described by the ID 25 (based on *RHU*) and the Horizontal by the ID 28 (based on *I*). The ID ISO and the ID 28 are the reference years better representing the walls in the five directions. The Hollow brick wall shows different exposition specific trends: the South facing exposition is better represented by the ID 34 (based on *T* and *RHI*), the East and West by the ID ISO, the North by the ID 7 (based on *T*, *RHU*, *RDW*) and the Horizontal by the ID 32 (based on *T* and *RHI*). From Figure 2 it is also possible to observe some overall results. The ID from 1 to 24, considering *RDW* are generally less representative for the most rain exposed directions (West and Horizontal). Exclusively *RDW* based years (21-24) are less representative than ID from 29 to 34, based also on *RIH*. For the Timber wall the ID from 25 to 28 and the ID ISO (not based on *RIH* or *RDW*) are better performing than the *RIH* based ones, while for the Hollow brick wall, their behaviour is similar.

## DISCUSSION

The relative standard deviations of the Timber wall are lower than the Hollow brick wall. This difference is due to the different hygrothermal properties of the materials. The Hollow brick wall external layer has higher liquid transport coefficient values than the Timber wall, which has also higher moisture storage function values, and that could lead in faster responses to the rainfall (larger water content variations), with larger differences from the historical data set results.

The moisture reference years depending on rain deposition on vertical wall (obtained from wind speed, direction and normal rain) led to less representative years than the ones generated by the standard method. This result could be related to the features of the climate of Turin (Italy), whose rains are brief and quickly dried afterwards. On the other hand, one of the reasons could also be the fact that the external material layers do not respond instantly to the transient hourly rainfall excitations (slower than the heat excitations) and that the total water content of the wall is more influenced by the long term mean values of the environmental excitations, which is also been discussed in Libralato et al. (2017).

## CONCLUSIONS

In this study, 34 moisture reference years (MRY, to be used for hygrothermal analysis of building structures) have been generated from a data set of measured weather files from the year 2002 to the 2016, in the city of Turin (Italy). Each MRY has been generated selecting the months from the historical data set, with a modified EN ISO 15927-4:2005 method, based on the rain deposition on vertical walls with different expositions. From the simulation of two wall types to all the 34 MRY, it has been observed that an orientation differentiation does not lead to more representative MRY for the two considered building structures in the considered climate.

The results suggest that, when the use of a single MRY is preferred, the MRYs obtained with the standard procedure EN ISO 15927-4:2005 better reproduce the results obtained with the simulation of the measured weather files and that it could be used, not only for the energy consumption simulations, but also for the moisture migration in building envelopes simulations. Considering exposition and material specific applications, that could benefit from the use of more than one MRYs, other generation methods presented in this work could be taken in consideration, depending on the building material properties and on the wall orientation. Further work will be carried out to establish if this approach could be extended to critical weather data design for moisture accumulation risk assessments and if the proposed MRY generation method could be used proficiently for other applications, like energy simulations in

which the efficiency of the components of the systems depends on moisture related environmental conditions, such as evaporative towers (De Angelis et al. 2013), evaporative cooling systems for industrial buildings (De Angelis et al. 2017a), shopping malls (De Angelis et al. 2017b) and other heat recovery systems (Chinese et al. 2017).

### **ABSTRACT**

Hygrothermal analysis of historical building envelopes is crucial in ensuring their durability and enhancing their performances. The use of hygrothermal dynamic simulation is the most effective approach to predict moisture related damages or risk of mould growth on ancient masonry envelopes. However, simulating the hygrothermal behaviour of a historic wall composed by stones or bricks and mortar joints, with a detailed two-dimensional (2D) model, is typically a complex and time-consuming process. For this reason, in numerical models, composite walls are often simplified with a one-dimensional (1D) layer, neglecting the mortar joints. An oversimplified numerical model could affect the evaluation of a retrofit intervention and lead to inadequate design choices. This study evaluates when the description of a historic wall as a 1D homogenous layer leads to an acceptable level of accuracy and when it is necessary the use of a more precise 2D model. We quantified the error by comparing 1D and 2D simulations of different massive walls in three Italian climate conditions. We examined a possible retrofit intervention with different internal insulation systems considering vapor tight, vapor retardant and capillary active solutions. Although simplified 1D models are reliable for thermal parameters, we have identified a different behavior regarding the hygric parameters. Whereas for a capillary active insulation system the 1D and 2D simulations show a reasonable agreement, the 1D approximation is no longer acceptable in the case of vapour closed insulation systems as it leads to large deviations. Knowing when it is possible to implement a simplified 1D model and quantifying the introduced error will support architects and energy consultants in the design process. It will guide them in the choice of the most suitable model depending on their specific requirements.

### **KEYWORDS**

Hygrothermal simulation, Interior insulation, Performance evaluation, Moisture related issues, Historic stonewall.

### **INTRODUCTION**

Historic buildings are highly energy-consuming parts of the city center, and their energy consumption provokes large CO<sub>2</sub> emissions due to the low performances of their thermal envelopes. A possible strategy to reduce this impact is to decrease the thermal transmittance of the outer walls. In the case of aesthetically valuable historic buildings, interior insulation has proven to be a reliable solution, but dynamic hygrothermal simulations are needed to avoid possible hygrothermal risks. In fact, the change of the original thermal and moisture balance could lead to a higher moisture accumulation into the wall [1] with a consequent spalling and cracking due to hygric expansion and contraction or frost-thaw cycles, or visual deterioration due to salt efflorescence [2]. A thorough understanding of the moisture transport is also primary to make an accurate choice of the correct inner insulation system. It is common practice, while performing a hygrothermal simulation, to simplify the historical wall as a homogeneous stone or brick layer. This simplification gives the user the possibility to have quicker results, but has the effect of

neglecting mortar joints, which could play a significant role in terms of moisture storage and transport; the resultant deviations are investigated in this paper. A previous study [3] analyzed the impact of the mortar joints for a massive brick wall exposed to real climate conditions showing that they have a negligible impact and concluding that typically the approximation to a homogenous brick layer is allowed. In the present work, we extend previous analysis considering a broader range of variants and situations. We analyze a historic wall that is retrofitted with the application of different types of internal insulation, we consider several materials for the composition of the historic wall, ranging from stone to bricks, and finally we examine different climates zones.

## METHODS DESCRIPTION

### Hygrothermal simulation tool

In order to perform a full hygrothermal assessment, the commercial software Delphin 6.0.16 is employed. We considered a full hygrothermal simulation, which includes heat transport, liquid convective transport and vapor diffusion [4].

### Boundary condition: Outdoor

In this study we focus on Italian climate; in particular we selected three locations to consider North, Middle and South latitudes and cover different climate zones. The hourly climate data files were generated with Meteonorm 7.0. They include hourly data of temperature, relative humidity, direct and diffuse short wave radiation, long wave radiation, wind direction, wind velocity, and rain. In Table 1, we summarize the main characteristics of the three selected climates, Udine, Ancona and Messina for a North-facing wall.

	Annual Wind Driven Rain [l/m <sup>2</sup> ]	Annual Global Radiation [kWh/m <sup>2</sup> ]	Winter T average [°C]	Summer T average [°C]	Winter RH average [%]	Summer RH average [%]
<b>Udine</b>	44.29	326.54	4.72	23.95	71.95	66.86
<b>Ancona</b>	31.53	344.76	6.51	23.22	72.69	69.24
<b>Messina</b>	50.14	358.08	10.07	24.75	72.22	68.49

**Table 1.** Environmental conditions highlights. Annual radiation is calculated on the wall.

The thermal resistance of the exterior surface was set to 0.04 m<sup>2</sup>K/W. The absorption coefficient for short wave radiation was set to 0.6 and the emissivity for long wave radiation exchange to 0.9. The rain exposure coefficient was set at 1.00 assuming no sheltering, since worst-case scenarios were assessed.

### Boundary condition: Indoor

The interior climate was calculated based on external daily temperature data, according to the adaptive indoor climate model presented in the standard UNI EN 15026 [5]. The selected temperature range is between 20 and 25°C, while relative humidity varies between 35 and 65% following the recommendation of the WTA leaflet 6.2 [6]. The thermal resistance of the interior surface was set to 0.125 m<sup>2</sup>K/W.

### Historical wall characterization

The construction technique chosen for the reference hygrothermal model is a traditional core masonry wall. It is a widely used technology of the ancient Italian buildings [7]. The materials for the simulations are chosen among the most commonly spread over the Italian context. Four different stones are selected: granite, limestone, sandstone and tuff. The brick masonry, generally widespread in the Center-North of the country, is also included in this study. The mortar and the plaster chosen for the reference wall are a Lime Cement Mortar and an historical Lime Plaster; their hygric characterization parameters, as for the other materials, are selected from Delphin Material Database 6.0. In Figure 1 and Table 2, we report the main hygrothermal characteristics of the chosen materials.

**Figure 1.** Liquid water conductivity,  $K_l$ , as a function of the relative humidity (left) and as a function of the capillary pressure,  $p_c$  (right). The three vertical dashed lines are drawn at the relative humidities 0.50, 0.95 and 0.99 in both graphs.

The 2D model includes irregular mortar joints of maximum 20 mm thickness. In figure 2 we show the full 2D description used in Delphin as well as the 1D approximated model.

**Figure 2.** Schematic of the 1D and 2D models (elevation view of the section) of the historical wall section, with dimensions (mm).

### Insulation systems

Three kind of insulation systems were investigated in this paper, classified by their vapor permeability: Vapor Barrier (VB), Vapor Retardant (VR), Vapor Open (VO). The thickness of each insulation layer is set to 120 mm. The VB insulation system consist of a mineral wool insulation layer plus a low permeability vapor barrier on its inner side. Two 12.5 mm gypsum board are used as surface coatings. As VR insulation system, we chose an extruded Polystyrene board installed with 20 mm of glue and a surface coating of 20 mm lime plaster. The VO insulation system is composed by a Calcium Silicate board, with 20 mm glue to attach it to the existing plaster, plus a surface coating of 20 mm lime plaster. The most relevant hygrothermal parameters of the insulation material are summarized in Table 2.

Materials	$\rho$ [Kg/m <sup>3</sup> ]	$C_p$ [J/KgK]	$\theta_{eff}$ [m <sup>3</sup> /m <sup>3</sup> ]	$\lambda_{dry}$ [W/mK]	$\mu_{dry}$ [-]	$A_w$ [Kg/m <sup>2</sup> s <sup>1/2</sup> ]
Mineral Wool	67	840	0.9	0.04	1	-
Extruded Polystyrene	35	1500	0.9	0.027	225	8e-06
Calcium Silicate	270	1158	0.9	0.069	3.8	1.114
Granite	2453	702	0.054	1.71	53.8	0.085
Limestone	2440	850	0.127	2.3	140	0.003
Sandstone	1967	264	0.12	0.95	106.9	0.012
Tuff	1450	925	0.299	0.48	10.4	0.098
Brick	1788	800	0.24	0.81	28.3	0.031
Lime Mortar	1878	758	0.223	0.8	36.9	0.036
Lime Plaster	1800	850	0.285	0.82	12	0.127

**Table 2.** Hygrothermal proprieties of the chosen materials. Density ( $\rho$ ), Specific Heat capacity ( $C_p$ ), Theta effective ( $\theta_{eff}$ ), thermal transmittance ( $\lambda_{dry}$ ), vapor resistance ( $\mu_{dry}$ ), and water absorption coefficient ( $A_w$ ).

### Investigated outputs

The choice of the output to analyze in this assessment is based on the prescriptions of the WTA leaflet 6.5 [6]. The analysis of frost damages is neglected, since in the studied locations temperatures barely go under zero. Moreover, this study had shown a good correspondence of surface temperature and relative humidity values between 2D and 1D simulations, so the mold germination risk is not strongly influenced by this simplification. Therefore, the most interesting outputs to discuss, as proposed in WTA leaflet 6.5 [6], are relative humidity and temperature behind insulation, averaged on the first 10mm behind the insulation layer.

### Error calculation

Outputs are evaluated on an hourly basis, in particular we compare the results of 1D and 2D simulations. The deviation between the two simulations is evaluated calculating the absolute error. In particular, for a given quantity  $X$  (that can be either the temperature,  $T$ , or the relative humidity behind the insulation,  $\varphi$ ) we define the absolute error as

$$\Delta X(t) = |X_{2D}(t) - X_{1D}(t)| \quad (1)$$

where  $X_{2D}(t)$  and  $X_{1D}(t)$  represent the parameter  $X$  calculated as a function of time in the 2D and in the 1D simulation respectively. Then we define the absolute mean error,  $\langle \Delta X \rangle$ , as the time average of  $\Delta X(t)$  over the last year of simulation and the maximum absolute error,  $\Delta X_{max}$  as the maximum over the all simulation.

## RESULTS

The thermal analysis shows a high correspondence of the simulation results between 2D and 1D case. In particular for the calculation of the temperature behind the insulation we get the following typical errors:  $\langle \Delta T \rangle = 0.12^\circ\text{C}$  and  $\Delta T_{max} = 1.4^\circ\text{C}$ . Contrariwise, more deviations exist for the hygric behavior reaching mean absolute errors up to 7% for the relative humidity behind the insulation. Figures 3, 4 and 5 show the average relative humidity behind the insulation in the simulations of Udine for each case: Vapor Barrier, Vapor Retardant and Vapor Open insulation systems. A similar behavior is observed also for the simulation performed in Messina and Ancona.

**Figure 3.** Relative humidity behind the insulation,  $\varphi$ , as a function of time (top panel) and corresponding absolute error,  $\langle \Delta \varphi \rangle$ , (bottom panel) for Vapor Barrier insulation system and for the climate of Udine. The different colors refer to different materials composing the historic wall.

**Figure 4.** Same as Figure 3 but for Vapor Retardant insulation systems.

**Figure 5.** Same as Figure 3 but for Vapor Open Insulation system.

## DISCUSSIONS

Figures 3, 4 and 5 show that depending on the insulation type and on the material that forms the historic wall we can get very different absolute errors between 1D and 2D simulations. For instance when considering the sandstone wall we always get very small errors, while the largest mean absolute errors are observed for the case of granite. Also in the case of the limestone wall we get significant deviations. In the specific case of the limestone wall with a vapor tight insulation system, the situation is particularly critical since the 1D and the 2D simulation have different behaviors. The 2D simulation reaches a quasi-stationary behavior, while the relative humidity in the 1D simulation keeps decreasing over the years. For the brick masonry wall we observe peaks up to 9% deviation. For the vapor open insulation system, we typically get small deviations while the largest errors are found in the case of vapor tight solutions. Conversely, we observe that the climate does not play a crucial role in the determination of the behavior of the absolute error. We only observe a small correlation between the quantity of wind driven rain that reaches the façade and the absolute error. In order to get a closer insight on the correlation between the observed error and the parameters varied in the simulations we represent in Figure 6 and 7 the distributions of the absolute mean error using box plots. In Figure 6 the absolute mean error distributions are grouped depending on the insulation type, while in Figure 7 according to the material of the historic wall.

**Figures 6-7.** Absolute mean error: Insulation system dependency, Material dependency.

Fig.6 confirms that vapour tight insulation systems lead to higher errors. In particular, decreasing the vapour tightness of the insulation system, we observe smaller mean absolute errors. For vapour open insulation systems the mean absolute error  $\langle \Delta \phi \rangle$  is, for almost all the cases, smaller than 2%, while for vapour barrier insulation system we get errors of up to 7%. When using a vapour retardant solution we get an intermediate behaviour. The use of a vapour tight system on the internal side of the construction strongly reduces the interaction of the wall with the internal environment and therefore the behaviour of the wall is mainly determined by the interaction with the exterior climate. This interaction strongly depends on the way in which the wall is modelled, thus a detailed description of the wall becomes more relevant in this situation. Fig.7 confirms that the material forming the wall plays a significant role in the determination of the mean absolute error. In particular, we observe smaller errors for materials that have a liquid water conductivity close to the one of the mortar in the range 80 – 99%. These observations strongly suggest that the approximation of a masonry wall to a homogenous brick or stone layer has to be used with caution, especially when looking at hygric properties of the wall.

## CONCLUSIONS

This study analyzed the effect of simplifying an historical wall with a homogeneous layer in hygrothermal assessments, comparing the results of a 1D approximated simulation with those of a detailed 2D simulation. Three Italian climates and five materials were investigated, in combination with three internal insulation systems: a Vapor Barrier, a Vapor Retardant and a Vapor Open one. Results had shown a high correspondence in thermal behavior. Contrariwise, higher deviations are found in hygric results, especially in vapor tight and retardant insulation systems, which are influenced by a moisture accumulation process. Regarding the historic wall composition, those materials that have a similar liquid water conductivity to the mortar in the relative humidity range of the simulation, lead to smaller deviations. Our results show that representing an historic wall with a homogenous 1D layer could be in some situations an oversimplified model. We identified the situations that lead to larger errors in the framework of the parameters that we varied. However, further investigation are needed to develop a systematic approach for the identification of those situations.

### **ABSTRACT**

Over the last decades, the implementation of innovative multifunctional materials for urban surfaces has produced a variety of paving solutions characterized by self-cleaning, self-healing, electricity conductive, solar reflective, sound absorbent properties and so on. Therefore, a key challenge is nowadays represented by the need for combining multi-physics properties in a single material or system for flooring. The present work concerns the development of a new outdoor paving application with enhanced acoustic, thermal, and optical performance. To this aim, eleven concrete mix-designs were tested. The composites were characterized by different aggregate size, material and additives. The aggregates included in the composite consist of (i) natural stones with different grain sizes, (ii) expanded clay aggregates, and (iii) glass fragments. Acoustic, thermal, and optical measurements were performed for each sample. Additionally, a dedicated in-field monitoring campaign was carried out to characterize the albedo under summer boundary conditions. Finally, the thermal behaviour of the samples was tested in an environmental chamber using controlled boundary conditions in terms of temperature, humidity, and radiation. The results demonstrate that bigger grain size presents the best acoustic performance in terms of absorption capability, i.e. absorption coefficient of about 0.9 and 0.8 at 1000 Hz and 500 Hz, respectively. Moreover, the thermal-optical lab and field tests confirm previous literature results demonstrating that the mix-design with the smaller grain size has the best reflectivity potential.

### **KEYWORDS**

Paving materials; Optimized mix-design; Thermal-optical performance; Acoustic properties.

### **INTRODUCTION**

Urban environments are often affected by microclimate phenomena such as Urban Heat Island (UHI), a local condition that can significantly harm the health and the quality of life of citizens. In particular, the UHI consists of a significant increase in temperature in the urban area compared to the surrounding rural areas (Vardoulakis, Karamanis, Fotiadi, & Mihalakakou, 2013). Such phenomenon is generally influenced by the thermal and radiative properties of the typical urban surface materials (i.e. asphalt, cement) where the absorption of solar radiation prevails over its reflection (Taha, 2008). Moreover, the human action and the buildings operation strongly contribute to the overheating of urban areas. Such contribution is (i) direct, through traffic, industrial activities and HVAC systems, and (ii) indirect, through the alteration

of the radiative properties of the atmosphere due to the high levels of associated pollution (Pisello, 2017). Over the last few decades, many techniques have been proposed for the mitigation of such phenomenon. Among the main ones there is the use of permeable surfaces in urban environment, consisting of gravels or vegetation able to generate surface cooling by means of evapotranspiration. Furthermore, "cool" materials represent another suitable solution for reducing high urban temperatures (Santamouris, Synnefa, & Karlessi, 2011). These materials are characterized by a high solar reflectance and thermal emissivity that avoids overheating of the surfaces and the air near them. The benefits achievable when installing a cool material over urban paved surfaces can be summarized as follows (Rosso et al., 2017): (i) mitigation of the urban overheating thanks to the capability to reflect most of the incoming incident solar radiation and (ii) consequent reduction of CO<sub>2</sub> emissions emitted in the environment. Another issue typical of urban environments relates to the high noise levels in cities and is referred to as Urban Noise Island (UNI), where depending on the road and tires characteristics and of course on the vehicles' speed, the prominent noise peak very frequently is found at 1000 Hz but it may also be shifted within the range 630-2000 Hz (Sandberg 2003). It is generated by the combination of the different and multiple sources of noise (such as traffic, industrial activities, etc.) that generate sound pollution in urbanized environments (Asdrubali et al., 2015). The study of this phenomenon, which depends on both the generation and propagation of sound, involves the environmental analysis of the external and internal sources at building level, of the control actions on the source, on the propagation path and on the receptor, as well as on the analysis of the response of the human ear to sound stress. In this case, the main mitigation techniques consist of passive type protections that act on the propagation path or on the receptor. In this sense, to reduce the problem of urban noise it is possible also to act on the shape of the buildings, i.e. mainly on the acoustic requirements of the façade (i.e. acoustic insulation). Based on the framed background, the present research work deals with the development, characterization and optimization of concrete-based materials with high-thermal and acoustic performance for urban paving applications. The aim is therefore to implement innovative materials able to mitigate both the UHI and UNI when installed over urban pavements. To this purpose, an extensive experimental laboratory and field campaign was carried out and different mix design were tested and compared in terms of their coupled thermal-acoustic behavior.

## **MATERIALS AND METHODS**

Five different components were selected and used to produce advanced concrete mix designs with enhanced acoustic and visual performance to be used as urban pavements: sand (i.e. fine grains, 0-4 mm), pebbles (i.e. medium grains, 2-5.6 mm), chippings (i.e. large grains, 4-12.5 mm), glass fragments (4-12.5 mm) and expanded clay spheres (2-5 mm). These components were alternatively treated with titanium dioxide to maximize their capability to reflect solar radiation. The samples had a diameter of 10 cm and 2.9 cm and a thickness of 6.5 cm for the laboratory acoustic tests (i.e. for the evaluation of the acoustic absorption).

Starting from the first basic paving mix-design (i.e. traditional paving recipe chippings-based), additional samples were prepared, by varying (i) type of aggregate (sand, pebbles, chippings, expanded clay spheres, and glass fragments), (ii) TiO<sub>2</sub> treatment, and (iii) kind of additive (i.e. dynamon floor 20 and bt02) in the case of the pebble mix design.

### **Thermal-optical in-lab experimental analysis**

Firstly, spectrophotometric measurements were carried out to investigate the reflectance capability of the different evaluated samples. The experimental campaign was performed by using a Shimadzu UV-VIS-NIR spectrophotometer equipped with a double-radius optical system over time and integrating sphere. Moreover, the calculation of the spectral solar reflectance in the range 300-2500 nm was carried out according to the ASTM E903-12

Standard Test Method (American Society for Testing and Materials, 2010b). Secondly, the thermal emissivity of the samples was measured by means of a portable emissometer according to the ASTM C1371 Standard Test Method (American Society for Testing and Materials, 2010a). Finally, a DM340SR (ATT) climatic chamber was used to test the thermal behavior of the samples within controlled dynamic conditions in terms of temperature, humidity and solar radiation (Fabiani & Pisello, 2017).

### Acoustic in-lab experimental analysis

In order to characterize the acoustic properties of the selected materials, the impedance tube was used. To this aim, a Brüel & Kjær Kundt's tube with all the related equipment and accessories was used. The measurements were carried out according to the classic standardized procedures in materials analysis in the lab (Asdrubali et al., 2015). The test procedure involved at least three measurements for each sample to obtain an acceptable result reliability. Finally, the comparison between the absorption coefficients of the different samples was made considering the average value of the measurements carried out for each sample.

### Albedo field monitoring

After the preliminary in-lab experimental campaign, the albedo of the samples was monitored in-field by means of a dedicated double pyranometer or albedometer, an instrument able to measure both the incident solar radiation and the one reflected from the surface between 300 and 2500 nm. The experimental measurement campaign was carried out according to the ASTM E1918-06 international standard (2006). The experimental campaign was performed in the period from 10 July to 10 August 2017 to characterize its reflectance potential when the climatic forcing to the boundary and the meteorological conditions vary. To this end, after the measurement of black and white reference samples (Akbari, Levinson, & Stern, 2008) the different samples were monitored on typical summer days.

## RESULTS

### Thermal Emissivity and Solar Reflectance

In this section, the results of the testing of the thermal-optical properties of the samples are presented. In particular, Figure 1 shows the trend of the solar reflectance of fine sand, mortar and pebbles concrete mix designs, and the obtained solar reflectance (SR), emissivity ( $\epsilon$ ) and solar reflectance index (SRI). It is clear how the solar reflectance increases as the grain size decreases. In fact, as can be seen by comparing the pure mortar with the mix designs produced by introducing the same amount of sand or pebbles, the sample with fine sand shows the greatest solar reflectance, followed by pebbles and the traditional mortar. In terms of thermal emissivity, the values are generally high, i.e. varying from 0.91 (mortar) to 0.99 (fine sand).

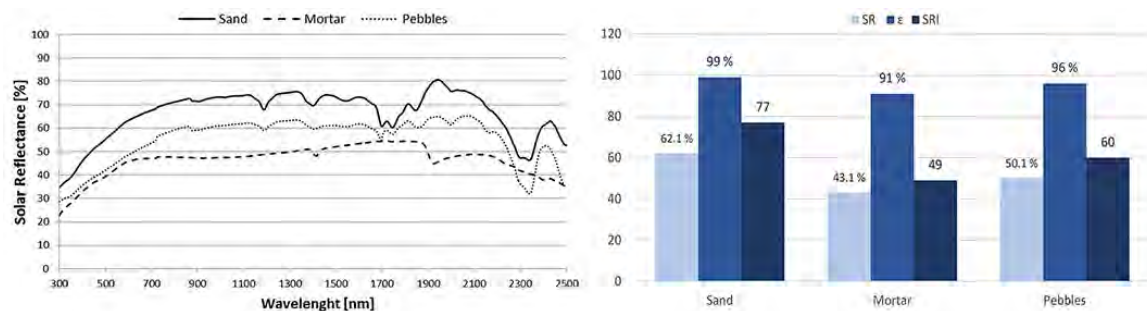

Figure 1. Solar reflectance profiles in the range 300-2500 nm, SR,  $\epsilon$  and SRI of the samples.

### Dynamic controlled environment: climatic chamber

This section summarizes the results of the tests carried out in the climatic chamber. The purpose of the tests was to investigate and compare the thermal behavior of the samples under the same controlled dynamic environmental conditions, i.e. a typical summer day in the Rome climate zone taken from the TMY (Typical Meteorological Year). Therefore, the surface temperatures of the upper and lower face of the samples was measured with varying air temperature, relative humidity, and incident solar radiation.

Figure 2 shows how the samples containing fine sand present the best surface thermal behaviour, followed by the mortar and the pebbles mix design with the Dynamon 20 additive, which possess the highest thermal inertia due to their highest density and the samples with TiO<sub>2</sub> and glass fragments, which are capable to reflect the highest amount of the incoming radiation (an average direct radiation on the horizontal surface of 820 W/m<sup>2</sup> was imposed through the halogen lamp according to data from the TMY). On the other hand, expanded clay sphere and pebbles samples with bt02 or without any additive, which are characterized by a larger grain size and lower densities, show the worst performance in terms of surface temperature, reaching up to 68°C.

Figure 2. Average temperatures of the upper (left) and lower (right) surface of the samples.

### Albedo in-field measurements

Table 2 shows the albedo values measured in the field during typical summer days (July 2017) for the different samples of paving material produced. It is evident how the paving recipe characterized by the presence of glass fragments and TiO<sub>2</sub> treatment present a greater albedo than all the other samples, followed by the expanded clay spheres with TiO<sub>2</sub> treatment. The paving samples produced using the original recipe with chippings included, and the one characterized by the presence of pebbles are those with lower potential in terms of albedo. These results are consistent with previous studies showing that albedo increases with decreasing grain size.

Table 2: Albedo test results.

Sample	Traditional asphalt	Original paving recipe	Expanded clay spheres+ TiO <sub>2</sub>	Glass fragments + TiO <sub>2</sub>	Pebbles
Albedo (12-3PM)	~7	37.9	40.8	44.4	36.8

### Acoustic absorption coefficient

Figure 3 shows the trend of the acoustic absorption coefficient for the various samples tested with respect to the original paving recipe. The sample of the original pavement recipe is not very absorbent. In fact, the maximum absorption coefficient is equal to 0.2 at 450 Hz. As for the mortar sample, this has a maximum absorption coefficient equal to 0.2 at 600 and 1300/1400 Hz. As regarding the samples with aggregates of different grain sizes, the sand has a maximum absorption coefficient of 0.2 at 400 Hz, and then remains almost constant ( $<0.1$ ) at the other frequencies. The sample with pebbles, on the other hand, presents a bell-shape absorption coefficient with a positive peak of 0.85 just before 600 Hz and a negative peak of less than 0.2 at about 1600 Hz. The clay sphere sample is characterized by a high absorption coefficient, with a peak of 0.9 at 600 Hz. As for the mix design with chippings and  $\text{TiO}_2$ , a maximum absorption of 0.3 between 500 and 600 Hz is reached. Subsequently, the absorption capacity decreases at about 0.1 between 800 and 1200 Hz, then decreasing again. By adding the bt02 additive, the aforesaid sample becomes very absorbent, with a maximum absorption coefficient of 0.9 at 500 Hz. By adding a different type of additive ("Dynamon"), the absorption coefficient reaches a value of almost 0.8 at 500 Hz. The sample produced using expanded clay spheres and  $\text{TiO}_2$  has a very high absorption capacity, up to a maximum value of 0.8 at 500 Hz. The sample with glass fragments, on the other hand, has a low absorption capacity, with a maximum of less than 0.2 at 450 Hz. By adding the  $\text{TiO}_2$  to the present recipe, the absorption coefficient increases slightly to 0.25 at 600 Hz and then decreases at the other frequencies.

Based on such results, the mix-design showing the highest absorption coefficient is that with pebbles, with and without additives, and the expanded clay spheres one, with and without  $\text{TiO}_2$ . All the other samples examined show absorption coefficient peaks ranging from about 0.2 to 0.3. On the other hand, samples with pebbles and expanded clay spheres reach peaks of almost 0.9 with respect to the traditional paving recipe which almost does not reach 0.2. It is also possible to notice that all the tested samples have an absorption coefficient peak between 400 and 600 Hz.

Figure 3. Comparison among the acoustic absorption coefficients of the tested samples.

### CONCLUSIONS

The present work aimed at developing and experimentally characterize the thermal and acoustic performance of composite materials for external urban paving. To this purpose, samples of different materials were produced, with varying mix design, particle size, and components (i.e. natural gravel, glass fragment, expanded clay). Results from the experimental campaign allowed to identify the best recipe for urban paving application depending on the need to optimize the performance in terms of solar reflectance, thermal emissivity, albedo, surface temperature and/or absorption and sound insulation potentiality. In general, it was found that to optimize the thermo-optical performance of the paving it is necessary to reduce the grains size of the aggregates as much as possible. In fact, the solar reflectance increases as the particle size of these components decreases. As far as the albedo is concerned, the tests demonstrated that to

improve the performance of the original paving mix it is appropriate to integrate glass fragments and  $\text{TiO}_2$  (40% enhancement of the albedo compared to the traditional base-case paving recipe). As for the optimization of the acoustic behavior, it was shown that the best absorption performances are achieved by the samples in loose configuration, due to the interstitial voids that increase the amount of sound energy dissipated by the interaction between the solid matrix and the air molecules. Furthermore, it was possible to notice how the two different configurations (i.e. low density and high density mix design) work properly at different frequencies. Therefore, to maximize the acoustic performance of urban paving materials it is necessary to select materials that work well at low frequencies. In this view, the best materials in terms of acoustic absorption potential are those ones with expanded clay balls, which allow an improvement up to 0.6 (300%) compared to the original paving.

## ACKNOWLEDGEMENT

The authors' acknowledgements are due to Luigi Metelli S.p.A. for supporting the development of Regional 598 project named COOL CRETE. The authors would like to thank Dr. Antonella D'Alessandro and Dr. Emanuele Piccioni for helping them in the preparation phase.

## **Intrinsic Evaporative Cooling with Natural Ventilation and Shading for Adaptive Thermal Comfort in Tropical Buildings**

### **ABSTRACT**

Hygroscopic materials, including earth- and plant-based materials used in tropical vernacular architecture, often sorb significant moisture from the atmosphere during humid nighttime hours; evaporation the following day then provides a pronounced cooling effect, particularly in semi-arid regions. While such intrinsic evaporative cooling is also active in wet-tropical climates, it cannot maintain indoor comfort, and vernacular structures are highly open to facilitate air movement. Recently, new hygroscopic materials have been developed from coconut agricultural wastes that show great potential for intrinsic evaporative cooling and indoor humidity control in contemporary tropical buildings. As expected, however, they must be combined with additional cooling strategies to maintain thermal comfort. This investigation explores the integration of intrinsic evaporative cooling with natural ventilation and shading to determine the extent to which indoor thermal comfort, as evaluated by the ASHRAE 55 adaptive thermal comfort standard, may be maintained in the representative wet-tropical climate of Ghana, West Africa.

### **KEYWORDS**

intrinsic evaporative cooling, hygroscopic, agrowaste, natural ventilation, passive cooling

### **INTRODUCTION**

Hygroscopic materials, including adobes, grasses, fibers, and leaves used widely in tropical vernacular buildings can sorb significant moisture from the atmosphere during humid nighttime hours; evaporation the following day can then offset appreciable solar gains. This phenomenon, termed intrinsic evaporative cooling, has recently been characterized in diverse earth materials and semi-arid climates (Rempel 2016) as well as in agrowaste fibers and fiberboards in humid and subtropical climates (Lokko 2016). Intrinsic evaporative cooling in itself, however, cannot maintain indoor comfort in humid tropical climates (Lokko 2016). While moisture sorption by hygroscopic agrofiber envelope materials has previously been shown to lower indoor humidity to as little as 70% of outdoor daytime levels (Lokko 2016), indoor operative temperatures remained outside adaptive thermal comfort standards (ASHRAE 2017) and higher than outdoor conditions. The present study addresses these comfort issues by incorporating the effects of shading and natural ventilation, using window operation strategies common in tropical cities like Accra, Ghana, and evaluating results in light of the adaptive comfort standard (ACS) to reflect the relaxation of thermal expectations and higher levels of perceived control observed in naturally ventilated buildings (Brager 1998). Following natural ventilation strategies used in vernacular and contemporary buildings, which facilitate air movement through occupied zones, this work studies the impact of shading and natural ventilation on two scales of window openings. While the ACS applies to sedentary activity and may not account for the changing thermal preferences of tropical building inhabitants who have become accustomed to air-conditioning, it is used here to reflect the broad thermal adaptation typical of people living in the tropics.

### **METHODS**

A simple gabled rectangular building with multiple window and shading configurations was

**Figure 1.** Study building dimensions, window configurations, and shading elements.

modeled in EnergyPlus 8.7, using Euclid 0.9.3 for geometry input (Fig. 1). Oriented along the east-west axis, the roof and walls were simulated as hygroscopically-active coconut fiberboard assemblies surrounding a tiled concrete floor in contact with the ground. Internal gains assumed a single occupant, with a sensible heat fraction of 0.3, activity level of 90-120 W/person when occupied, and 5pm-9am residential occupancy. To understand heat, air, and moisture transfer patterns, the EnergyPlus Heat and Moisture Transfer (HAMT) algorithm was used to simulate the effects of evaporation from, and condensation onto, building materials following established procedures (Rempel 2016). Infiltration and natural ventilation were simulated with airflow networks, allowing EnergyPlus to calculate wind pressure coefficients from the orientations of wall and roof surfaces with respect to wind speed and direction. Infiltration, active in all models, was governed by an air mass flow coefficient of 0.001 kg/s at reference conditions of 20°C with a cross-crack pressure difference of 1 atm, for wall and roof assemblies, and 0.01 kg/s at the same reference conditions for window perimeters, reflecting typical construction practices. Natural ventilation, in turn, assumed openable areas equal to the window areas specified (Fig. 1), with discharge coefficients estimated conservatively at 0.65. To reveal the effect of natural ventilation on indoor operative temperatures, independent of shading, models possessing either small or large windows (Fig. 1) were simulated with a baseline condition of closed windows (i.e. with infiltration only) and with two predominant ventilation control practices found in Ghana in the hottest months: one with windows open only during the day, and one with windows open both day and night. Natural ventilation was anticipated to improve thermal comfort in three ways: first, by removing warm indoor air and replacing it with cooler outdoor air; second, by cooling thermal mass; and third, by increasing indoor air velocity, thereby accelerating evaporation of moisture from skin and effectively expanding the thermal comfort zone. Because of this, building indoor operative temperatures (°C) and air velocities (m/s) were compared to adaptive comfort boundaries in each case. All simulations used the SWERA weather file for Accra, Ghana, and results were reported for one representative week in March, the warmest month of the year.

**Table 1.** EnergyPlus Model Parameters

Construction	Material	Density (kg/m <sup>3</sup> )	Thickness (m)	<i>k</i> (W/m-K)	<i>c</i> (J/kg-K)

## RESULTS

**Intrinsic evaporative cooling.** Typical outdoor air temperatures in Accra, Ghana in March, the warmest month of the year, fluctuate from the high 20's to low 30's Celsius, while outdoor relative humidity typically rises above 80% overnight but falls to ~60% at mid-day (Fig. 2a). Sorption of moisture from humid nighttime air by hygroscopic coconut fiber materials is evident in latent heat transfer into wall and roof surfaces, shown by negative values. Evaporation from these surfaces, in turn, which provides cooling, is shown by positive latent heat flux values, resulting in an average daytime evaporative cooling effect of ~50 W/m<sup>2</sup> for wall and ~15 W/m<sup>2</sup> for roof surfaces. While this process effectively diminished indoor relative humidity compared to outdoor levels (Fig. 2a), indoor temperatures remained uncomfortably high (e.g. Figs. 3a, c).

**Figure 2.** Intrinsic evaporative cooling in the study building, showing a) March outdoor air temperatures (orange dots) and relative humidities (blue dots) and indoor relative humidity (blue dashes), as well as latent heat fluxes across b) coconut fiberboard walls and c) roof surfaces.

**Natural ventilation.** Without natural ventilation, i.e. with only infiltration to exchange indoor and outdoor air, indoor operative temperatures reached ~40°C at mid-day, with small-windowed models remaining only slightly cooler than the large-windowed counterparts (Figs. 3a,c). This shows the importance of heat transfer through the lightweight, relatively conductive coconut envelope panels, which contributed more than window solar transmission or infiltration to total heat gain. At the same time, this envelope allowed “No Vent” models to cool to near-outdoor temperatures each night, such that near-comfortable conditions were predicted during most occupied hours (6pm-8am). Adding daytime ventilation (8am-8pm) diminished daytime operative temperatures dramatically, lowering peak values by about 6°C in the days shown (Fig. 4) and bringing 2-4 additional hours per day into the adaptive comfort zone, easily encompassing the occupied hours. Night operative temperatures dropped as well, though less extensively, reaching minima ~1-2°C lower than observed in “No Vent” models. This drop was associated with lower mass surface temperatures, showing that the limited mass provided (0.5cm ceramic tile over a 10cm concrete floor) was able both to sustain higher nighttime temperatures when ventilation was eliminated, and to facilitate additional cooling when it was permitted, even during the day. Adding night ventilation, i.e. opening windows for 24h daily, did not noticeably affect indoor operative temperatures in either small- or large-windowed models (Figs. 3a, c). This was unexpected, given the massive floor, but closer inspection revealed several explanations. First, March nighttime winds are typically low in Accra ( $\leq 3$  m/s in >90% of hours), compared to daytime values of 4-6 m/s, diminishing night ventilation effectiveness. Second, infiltration exchanged sufficient air at night in the “12h Vent” model that open windows added only modest air exchange. Third, consistent with the previous two points, the mass floor did not become appreciably cooler in the “24h Vent” models, showing that the additional air exchange was not enough to lower floor mass temperatures to an extent relevant to thermal comfort.

**Figure 3.** The predicted natural ventilation alone on indoor operative temperatures and adaptive thermal comfort (shaded areas) over six representative March days in Accra, Ghana, for dwellings with small (a, b) and large (c, d) window Vent”: “12h Vent”: windows open 8am-8pm; “24h Vent”: windows open at all times.

To reveal whether increased air velocity brought some of the warm hours into the velocity-expanded comfort zone (ASHRAE, 2017), air velocity was next plotted against operative temperature (Figs. 3b, d). “No Vent” models predicted considerable indoor air motion from infiltration; this was calculated as a function of pressure difference across each crack, which is a function of both temperature difference and wind pressure (USDOE, 2016), with the result that high indoor air temperatures drove considerable exfiltration (coinciding with calm indoor air, shown as pronounced rows of high-temperature, zero-velocity symbols (Fig. 3). Adding daytime ventilation (“12h Vent”) replaced this hot-hour exfiltration with cooler air of considerably higher velocity, allowing thirteen hours with operative temperatures  $>30^{\circ}\text{C}$  to enter the velocity-expanded comfort zone over a six-day period, or  $\sim 2\text{h}$  per day. Adding all-day ventilation (“24h Vent”) had little effect on daytime conditions, as expected, but diminished the bursts of infiltration-driven high air velocity that occurred during the coolest hours of the night in the previous two models, replacing them with steadier, lower-velocity air movement.

**Shading.** The cooling effect of shading alone was investigated by comparing a configuration with no shade at all (“No Shade”) with two having external overhangs that shaded half or all of the south-facing wall at noon, including the entire south-facing window in both cases (“Half Shade” and “Full Shade”, respectively). As expected, shading noticeably lowered indoor temperatures: while unshaded models reached peak operative temperatures of  $\sim 40^{\circ}\text{C}$  on typical March days (Fig. 4), far beyond the thermal comfort range, half-shading reduced these peaks by  $1\text{--}1.5^{\circ}\text{C}$ , and full shading reduced them by  $2\text{--}3^{\circ}\text{C}$ , providing significant cooling given the un-

shaded, relatively conductive roof. Shading alone did not, however, bring additional hours into the adaptive comfort zone (Fig. 4), showing that further cooling measures would be necessary.

**Figure 4.** The predicted effect of shading alone (i.e. without natural ventilation, apart from infiltration) on indoor operative temperatures and adaptive thermal comfort (shaded areas) in six representative March days in Accra, Ghana, for dwellings with small (a) and large (b) window configurations. “No Shade”: windows are unshaded at all times; “Half Shade”: walls are half shaded at noon by exterior overhangs; “Full Shade”: walls are fully shaded at noon by exterior overhangs.

**Combinations.** Since shading showed cooling ability independent of natural ventilation, combinations of “12h Vent” and “24h Vent” with “Half Shade” and “Full Shade” were next investigated. As expected, these out-performed each individual strategy, reducing peak operative temperatures by  $\sim 1^\circ\text{C}$  each day in both small- and large-windowed models (Figs. 5a, c) and bringing them to within  $1^\circ\text{C}$  of the outside air temperature. They did not, however, cool additional hours below the  $30^\circ\text{C}$  threshold of the adaptive comfort zone; instead, additional cooling appeared confined to the warmest hours of the day. Furthermore, shading did not improve the ability of natural ventilation to bring additional hours into the comfort zone through air velocity; 12-14 warm hours were made comfortable by air movement regardless of shading level (Figs. 5b, d).

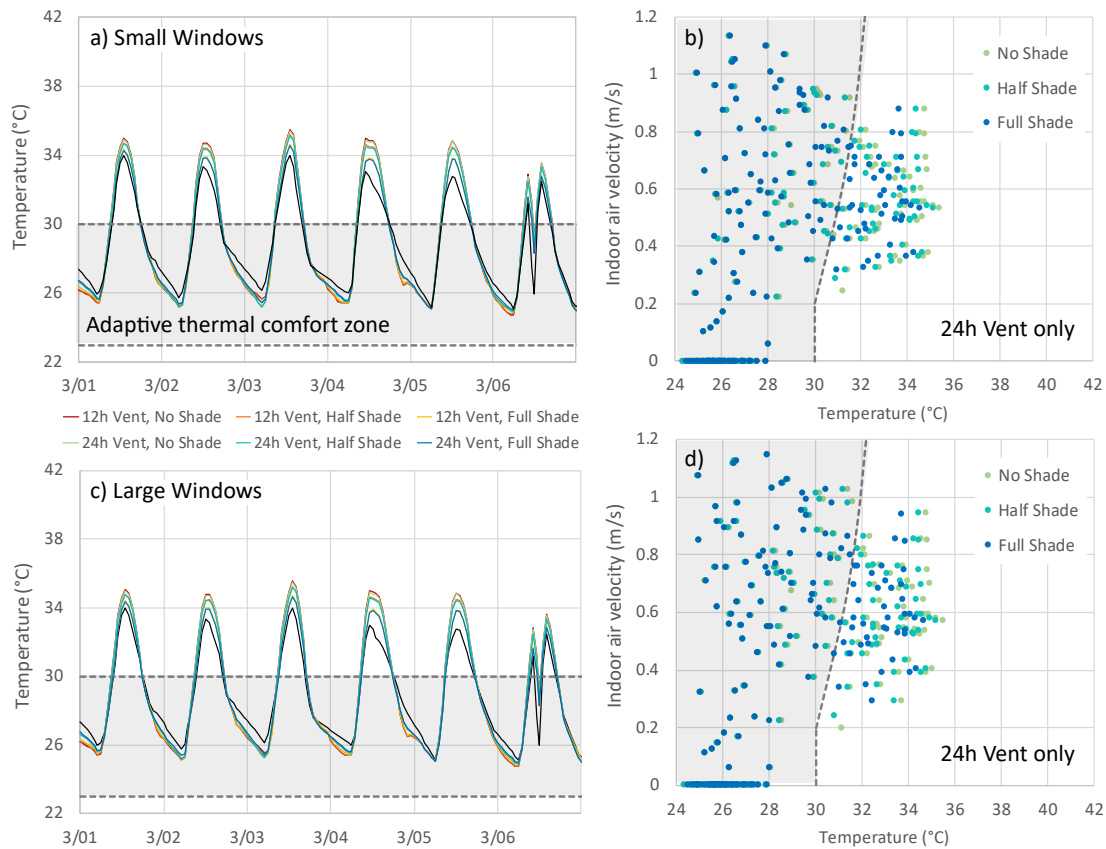

## DISCUSSION

While building simulations are vulnerable to numerous sources of error, including algorithmic simplifications (USDOE, 2016), failure to capture occupant usage patterns accurately, etc., they are invaluable for revealing priorities for subsequent investigations. In this study, the modest effect of wall and window shading, combined with high heat gains through the roof, revealed the likely importance of ventilated attics that allow roofs to shade interior ceilings in such lightweight construction. Likewise, the ability of cross ventilation to expand the hours of adaptive comfort by two per day through increased air velocity suggests a valuable resource worthy of field investigation; thermal mass configurations were similarly shown to be in need of further study in this climate, with little diurnal temperature variation, given the nearly identical results generated by 12h and 24h ventilation patterns. Finally, any interdependence among intrinsic evaporative cooling, shading, and natural ventilation remains mysterious, although interaction is likely: a shaded wall is expected to evaporate less moisture, for example, while a naturally-ventilated interior might evaporate more.

## CONCLUSIONS

Together, shading and natural ventilation, in the most effective combinations, lowered predicted indoor operative temperatures in the coconut-material study building from peak levels that exceeded outdoor temperatures by  $\sim 10^\circ\text{C}$  to levels approximating outdoor temperatures.

**Figure 5.** Predicted effects of combined shading and natural ventilation on adaptive thermal comfort (shaded) in March in Accra, Ghana, for dwellings with small (a, b) and large (c, d) window configurations. “No Shade”: unshaded at all times; “Half Shade”: walls half shaded at noon by exterior overhangs; “Full Shade”: walls fully shaded at noon by exterior overhangs; “No Vent”: infiltration only; “12h Vent”: windows open 8am–8pm; “24h Vent”: windows open at all times.

While further cooling is necessary for daytime comfort, this represents significant progress. The upcycling of local agricultural waste such as coconut husk into building materials has the potential to expand the economic value chain of coconut producers in tropical nations while producing low-embodied energy materials. Because of this, further investigations of their effective integration into buildings, allowing them to provide reliable thermal comfort without energy-intensive mechanical air conditioning, hold economic, environmental and social value.

## Long term measurements and HAM modelling of an interior insulation solution for an office building in cold climate

Paul Klõšeiko<sup>1,\*</sup>, Targo Kalamees<sup>1</sup>

<sup>1</sup>Tallinn University of Technology, Estonia

*\*Corresponding email: paul.kloseiko@ttu.ee*

### ABSTRACT

Excessive mould damage was detected in an office building in Northern Europe and thus a renovation need was established. This paper studies a renovation solution using measurements and heat, air & moisture (HAM) modelling. Polyurethane (PUR) foam was used to fill the air gap in masonry while capillary active calcium silicate (CaSi) insulation was used on the interior surface at thermal bridges. During renovation works temperature and relative humidity ( $t$  &  $RH$ ) and heat flux sensors were installed throughout the wall.

Nearly 3 years of measurements are presented. Average thermal transmittance ( $U$ ) of the wall was reduced around 3 times. While the climate was probably not critical during the monitoring, the measured values stayed within hygrothermally safe limits.

The paper also compares the measurement data to 2D HAM modelling and discusses the discrepancies. Calibrated models were used to model the wall using real 42-year weather data and give a more thorough assessment of the hygrothermal performance. Although the original wall stayed fairly moist, no performance limits were exceeded and the interior surface became safer in terms of mould risk.

### KEYWORDS

interior insulation, HAM modelling, capillary active, cold climate, case study

### INTRODUCTION

Interior insulation has usually been disapproved in Northern Europe as a hygrothermally risky solution. However, “capillary active” insulation has gained ground in Central Europe and become a compelling choice by taking a different approach to mitigating the risks caused by insulation on the interior side (compared to traditional mineral wool + vapour barrier solution). This study took place on the last floor of an 8-storey office building (built in 1936; cultural heritage). Existing interior insulation (gypsum board, PE foil, min. wool) exhibited excessive mould damage and a renovation solution had to be found. Main challenges were: low surface temperatures, high thermal transmittance and avoidance of future biological decay. Preliminary HAM modelling showed that “closed cell” PUR foam injected into air cavities of the masonry and “capillary active” CaSi on the surface of the wall could perform well. This paper discusses the monitoring and modelling of the chosen solution.

### METHODS

#### Measurement setup

Vertical and horizontal sections of the studied wall are given in Figure 1. The wall structure, renovation solution and sensor placement are also shown. Sensors and their positions were selected both to assess the hygrothermal situation after the insulation and to have enough reference points to calibrate the HAM models.

The following measurement devices were used: T&RH probes: Rotronic HygroClip HC2-C05 (accuracy  $\pm 0.3^\circ\text{C}$ ,  $\pm 1\%\text{RH}$ ); heat flux plates: Hukseflux HFP01 (accuracy  $\pm 5\%$ ); data logger Grant Squirrel SQ2020 1F8 (accuracy  $\pm 0.05\%$  of readings  $\pm 0.025\%$  of range); temp. probes & logger: Onset Hobo UX120-006M & TMC6-HD (accuracy  $\pm 0.15^\circ\text{C}$ ); T&RH data loggers: Onset Hobo U12 and UX100 (accuracy  $\pm 0.21^\circ\text{C}$ ,  $\pm 2.5\text{--}3.5\%\text{RH}$ ). Measurement interval: 1h.

Figure 1. Vertical and horizontal sections of the wall showing sensor placement and wall layers.

### Performance criteria

WTA Merkblatt 6-5 (Künzel et al. 2012) proposes to avoid frost and condensation in insulation and glue. Assessment according to saturation degree should be carried out – maximum of  $30\%\text{sat}$  is allowed to avoid frost damage. However, our previous research (Klöße et al. 2017) showed that freeze-thaw cycling affected tensile strength of capillary active insulation material even though saturation degree stayed below the  $30\%\text{sat}$  limit. Therefore, slightly stricter limits of  $RH_{\text{crit}} = 95\%\text{RH}$  and  $t_{\text{crit}} = -5^\circ\text{C}$  (Künzel 2011) are used in this study. Minimizing freeze-thaw cycles of the limestone cladding was not a criterion as conversion to ventilated façade is planned for the building.

### Hygrothermal modelling

IBK Delphin 5.9.0 (Grunewald 1997; Nicolai et al. 2009) was used to model the hygrothermal performance of the exterior wall. Modelling consisted of 2 steps: 1) model calibration and 2) modelling with 42-year weather data. 1D and 2D models of the masonry section were created (while brickwork was treated as a homogenous material for both). Concrete bond beam was modelled as a 1D case. Model geometry is given in Figure 1.

During calibration, measured ( $t$ ,  $RH$  (+ calculated vapour pressure), heat flux) and modelled data were compared. Then the HAM models were iteratively changed within plausible extents to achieve a better match between the two. Different bricks and concrete types from Delphin material database were tested (finally settling with ID 543 and 569 for brick and concrete respectively), PUR foam properties were fine-tuned according to limits given in its datasheet (based on ID 195; following changes were made:  $\rho = 39\text{ kg/m}^3$ ,  $\mu = 39$ ,  $\lambda = 0.022\text{ W/(m}\cdot\text{K)}$ ). Rest of the material IDs from Delphin database used in models were 464, 143, 424, 21, 230.

Boundary conditions for model calibration were:  $t$  &  $RH$  (measured on site); wind, rain (measured 10km away) and solar radiation (measured 165km away). 42-year weather data ( $t$ ,  $RH$ , wind, rain, solar radiation; all measured 165km away) was used to assess the performance in more critical conditions. As the indoor humidity load in the test room was very low, more critical indoor  $t$  & moisture excess profiles were used for 42-year modelling (roughly moisture class 2 given in EN ISO 13788 Table/Figure A.2). They were based on an earlier study in a similar building (Klůšeiko & Kalamees 2016).

## RESULTS & DISCUSSION

### Measurement results

Temperatures behind CaSi (Figure 2 top, sensors TRH1, 3, 4) were closest to limits during the winter of the first year. At sensor TRH4 (concrete section) they fell to as low as  $-2.5^{\circ}\text{C}$ , but not reaching the critical  $-5^{\circ}\text{C}$ . In masonry section the temperatures were higher due to PUR insulation adding further thermal resistance. Consequently, sensors on the exterior side of PUR (TRH2 shown here) measured far lower temperatures than between CaSi and concrete bond beam. Figure 2 (bottom) gives the measured relative humidities. Dryout of the built-in moisture to stable levels took about 2.5...3 months.  $RH$  values between exterior brick leaf and PUR (sensor TRH2) were quite stable (fluctuating about  $5\%_{RH}$  throughout the year) after the dryout of CaSi built-in moisture.

Figure 2. Measured temperatures (top) and relative humidities (bottom) throughout the monitoring period.

Moisture excess during the measurement period in the test room was very low (close to moisture class 1 according to EN-ISO 13788 A.2), as a well-functioning HVAC system was installed. Analysis of measured data hints that moisture contents of air in the pores of exterior masonry leaf are governed by outdoor climate while lagging about half a week. A  $\sim 4 \text{ g/m}^3$  rise in moisture contents compared to indoor and outdoor air in autumn (mid-Aug...Oct.) is pronounced, possibly due to rain. However, moisture does not seem to be accumulating in the wall over time, which could be the case with vapour tight interior insulation and heavy wind

driven rain loads. Sensors behind CaSi insulation measured moisture contents quite close to that of the indoor air throughout the year. A lag of a couple of days was detected.

Temperature indexes ( $f_{Rsi}$ ) were calculated from surface temperatures to assess mould and condensate risk on the wall surface. The worst situation was detected at wall-floor intersection ( $f_{Rsi} = 0.79$ ) and at concrete bond beam ( $f_{Rsi} = 0.83$ ). None of those results should indicate a risk, however, as indoor moisture load was low.  $f_{Rsi}$  values at the rest of the intersections were also considerably higher (i.e. safer).

Average heat flux and temperature data from 1. Nov. 2015... 29. Feb. 2016 was used to calculate the thermal transmittances ( $U$ ) of the insulated wall (see Figure 1 for placement of the sensors). At tie bricks (HFP2)  $U = 0.52 \text{ W/(m}^2\cdot\text{K)}$  was measured and between tie bricks (HFP1) the value was  $U = 0.31 \text{ W/(m}^2\cdot\text{K)}$ . 2D thermal transfer modelling of the insulated structure results in average thermal transmittance of  $U = 0.39 \text{ W/(m}^2\cdot\text{K)}$ , which is  $\sim 3$ -fold reduction compared to the uninsulated case ( $U = 1.14 \text{ W/(m}^2\cdot\text{K)}$ ).

### Calibration of HAM models

Results from the models which achieved the best fit and positions that are most relevant to the assessment criteria are presented here. Figure 3 shows data from TRH2 (between CaSi and tie brick) and TRH4 (between CaSi concrete bond beam). Relative humidity is given as it integrates the errors in thermal and moisture calculations.

Agreement of calculated and measured temperatures (TRH3 2D model; TRH4 1D model) was within  $\pm 1^\circ\text{C}$  for most of the year with overestimation of temperatures by  $2\ldots 3^\circ\text{C}$  taking place in summer (possibly due to deficiencies in solar modelling of the south facing wall). TRH3 1D model exhibits too low temperatures which results in higher than measured  $RH$ . Modelled  $RH$  values exhibit less fluctuation in all cases, however, that seems to be the characteristic of the Delphin program (Klöße et al. 2015; Klöße & Kalamees 2016; Klöße et al. 2017). 24h avg. heat fluxes in masonry section achieved less than  $\pm 1 \text{ W/m}^2$  ( $\sim 5\ldots 10\%$ ) difference for most of the heating period using 2D model; in case of 1D models, the errors were 4...8 times higher. Possible sources of errors could be: material data (limestone as location specific and inhomogeneous material; only basic parameters were measured for brick), unknowns concerning the actual wall structure, wind driven rain modelling, solar radiation modelling.

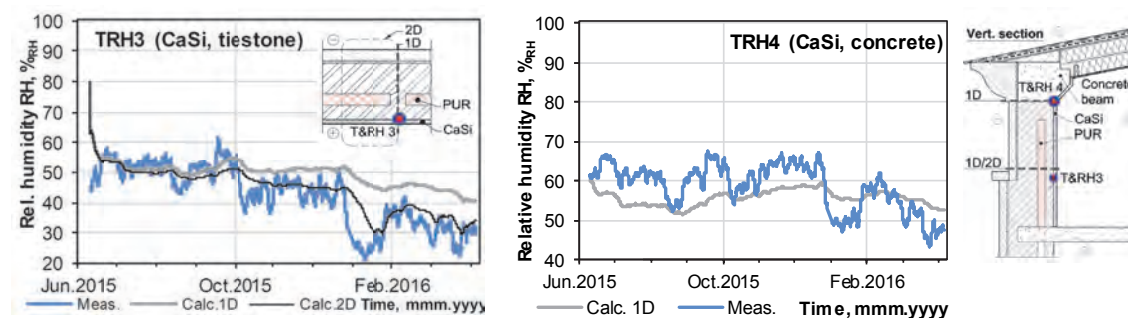

Figure 3. Comparison of measured and modelled relative humidities at TRH3 (between CaSi and tie brick; left) and TRH4 (CaSi insulation on top of concrete; right).

The correlation between measurements and modelling was deemed satisfactory. For performance assessment of CaSi insulation the 1D model of the masonry section might be good enough as the errors on that part were conservative. However, as wind driven rain could cause accumulation of moisture in the exterior masonry leaf, 2D model is also necessary.

### Modelling with 42-year weather data

Due to limited space only the most critical point in the wall (TRH4 behind CaSi on concrete bond beam) is discussed here. Modelled  $t$  &  $RH$  values are given in Figure 4. Yearly minimum temperatures and maximum relative humidities are shown so the most critical year can be highlighted. In the case of TRH4, the 1986/1987 season was the harshest and is shown in Figure 4 (right). Yearly maximum relative humidities are much more stable than temperatures. “Flattening” the peaks of the RH graphs is possibly due to relatively high moisture capacity and redistribution of moisture in both concrete and CaSi.

Figure 4 also illustrates that 42-year modelled  $t$  &  $RH$  are far more critical than measured values. While lower  $t$  is largely the result of colder outdoor climate, the significantly higher modelled  $RH$  are caused by using higher indoor moisture load.

During 10 out of 42 years (~24%)  $t$  behind the insulation fell below critical  $-5^{\circ}\text{C}$ . Still,  $RH$  was far below the 95% $_{RH}$  limit. Thus, according to the modelling data, frost damage in insulation system will not be a problem and the solution could be approved for use in the rest of the building. However, as previous research (Binder et al. 2013; Klöšeko et al. 2017) has shown, the modelling results of “capillary active” materials can also be non-conservatively skewed, especially when higher moisture contents are concerned and values are closer to the performance limits. To overcome that, development of improved liquid and vapour conductivity curves for CaSi as well measurements of limestone and brick properties are in progress.

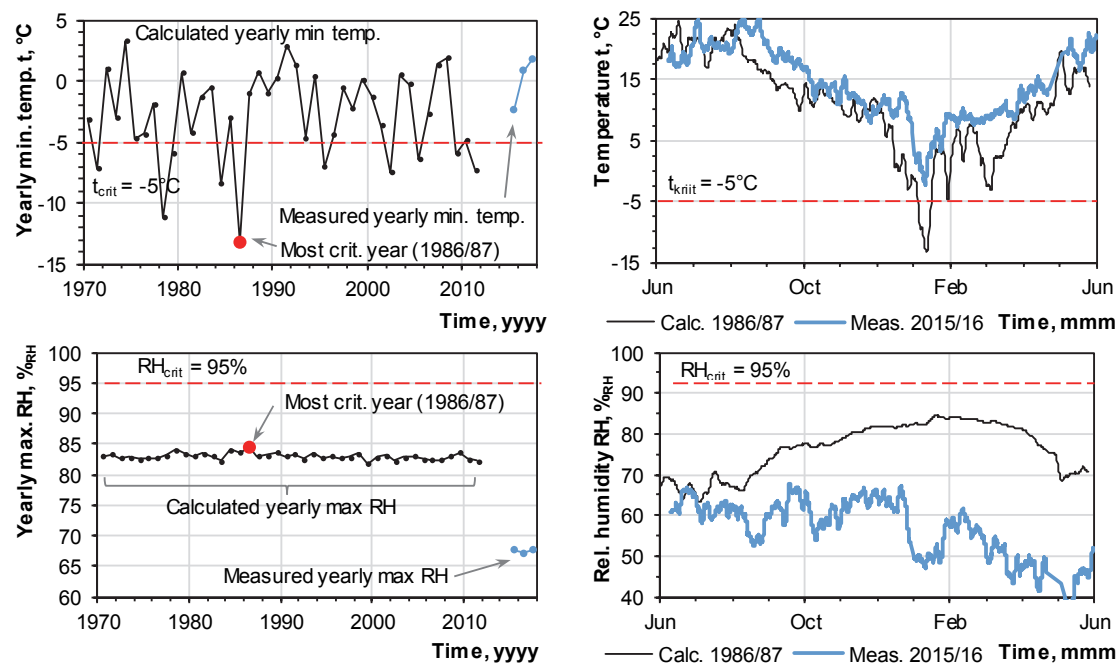

Figure 4. Most critical point in the wall (TRH4 – betw. CaSi insulation and concrete beam): yearly min. temperatures (top left) and max. rel. humidities (bottom left) of the 42-year HAM modelling and hourly values for the most critical year (right) compared to the measured values.

## CONCLUSIONS

Measurements show that interior insulation can perform well at least if HVAC systems function nominally. Wind driven rain did not cause a notable accumulation of moisture on the exterior side of “vapour tight” PUR foam. Comparison of modelled and measured data shows that 2D modelling should be used for this type of structure. If interior insulation layers are thin, the HAM models can still fairly adequately portray the processes behind the insulation even if detailed material data for existing wall is unavailable.

Modelling results suggest that even in the case of increased moisture load, the CaSi boards are quite a robust solution and provide an extra layer of safety thanks to quite high moisture capacity and lack of biological decay. Modelling with long-term weather data gives an increased confidence in the results. For example, if test reference years are used, the principle of their selection might not always match that of the current modelling aim. Also, the measured data was far on non-conservative side compared to 42-year modelling results, partly due to current winters being quite mild. To test an experimental structure in more critical boundary conditions, modelling with historic data and calibrated model can be a viable option.

## ACKNOWLEDGEMENT

This research was supported by the Estonian Centre of Excellence in Zero Energy and Resource Efficient Smart Buildings and Districts, ZEBE, grant TK146 funded by the European Regional Development Fund, and by the Estonian Research Council, with Institutional research funding grant IUT1–15 “Nearly-zero energy solutions and their implementation on deep renovation of buildings”. The authors wish to thank Tallinn City Government for fruitful collaboration and Estonian Weather Service for providing the weather data.

### ABSTRACT

Light is a key element of our world's beauty. Chinese scholar Wu Shuoxian put forward the concept of "Lightscape", and proposed its research as a parallel discipline of the "Soundscape". As a special aspect of the visual-scape, lightscape can give us a comprehensive and multi-disciplinary perspective of living environment. Many traditional lightscape cases have always been remembered as the representations of specific regional cultures. This article presents several cases of modern lightscape created with new technologies and methods. Included in these cases are: outstanding lightscape and art installments created by artists using light as a key element and fulfilled with the help of new materials; preservation of nostalgia by transforming and flourishing the traditional lightscape; multidisciplinary cooperation where artists, scientists and engineers use digital technology and biology knowledge to create intriguing lightscape.

### KEYWORDS

Lightscape Lighting technology creation

### INTRODUCTION

The concept of lightscape, put forward by the Chinese scholar Wu Shuoxian as a special aspect of visual-scape, refers to the special visual-scape that utilizes light source, shadow and their transformations to form landscape and to invoke strong visual impression. We advocate it as a parallel discipline of "soundscape" and "smellscape", so that it can play an important role in inheriting human culture and creating a human habitation for a better living (Wu Shuoxian, 2017).

Since antiquity, the significance of light has gone beyond the practical level of delivering information. As a unique aspect of visual-spect, lightscape has specific records and meanings in various cultures. Historically, there was appreciation of the natural lightscape as well as the description of artificial light-based scenery. For instance, in China, the torch festival in minority areas is originated from primitive times ceremonies where the laboring people commemorated the harvest. The Lantern Festival, began at Han Dynasty, celebrates the first full moon night of the New Year. actually, the whole human-world has been creating wonderful lightscapes for thousands of years. This paper aims to tell that, with the help of new technology and its application, creative artificial lightscape will emerges constantly.

### 1. NEW LIGHTSCAPES AROUND THE WORLD

Human's beauty-love instinct is global. Civilization has been given new connotation by the developing science. Wonderful lightscape works supported by new technologies amaze people all over the world.

picture taken from:  
<http://www.nipic.com>

### 1.1 Breathtaking light shows

There are light shows coming forward in well-known cities and famous scenic spots around the world. Compared to traditional performance, those emphasize more on the combination of light, shadow and other medias, with the addition of various means including music and installation art, to give a comprehensive sensory experience to live audiences.

**Light and Sound Show of the Pyramids** The Light and Sound Show in the Giza region, Egypt, uses dramatic narration means to present the tales of pyramids, the sphinx and influential persons. During the show, lasers are projected on the pyramids to form the shapes of inner structures, along with explanations. Accompanied by a mysterious voice that seems to come from ancient times, lights are cast on the pyramids making diversiform shadows. This hour-long show tells the story of ancient pharaohs in such a vivid way, that the audiences indulge in it as if they have taken an journey through the time.

**Dame de Cœur of Notre-Dame De Paris** To mark the centenary of the end of the first world war, Notre-Dame De Paris dedicated the "Dame DE Coeur" 3D sound and light show directed by Bruno Seillier in November 11, 2017. In virtue of the touching story of a soldier and a nurse, history had a dialogue with art across the time. The magnificent and eye-dazzling 850-year-old Notre Dame cathedral was granted a full-bodied sense of technology. The frontal lines, the sculptures on the exterior wall and projections were fused with each other. Classic paintings joint performance of firework were all exhibited in 3D perspective.

Fig.2 light show, Notre-Dame De Paris,

Fig.3 Artwork, Guggenheim Museum Bilbao  
picture taken from:  
<https://www.theguardian.com>

**Artwork of Guggenheim Museum Bilbao** On October 2017, Guggenheim Museum Bilbao created a 20-minute public artwork for the 20th anniversary of Frank Gehry's architectural masterpiece in Spain. This artwork combining light, music and projection were played on a loop across four evenings. 59 Productions, the world leader in projection-mapping, was commissioned to produce a 20-minute public artwork called Reflections. This special anniversary program celebrated the role this museum has been playing in making Bilbao and the Basque region a thriving artistic centre.

### 1.2 Famous light festivals around the world

**Lyon Festival of Lights** The Lyon Festival of Lights, held on December and usually lasts for four days, is a centuries-old religious tradition where people use candlelight to express gratitude toward gods.

Today, the festival does still retain the art form of candlelight: every house still places candles along the outsides of all the windows to produce the spectacular ambience throughout the streets; a romantic candle show is held in Odeon of Lyon every year. On the other hand, it also integrates modern lightscape that sparkles in this old city: there are contemporary lighting artworks in the center and dozens of other places on the periphery, where sound, light, electricity, lasers and 3D special effects are widely used. The whole city is checkered with light and shades, attracting artists from France and all over the globe to show their talent here. Among pieces of

Fig.4 Lyon Festival of Lights  
picture taken from:  
<http://www.sohu.com>

art equipment, we can find some amazing works of traditional culture, such as the elegant colored drawing LUMIÈRE DE VERRE, Homer's epic Odysseus, were expressed using modern techniques. A astonishing and modern light and sound show is staged annually in the front of the gothic cathedral Saint-Jean Baptiste.

In Lyon, traditional and modern lightscape coexist ideally in harmony.

**Vivid Sydney Light Festival** Vivid Sydney light festival, started in 2009 as the smart light festival which promoted energy conservation , has become a famous stage for universal creativity competition. During the 3 weeks from May to mid-June every year, there are tens to hundreds of exhibitions and events, including lighting sculpture, multimedia interactive works, as well as the show of water, fog, light and shadow. Most astonishing among those are the projections of landmark, including the eye-catching super light show of Sydney Opera. In Vivid Sydney, the public are guided to communicate and have a discussion on art, where they have sufficient chances to interact with unique lighting technology.

So much unprecedented lightscape has been created thanks to technology development; in correspondence, unique lightscape also shortens the distance between those technologies and human.

## 2. NEW LIGHTSCAPES IN CHINA

As China grows in economy, science and technology, there have been many high-profile events held in China in recent years, including G20, Fortune Global Forum 2017 and other worldwide theme activities. Guangzhou International Light Festival has been held annually for 7 years, and in 2015 was selected to International Year of Light large-scale cultural event by UNESCO(United Nations Educational, Scientific and Cultural Organization), with a special recommendation on the website of International Year of Light.

### 2.1 Group of 20, 2016, Hangzhou, China.

On October 2016, Hangzhou city undertook the G20 conference. Hangzhou, located in East China, is the most beautiful landscape city of China with the world-renowned west lake scenic spot. Zhang Yimou, the chief director of the opening ceremony of 2008 Beijing Olympic Games, directed a overwater artistic performance "Enduring Memories of Hangzhou" for G20, in which the application and effect of high-tech light and shadow was unprecedented. With the stage set 3cm under water, the traditional atmosphere “glistening wave and reflective water” of Chinese gardens was best portrayed. The show used the Pepper's ghost holographic projection technology to integrate images into the show harmoniously, where the performers were even able to interact with the lights. It was hard to tell the authenticity of bridges, lotus pond and pavilions in the view of natural lake, trees and mountain; the combination of light, music, scenery and performances brought audiences into the wonderland of Chinese classical landscape beauty.

**Swan Lake ballet on water** On the west lake, graceful dancers performed the classic ballet Swan Lake while shuttling through the milky way of an ancient bridge. This program uses holographic projection where real actors and virtual images interacted and completed the performance together. One of the most breath-taking scenes was: under the arched light bridge between landscape, a little swan appeared gracefully. After

Fig.6 Swan Lake ballet on water  
picture taken from:  
<http://www.wekeywu.com>

several challenging rotations, it split into 2 little swan, then 4, then 8... Suddenly, a group of swan girls magically appeared, and danced lightly, unanimously and gorgeously.

**Piano playing “Clair de lune”** Moonlight has always been an important part of the west lake scenery, evidenced by the natural lightscapes "Autumn Moon over the Calm Lake" and "Three Pools Mirroring the Moon". The performance combined the moonlight with the piano piece "Clair de lune", one of the most well-known works by French composer Debussy. When the smooth and stretched music was played craftily by the pianist, LED lights shaped the poetic hazy background atmosphere. The holographic projection of the moon entwined with the reflection of the moon in the water, coupled with the distant picturesque nightscape, composed a modern view of the west lake lunarscape.

picture taken from:

<http://www.xinhuanet.com>

**Play "A Beautiful Love Story"** "The Butterfly Lovers" is one of the four folk love story in ancient China, which tells the tragedy of a pair of young lovers who fell in love with each other but could not stay together, and reputedly they turned into two concomitant butterflies in their deaths. The play "A Beautiful Love Story" is based on this myth. On the performance, when two dancers danced to the waves like two chromatic butterflies flying to the center of the stage, a huge fan was slowly unfolded from the surface of water. Then, patterns on the fan transforms continually between various elements of traditional Chinese realistic painting including peony, orchid, peacock, blue and white porcelain, landscape and human characters. As the story continues, the face rotated tridimensionally following the rhythm of music until the last note gradually faded away. Finally, the giant fan submerged into the water and the lake returned to calmness.

The fan is a traditional Chinese handicraft as well as a special local product in Hangzhou. This special mechanical folding fan, believed to govern a representative temperament of Hangzhou, measures up to 20m in diameter with a total weight of 20 tons. When spread out, the fan becomes a upright screen for well-designed 3D video to project on using 3D mapping. When it is furled, it is hidden underwater. The opening and closing of the fan have achieved precise synchronization with the live music, the video projection and dance tempo of the dancers in the performance.

## 2.2. Guangzhou International Lighting Festival

Guangzhou is a diversified southern metropolis. Over 2200 years of history blesses it with a deep traditional culture as well as opening, innovative and inclusive temper.

Beginning in 2011, at the end of every year, the Guangzhou International Lighting Festival is held at Flower City Square on the "new city axis of Guangzhou". The festival revolve around different themes each year and each has its own merits; for example, in 2015, representatives from Lyon, Sydney and Singapore were invited to communicate in present, and the 3D projection work "Illusion", which had shined on Vivid Sydney, was on display, while "People Screen" connected Perth in Australia with Guangzhou via internet.

The lighting festival has now become a tourist interest in Guangzhou. The 2017 Guangzhou Lighting Festival lasted for 24 day, had served more than 8 million people; moreover, the original artwork "Rain Beating Plantain" will visit Guangzhou's sister city Lyon for its lighting festival.

## 3D Print Work: Butterfly-changing Canton, 2016

The annotation of metamorphosis in Chinese represents a striking change towards perfection, similar to the rapid transformation of a pupa into an butterfly. At the main venue of 2016 Guangzhou International Light Festival, two gaudily-dressed "butterflies" perched on the side pool of Guangzhou Grand Theatre, contrasting with the streamlined main building of the very

Fig.9 The Butterfly-changing Canton, picture taken from: <http://itbbs.pconline.com.cn>

dynamic Theatre. To demonstrate the connotation of another butterfly-changing of Guangzhou city as the capital of commerce for thousands years. This work is actually an experiment in the field of architecture, as a bold attempt combining 3D printing technology and architectural digital design. The big "butterfly" span up to 6.6m and is 12 meters long, with only two supporting points, but the body part is only 3.8 cm thick. Its irregular hyperbolic form and texture are like the microscopic veins of the leaves. The entire set of the thin shell weighs 500 kg and was assembled from nearly a thousand units printed by 50 3D printers.

**"Rain Beating Plantain", 2017** Canton music is one of the traditional Chinese local musics, and "Rain Beating Plantain" is the most representative and well known. Plantain, also known as Chinese banana, is a common native plant in Guangdong. 《The artistic lightscape installation "Rain Beating Plantain" involves environmental elements that frequently appear in Canton music such as plantain, moonlight, mini bridges, lotus leaves and colorful cloud, with the virtual rain scene to strengthen austral atmosphere, all created with light. The main artwork is formed with LED light source; the light outlines shape of plantain leaves and their venation. The moon in the background is made up of LED light pixels, which projects changeable clouds, and the luminance changes following the rhythm of the background music. As a gesture of friendly communication, this lightscape artwork is going to attend the festival of Lyon. There will be interactive factors added at the time, making the production more interesting.

Fig.10 "Rain Beating Plantain" picture taken from: <https://mp.weixin.qq.com>

### 2.3 Fortune Global Forum 2017, Guangzhou, China.

Fortune Global Forum is one of the most influential financial forums in the world, and the vibrant city Guangzhou was chosen to host it in 2017. More than 1000 business leaders, politician and economists attended.

**Drone Formation Performance** In the evening of December 7th, a welcome cocktail party was held in Canton Tower, while 1180 unmanned aerial vehicles flew over the Pearl River, performing a 8 minute technological dance. First, the drones formed the Chinese character "财富", which means "Fortune", and then changed to "FGF". Then, the formation transformed into different patterns, in the order of ship (Since Guangzhou is an old port city), the Chinese character "开放", "创新" which means correspondingly "open" and "innovation", English letters "I LOVE GZ", and last but not least the map of China, which marked the end of the show. Only 1 computer was needed to control the total of 1180 flying drones, and the error tolerance of precise positioning was 2cm. The lighting sets carried on the drones can create 60 thousand kinds of color, and change intensity as freely as

Fig.11 the drones formed the Chinese character "财富" picture taken from: <http://gd.people.com.cn>

breathing lights, which means designers can construct almost any pattern as they wish.

**River Bank Animation Show** Guangzhou is close to the South China Sea. It has been the departure port of Ancient Maritime Silk Road, and was the only port open to the overseas merchants in Qing dynasty. As the Pearl River flows from west to east across the urban area of the city, the beautiful scenery on both sides is an important tourist resource of this city with intriguing history and culture.

During the 2017 Fortune Global Forum, guests took a cruise along the "Pearl River Night Tour" route to enjoy the lightscape animation that was shown on continuous facades of the 24 buildings on the north shore. The animation called "Stories of Guangzhou" is ten minutes long, divided into two parts. The first part, called

Fig.13 cars play in the water  
picture taken  
from: <http://s.dianping.com>

"Southland Pearl, Thousand Years", depicts the prosperity of the ancient "Maritime Silk Road"; the second part, called "Amorous City of Lingnan", shows the traditional culture of porcelain, jade, tea culture, spices, embroidery, food culture, as well as characteristic Lingnan elements such as gardens, fruits, kapok, carp and lotus pond. This work utilized 210 thousand efficient LED lamps, which were coordinately controlled on the big data platform. The installation lasted for four months, involved the cooperation of as many as 1500 construction workers, including 500 steeplejacks.

from: <http://news.sina.com.cn>

## EPILOGUE

This paper shows some light-works closely related to our life. Modern scientific and technological means can both create unprecedented lightscape and give traditional lightscape vitality, enabling its survival and further development. We wish, with the support of modern technology, designers would use more lightscape, soundscape, smellscape, and allow their combination with other forms of art, and more brilliant buildings, gardens and cities would turn up.

## **Optical Performance of Polycarbonate Multi-Wall Panels in the form of Transparent Insulation Based on Long-Term Outdoor Measurements**

Miroslav Čekon<sup>1,\*</sup>

<sup>1</sup>Brno University of Technology, Brno, Czechia

*\*Corresponding email: cekon.m@fce.vutbr.cz*

### **ABSTRACT**

Buildings are subject to strongly time variable solar radiation impacts, which are phenomena that typically occur at a characteristic timescale resolution. Recent technologies and advances which are currently being used to produce polycarbonate-based materials may be used in applications where it is useful to activate the solar transmittance functions of building envelopes. In general, systems utilizing polycarbonate as a type of transparent insulation material exhibit the thermal performance of standard glazing systems. This study is focused on the optical characterization of several polycarbonate panels for buildings that are based on different numbers of chambers and differing geometries. The optical performance was analyzed in order to monitor the long-term solar properties of polycarbonate panels, by means of outdoor measurements in order to demonstrate the impact of year-round aspects on solar transmittance. This represented a specific methodical approach incorporating real full-scale components. Finally, the solar transmittance is evaluated with regard to the various outdoor time scales (hourly/daily, monthly and year-round). The studied multi-wall polycarbonate panels indicate that they may have very specific characterization from the solar transmittance perspective regarding the solar radiation that penetrates throughout their internal structure. The solar transmittance of polycarbonates, to which the timescales of the outdoor conditions respond, may significantly vary. Overall, the differences in total solar transmittance for laboratory, declared and outdoor test methods are very obvious; they differ by tens of percent. The study provides an initial insight into the optical behaviour of polycarbonate multi-wall panels and a very large set of data in order to make careful use of these parameters concerning their specificity and time dependent characteristics in thermal analysis of building integration.

### **KEYWORDS**

Transparent insulation, Polycarbonate system, Outdoor testing, Solar transmittance

### **INTRODUCTION**

Transparent Insulation Materials (TIMs) (Kaushika and Sumathy 2003) have the potential to be predominantly used in current concepts that are being put forward in an attempt to replace conventional insulating materials. However, their involvement in the building envelope is specific and so their application in building practice is currently rather rare. Several early studies described the benefits, disadvantages and options for the application of TIMs in the 1990's (e.g. Braun et al. 1992). Nevertheless, they are generally too expensive, though many cheaper materials have been diffusing such as polycarbonate sheets and panels. This represents one approach involving TIMs, which may be applied either directly as a transparent part of the building envelope, or as a part of potential solar façade concepts to obtain both transparency and thermal insulation. Various types have already been developed with different numbers of chambers and differing geometries. This development is specifically concerned with improvements from the thermal aspect. Furthermore, there could be potential in the development of polycarbonates regarding their optimal optical performance and

selective properties. Hence it is necessary to analyze in detail data for the materials which are already available, and their optical variation needs to be investigated from the spectral, angular and real outdoor perspectives. A variety of studies have been produced concerning different transparent glazing systems (e.g. Juráš et al. 2017), although some early studies aimed at measuring solar transmittance were performed on various honeycomb-type structures with an indoor solar simulator more than 25 years ago (Platzer 1992). In this relation, outdoor measurements using the sun as the source might be a good option. Overall, apart from Čekon et al (2017), there is a lack of information regarding real outdoor test in the literature dealing with solar transmittance measurements. Nevertheless, this may represent a very simple yet highly feasible way of measuring the total solar transmittance at a particular site, though Platzer (1992) pointed out that it is not an acceptable approach for Central European climates. Fundamental principles are already well implemented in the standard method of testing the solar transmittance of sheet materials using sunlight with detailed specification and procedures stated in ASTM (2015). In this relation, the key aim of this study is to investigate the optical performance of polycarbonate components that are primarily based upon multi-wall systems via real outdoor measurements. Based on the large quantity data obtained during long-term measurements, the aim of this study is to summarize these data with regard to their specificity and to provide time dependent characteristics.

## MATERIALS AND METHODS

Three different polycarbonate systems were analyzed at the year-round scale. Table 1 shows all the measured components (PC10, PC25 and PC32) and their properties. The main difference between them lies in their overall thickness and the structure of their internal chambers. The analysis employs long-term measurements performed on vertical south-east (SE) oriented full-scale components located at the AdMaS centre operated by Brno University of Technology (Čekon et al. 2016) (longitude 16°34', latitude 49°14', altitude 297.23 m). Although there are many specific issues to take into account, such as inclined angular dependence, fluctuations of solar irradiation and overall solar distribution as well as cardinal point aspect, the estimation of solar transmittance via real outdoor measurements following ASTM (2015) principles was employed. This main objective is achieved via the analysis of optical performance studies carried out at different time-scale levels. The solar transmittance is then evaluated over various outdoor timescales (hourly/daily, monthly and year-round) and a comparison with values declared by the producers is provided as well.

Table 1. Description and key parameters of polycarbonate systems

Type	Thickness [mm]	Declared $T_{decl}$ [-]	$\tau_{\lambda}$ * ASTM G 173	Measured** ASTM E1084-86	Geometry
PC10 Clear 2walls	10	0.82	0.74	0.63	
PC10* PC10 + prismatic glass	10+5	n/a	n/a	0.57	
PC25 Clear 3walls /diagonals	25	0.63	0.48	0.54	
PC32 Clear 6walls combined	32	0.53	0.43	0.53	

\* obtained based on Čekon et al. (2017b); \*\* averaged values measured over 2017

Two photodiode elements were mounted in the air cavity behind each polycarbonate sample and a third additional element was left exposed to outdoor conditions. A commercial Star Pyranometer FLA 628 S was additionally used for photodiode comparison and accuracy correlations. Diode error depends on many factors and could not be directly determined. Based on the data obtained during diode circuit calibration procedures, the maximum error could be estimated at less than +/-10% of the measured value. However, a detailed analysis was conducted in relation to the measurement of solar radiant flux using a photodiode (Čekon et al 2016), its optimization and the estimation of its correction factor during measurements

(Slávik and Čekon, 2016). Finally, the ratio between the two solar intensity rates obtained by the silicon pin photodiodes represents the solar transmittance values.

## RESULTS

As the focus on the long-term monitoring of real full-scale components is to demonstrate the annual progress of the total solar transmittance and passive solar gains of multi-wall panels, the fundamental principles of a standard test method an extraordinary mode was used. This section presents results from different timescales that depend for the purpose of evaluation on variables corresponding to hourly/daily, monthly and year-round progressions.

### Hourly/daily-based timescale

The results presented in Figure 1 and 2 cover two different measurement days during which clear sunny and total cloud cover conditions prevailed. This corresponds to a combined hourly/diurnal time scale, where the detailed influence of polycarbonate structure can be observed. For the clear sunny period shown in Figure 1a, the results are strongly hourly sensitive due to the non-homogeneity of the tested polycarbonate systems and their internal structure (Figure 1b). This factor is demonstrated by the continuous variation in solar transmittance by several tens of percent resulting in a presence of multiple internal reflection of the incoming direct beam radiation distributed over a large-scale area towards the measurement sensor. The overall inhomogeneity and sun incident angle effect, occurring in both the parallel and perpendicular partitions over each tested structure, involve strong uniformly throughout the materials. On the other hand, very stable progressions are observed during overcast conditions (Figure 2a). For both test periods, the higher the maximum level of solar intensity, the higher the daily solar transmittance obtained.

Figure 1. Measurements taken at an hourly/diurnal timescale under clear sky conditions; a) solar radiation rates measured; b) total solar transmittance derived.

Figure 2. Measurements taken at an hourly diurnal timescale under total cloud cover; a) solar radiation rates measured; b) total solar transmittance derived.

### Monthly-based timescale

The results shown in Figure 3 are an example of monthly-based result evaluation that is dependent on solar intensity rates and the relation with the angle of incidence of the sun above the horizon (altitude  $\alpha$ ). Outdoor solar intensities greater than  $60\text{W/m}^2$  obtained at the vertical level of test samples are included starting at  $135^\circ$  from the north azimuth. The results are presented using point clouds. Linear tendencies are indicated so as to generalize these strongly time variable and numerous data. In this regard, resultant linear relation is derived, and the monthly dependencies shown in Table 2 are provided for each PC panel. It should be noted that the linear functions do not represent the measured values adequately as this is first preview gained from the analyzed data; in the case of this study it provides an initial insight.

Figure 3. An example of measurements taken at a monthly-based timescale: a) the relation to the amount of total vertical solar radiation, b) the relation to the angle of incidence of the sun.

\* Sample PC10 coupled with prismatic glass

### Year-round time scale

Similarly, in Figure 4 and 5, year-round progressions are interpreted based on the same visualizations, and again linear relations are derived for each polycarbonate panel. The data obtained during year-round monitoring are divided into two presented periods. One corresponds to the first half of the year, and the other to the second half; during these two periods the maximum midday height of the sun above the horizon ranged from  $17^\circ$  to  $61^\circ$  and from  $64^\circ$  to  $17^\circ$ , respectively. In both periods, not surprisingly due to the angular aspects involved, the solar transmittance decreased with higher angles of incidence of the sun (see Figure 4). If Figure 5 is studied in detail, one can observe some angular selective functions of panel PC32 as well as PC10 combined with prismatic glass (PC10\*). In contrast, the solar transmittance increases with increasing solar intensity rates, and vice versa, a trend that really corresponds to the height of the sun above the horizon during the whole year. This means that the differences in the behavior of the full-scale samples in relation to solar conditions become higher with increasing solar intensity, and vice versa.

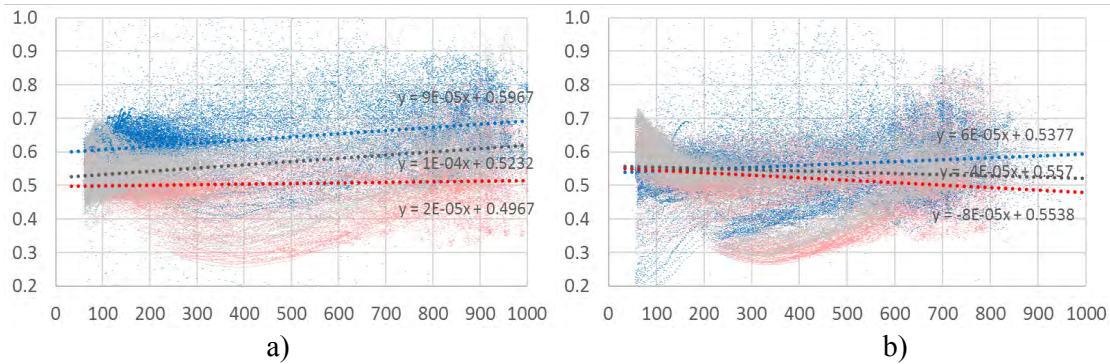

Figure 4. Measurements taken at the year-round timescale regarding the amount of total vertical solar radiation in a) the first half year before 1<sup>st</sup> June, b) the second after 1<sup>st</sup> June.

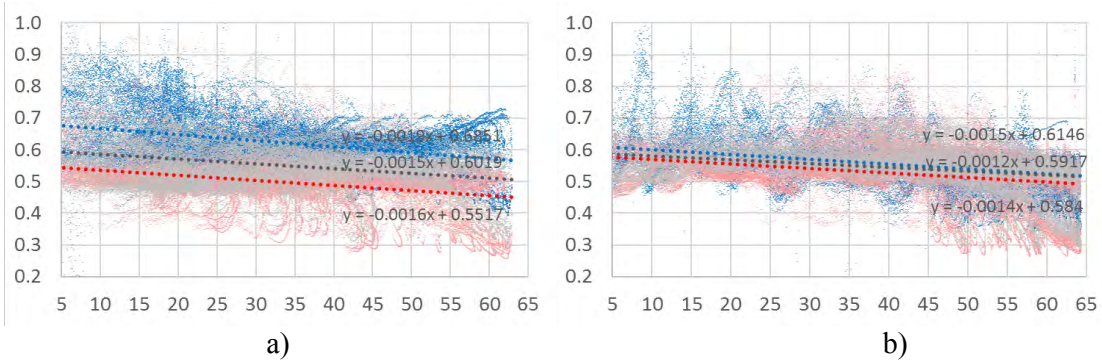

Figure 5. Measurements taken at the year-round timescale regarding the angle of incidence of the sun in a) the first half year before 1<sup>st</sup> June, b) the second half year after 1<sup>st</sup> June.

## DISCUSSIONS

Based on the results presented, it can be observed that analyzed panels exhibit time-sensitive solar transmittance parameters. Looking at the hourly and/or daily scaled values, a continuous variation in solar transmittance of several tens of percent can be clearly detected. For the presented day with a clear sky, the obtained diurnal values are in the area of 0.79 (PC10), 0.53 (PC32) and 0.63 (PC25). This principally corresponds to the declared values (see Table 1). On the other hand, looking at the detailed hourly based progressions it can be seen that strong fluctuations occurred. This contrasts with overcast conditions, under which the average daily values are approximately 0.63 (PC10), 0.44 (PC32) and 0.52 (PC25). In this case the values correspond to those measured in the laboratory. Overall, the discrepancy in lab tests are that the incoming beam radiation is distributed disproportionately throughout the tested materials in range of approx. 15 nm diameter of spectrophotometer detector, while using outdoor tests, the transmittance is averaged over a large area. As regards the real outdoor measurements during longer timescale periods, the gained data concerning the influence of different solar intensity, angular and time dependent conditions on the solar transmittance is highly variable. The values obtained regarding solar intensity rates range from 0.50 to 0.55 (PC32), from 0.52 to 0.56 (PC25), from 0.60 to 0.67 (PC10) and from 0.54 to 0.60 (PC10\*). Meanwhile, the values obtained regarding the angle of the sun above the horizon range from 0.59 to 0.49 (PC32), from 0.61 to 0.51 (PC25), from 0.68 to 0.57 (PC10) and from 0.61 to 0.52 (PC10\*). However, the prevailing values show significant movement away from a linear tendency.

## CONCLUSIONS

The paper presents the results of the long-term optical characterization of multi-wall panels utilizing co-extruded polycarbonate as a transparent insulation material (TIM). The study

evaluated the impacts of polycarbonates with different numbers of chambers and differing geometries. The experimental monitoring of full-scale components was focused on annual optical performance as a fundamental step towards understanding overall interactions influencing the solar transfer of the presented polycarbonate TIMs. Regarding the real outdoor in-situ measurements using the sun as the source, this study applied a specific methodical approach introduced by this research using long-term solar radiation rate monitoring and its evaluation with three different multi-wall panels. This indicates that the internal structures and geometry currently used to produce polycarbonate-based materials may affect the solar transmittance functions of such components. The analysis demonstrated that from this perspective, the presented panels employ selective aspects regarding the solar radiation that penetrates throughout their internal chambers. Overall, the differences in solar transmittance for all tested periods are strongly variable; they differ by tens of percent. Finally, these results may be considered in order to make careful use of the data in thermal calculation models. Further studies should be focused on the advanced statistical analysis of obtained data in order to describe their overall dependencies more adequately.

### **ABSTRACT**

Potential of recycled aggregate concrete (RAC) has already been acknowledged by many researchers, but the focus was primarily on its mechanical and durability properties at material level. If the focus is shifted to element and whole building level, then the question can be raised; how building envelopes made from RAC behave when exposed to real environment? The present paper describes an experimental set up to monitor hygrothermal behaviour of one three-storey family house built with prefabricated ventilated sandwich wall panels made from recycled concrete and recycled brick aggregate. This type of building envelope can be classified as a heavyweight envelope. In ground-floor flat a wall in the living room facing south is analysed in terms of internal temperature evolution and humidity distribution. Conditions of indoor and outdoor environment were monitored as well. Time lag and decrement of temperature extremes were observed and these benefits can be attributed to the presence of thermal mass. Ventilation of air in cavity ensured acceptable humidity level in all characteristic layers of wall panel. Summer overheating occurred due to insufficiently shaded large transparent openings. Further step is validation of numerical model and assessing the suitability of presented envelope type to different climates. This paper indicates the great potential of RAC application in energy efficient and moisture safe building envelope design.

### **KEYWORDS**

Recycled aggregate concrete, prefabricated ventilated sandwich panels, heavyweight building envelope, field monitoring, hygrothermal behaviour

### **INTRODUCTION**

Recycled aggregate concrete (RAC) has been identified as sustainable alternative to conventional concrete. Its mechanical and durability behaviour has already been widely acknowledged by many researchers (Behera et al. 2014; Fraile-Garcia et al. 2017; Marco 2014). Contrary to that, its hygrothermal behaviour as an important aspect of overall performance, has only been scarcely investigated. There are fragmented research findings on thermal and hygric properties of different types of RAC at material level (Banjad Pečur et al. 2015; Fenollera et al. 2015; Zhu et al. 2015). Having in mind the influence that building envelope's hygrothermal behaviour has on buildings energy needs, service performance, indoor thermal comfort and air quality which is directly related to the health of occupants (Feng and Janssen 2016), obviously there is a strong need to predict hygrothermal behaviour of RAC at component and ultimately at entire building level. To establish trustworthy numerical model, experimental results are desirable for model validation. This paper investigates transient hygrothermal behaviour of ventilated heavyweight building envelope constructed with RAC prefabricated panels under real variable climate conditions and occupants' behaviour.

## DESCRIPTION OF MONITORED BUILDING AND EXPERIMENTAL SET-UP

The subject of this study is a 3-storey family house (approx. 268 m<sup>2</sup>) built within socially – supported housing program in City of Koprivnica, Republic of Croatia

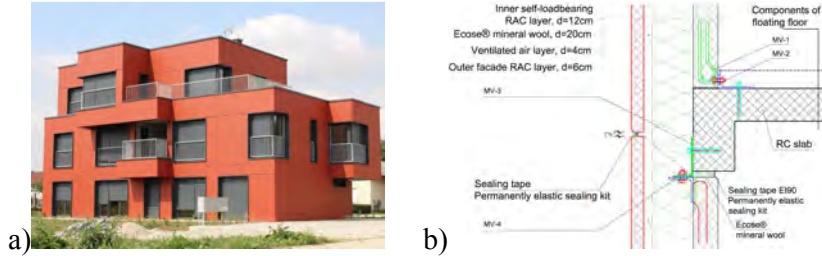

Figure 1. a) View of monitored building; b) Cross section of prefabricated ventilated RAC wall panel

Its building envelope consist of 42 cm thick prefabricated ventilated sandwich wall panels made from recycled aggregate. With surface mass of 458 kg/m<sup>2</sup>, building constructed with this type of envelope system can be classified as a heavyweight building. Based on thorough research of mechanical and durability properties (Banjad Pečur et al. 2015), replacement ratio of 50 % natural aggregate with recycled one deemed as the most favourable. As shown in Figure 1b), observed panel consists of four characteristic layers: outer RAC façade layer (6 cm), ventilated air cavity (4 cm), thermal insulation (20 cm), and inner self-loadbearing RAC layer (12 cm). The thermal transmittance of panel is approx. 0.16 W/(m<sup>2</sup>K).

For production of outer RAC façade layer (RAC-B), recycled brick from waste generated during manufacturing brick process was used, while recycled aggregate from demolition of old concrete structure was used for production of inner self-loadbearing RAC layer (RAC-C). Thermal insulation is formaldehyde-free glass wool with integrated wind barrier. Air cavity is placed between thermal insulation and outer façade layer, with aim to prevent possibility of water vapour condensation. The water-repellent coating was applied on outer façade surface. Main hygrothermal properties of target recycled aggregate concrete are shown in Table 1.

Table 1. Hygrothermal properties of RAC-C and RAC-B

	RAC-C	RAC-B
Dry density [kg/m <sup>3</sup> ]	2204.96	1948.22
Open porosity [%]	16.67	19.27
Thermal conductivity $\lambda_{dry, +10^\circ C}$ [W/(mK)]	0.944	0.745
Water vapour resistance factor $\mu$ [-]	41	28

to approx. 44% lower  $\lambda$  when concrete is used and approx. 56% when brick is used as recycled aggregate. It is suggested to use  $\mu$ -value for normal concrete as a constant value of 150. From Table 1, it can be seen that  $\mu$ -factors for RAC-C and RAC-B concrete are up to 80% lower compared to value suggested for normal concrete. This basic hygrothermal parameters indicate that more energy efficient building design can be achieved with RAC without compromising mechanical requirements – 43.3 MPa was mean cube compressive strength of RAC-C and 38.7 MPa of RAC-B, respectively.

Conventional concrete made completely with natural aggregates with a density of 2300 kg/m<sup>3</sup> has  $\lambda$ -value of approximately 1.7 W/(mK).

Replacement of 50% contributed

In ground-floor flat a wall panel in the living room facing south (marked red in Figure 2a) is analyzed in terms of internal temperature evolution and humidity distribution. Panel is 128.5×297 cm, with the first set of sensors centrally positioned 86 cm from the panel's bottom and second set of sensors 100 cm, respectively.

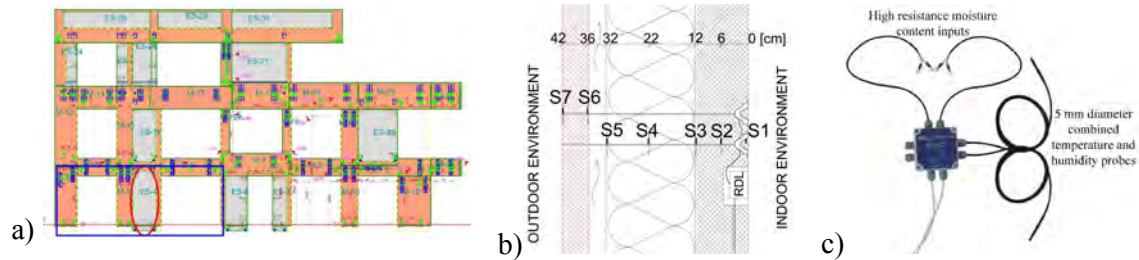

Figure 2. Measurement location: a) Position plan for southern façade; b) Arrangement of T-H sensors within panel layers; c) RDL Client-THR system

Temperature (T) and humidity (H) distribution was monitored in all four characteristic layers of presented wall panel, in total seven positions S1-S7 (Figure 2b), using the RDL Client-THR system from Caption Data Limited (Figure 2c). Installation of T-H sensors was carried out in precast factory during the moulding of panels (Figure 3). Presented monitoring system

Figure 3. Installation of T-H sensors

is a combination of wire-based and wireless measurement system. Sensors (S1-S7) at south measurement location are wired connected to

the central measurement unit in building's entrance hall, where sensors readings are recorded every hour and then sent by Internet on a dedicated server. The data can be accessed via custom Brightcore computer system. Further analysis of measured data was performed with Microsoft Excel software. Boundary conditions in terms of indoor and outdoor environment were also monitored. Indoor climate is dependent on the occupants' behaviour – young couple with small child. TFA Klimalogg Pro Thermo-Hygro-Station data logger was used for monitoring and recording the air temperature and relative humidity in living room of the house every 15 minutes. Basic meteorological data were measured every 5 min at nearest available meteorological station Herešín. These data are taken as representative for the Cfb climate of City of Kopřivnica (Köppen climate classification).

## RESULTS AND DISCUSSIONS

Period of almost one year was monitored (March 9, 2017 – February 28, 2018). In winter months outside temperature was occasionally under  $0^{\circ}\text{C}$  with peak of  $-17.3^{\circ}\text{C}$  at the end of February 2018. Five days in a row was the longest continuous period of temperature under  $0^{\circ}\text{C}$  with mean value of  $-6.6^{\circ}\text{C}$ . Max value was  $38.3^{\circ}\text{C}$  in August 2017 and its average monthly value was  $22.5^{\circ}\text{C}$ . Inside air temperature (living room) was in range from  $19.5$  to  $29.1^{\circ}\text{C}$ . It needs to be noted that in this paper humidity distribution will be presented only in terms of relative humidity (RH). Used moisture content sensors are electrical resistance-based sensors with readings in [kohm] and establishment of correlation curves for both type of RAC is still in process. Those results will be published elsewhere. Figure 4a) and 4b) show the measured T and RH values within the panel. While the exterior surface T (S7) vary in a wide range (from  $-10.8$  to  $55.4^{\circ}\text{C}$ ) following the pattern of outdoor climate, T variations through inner RAC layer (S1 – S3) are more stable and limited from  $17.18$  to max  $31^{\circ}\text{C}$ . RH sensors at positions S1 – S3 (inner RAC layer) did not send any information (Figure 4b).

Fig 4. One-year monitoring data: a) Temperature b) Relative humidity

Figure 5 presents the measured RH in the mineral wool (MW) and RAC outer facade layer for period December 1, 2017 – February 28, 2018. MW is of big interest due to its thermal insulation function, while RAC outer façade layer presents the most humid area of the panel in winter by being directly submitted to wind driven rain. Despite high outdoor RH values (above 90%), for external surface of RAC façade layer RH oscillates mostly around 60%. This can probably be attributed to the water-repellent coating.

It appears that the RH is mostly, except the few occasional peaks, under 60 % at the surface of MW layer (S5). In the middle of MW (S4), RH is almost always under 50 % and mostly fluctuating around 40% which indicates the positive effect of air ventilation in cavity. To gain a deeper understanding of hygrothermal behaviour of observed south-facing panel, monitoring results are presented hereafter for the three coldest days of the winter period (February 26-28, 2018) and the three hottest days of the summer period (August 3-5, 2017), respectively.

Figure 5. RH inside RAC outer façade and MW layer of monitored panel during winter

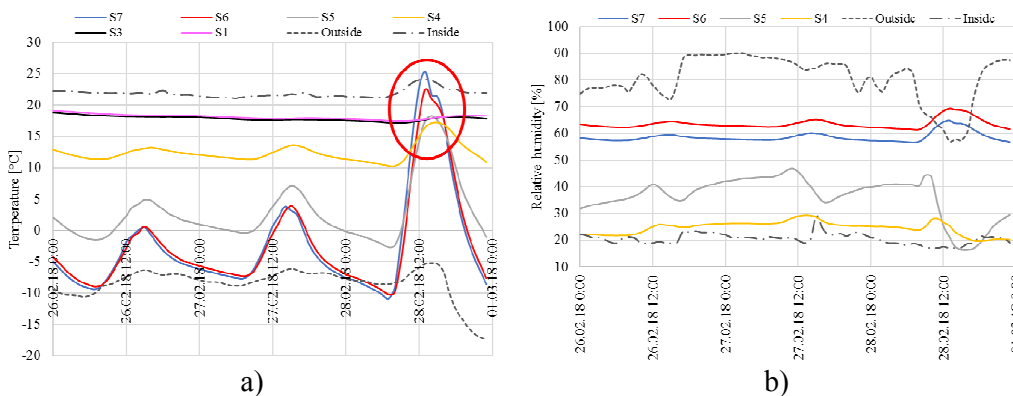

Figure 6. Hygrothermal responses within the panel for three coldest days: a) T; b) RH

Figure 7. Hygrothermal responses within the panel for three hottest days: a) T; b) RH

In February 2018, indoor air temperature varies between 21.1 – 25.5°C with a mean of 22.9 °C. Values of RH vary between 41.3 – 77 % with a mean of 58.8 %. During August 2017, indoor air temperature varies in a wider range from 29.1 – 23.7°C, with a mean of 26.2°C, while values of RH vary between 69.3 – 37.3 % with a mean of 53.3 %. The fluctuations of indoor temperature are limited by heating system (mechanical ventilation with recuperation system and radiators as additional heating system in winter but without additional cooling system in summer). The exterior surface temperature (S7) of observed south-facing panel follows the pattern of behaviour of the outdoor temperature reaching a high peak at 14:00h in summer conditions due to the solar exposure. The same pattern is followed by S6 – S4 but with decreased amplitude. Further and more progressive attenuation of T amplitude is present in S3 – S1 (inner layer). In winter period, high peak occurs on February 28 reaching 25.3°C at panel's exterior surface at 13:00h. This specific peak is most likely induced by increased solar radiation at clear winter day compared to previous days (Figure 8). Unfortunately, there was occasional interruption of measurement and some hourly solar radiation data are missing.

Besides attenuation of T amplitude, a time shift between the peaks can be observed. These appearances are due to the thermal inertia of RAC panel. Thermal inertia is evaluated in terms of time lag and attenuation of heat wave amplitude while propagating from the outer surface to the inner surface. February 27, 2018 is analysed for winter conditions and August 4-5, 2017 for summer conditions, respectively. In summer conditions, between S7 – S1 a

damping of approx. 57 % is measured. The panel attenuates the temperature very well with a time lag of 10h over a period of 25 hours. These two observations indicate that the panel has a good thermal inertia. For completely opposite boundary conditions, i.e. winter conditions, the min exterior surface temperature (-7.7°C) and min interior surface temperature (17.8°C) are analysed. In this case, time lag is approximately 6h over a period of 24 hours. High façade surface temperatures (> 50°C) in the summer indicate there may be periods of overheating that potentially could compromise thermal comfort of occupants. Living room has large transparent openings (marked blue in Figure 2a) oriented to south which ensures considerable solar heat gains. In Figure 9 coincidence of the measured psychrometric data in living room and the summer comfort zone is presented for period of June 1 to September 1, 2018. Used summer comfort limits are the ones defined for living spaces in residential buildings, Category II (HZN 2008). During summer, T and RH were in the comfort zone 57.7% of time.

Figure 8. Solar radiation data in February 2018

Actually, RH exceeds the upper threshold (60%) only 17.5% of the time, while T exhibited significant violation of upper threshold (26°C). This overheating is related to architectural design of building, where large transparent openings at south are not adequately shaded. To avoid installation of additional air-conditioning systems, application of adequate shading devices or/and external greenery should be considered. That would undoubtedly decrease operating temperatures in summer period.

Figure 9. Internal psychrometrics data vs. HRN EN 15251 summer comfort limits

## CONCLUSIONS AND FURTHER RESEARCH ACTIVITIES

The first in-situ monitoring results of family house constructed with prefabricated ventilated sandwich wall panels from recycled aggregate concrete (RAC) were analysed. Hygrothermal behaviour under real variable climate conditions and real use of occupants was experimentally monitored during one year. The south-oriented RAC panel exhibited a good thermal inertia - high damping capacity (>50 %) and time shift up to 10 hours in summer period. Air ventilation maintained relative humidity levels in mineral insulation under 60 % during winter months. Even though these results are preliminary results, they can already confirm that it is possible to upscale RAC from laboratory material experiments to full-scale construction product implementation and design sustainable, energy efficient and moisture-safe buildings. Special attention should be on preventing summer overheating. Further research steps are: i) analysis of west- and north-oriented (more shady) facades and their comparison with presented south panel; ii) numerical simulation of panels and validation with experimental results (assessing the panel's suitability for different climates); iii) continue with monitoring for at least next two years – possibility to confirm pattern of RAC's hygrothermal behaviour.

## **Review of the sky temperature and solar decomposition, and their impact on thermal modeling**

Farhad Hemmati<sup>1,\*</sup>, Fitsum Tariku<sup>2</sup>

<sup>1&2</sup>British Columbia Institute of Technology, Burnaby, BC, Canada

*\*Corresponding email: [fhemmati@my.bcit.ca](mailto:fhemmati@my.bcit.ca)*

### **ABSTRACT**

Performing accurate hourly building energy modeling requires presence of reliable boundary conditions. The required data for energy simulation model entries are exterior air temperature, exterior air relative humidity, solar radiation, sky temperature, wind velocity and cloud cover. Unfortunately, most available measured solar energy data is in the form of global horizontal radiation. Moreover, measured night sky temperature is normally not available. Proper energy modeling of a full building requires to have accurate solar radiation intensity on angled building envelope assemblies as well as precise sky temperature data available.

In this study, among several available models, three hourly horizontal global solar radiation decomposition models, four hourly diffuse radiation on inclined surface models, and five sky temperature estimation models are studied for Vancouver climate. For solar radiation validation perspective, 2013 one-year measured total solar radiation on a south-east oriented wall located at BCIT Burnaby Campus is compared with the results from selected solar models. For both solar radiation and sky temperature models, impact of using different models on transient heat transfer results of light-weight and mass-type walls (two walls) are reviewed. Results reveal high impact of both solar and sky temperature models on hourly heat transfer simulation results.

### **KEYWORDS**

Sky temperature, diffuse radiation on tilted surface, decomposition of global radiation, transient thermal simulation.

### **INTRODUCTION**

From the total energy spent in 2013 within Canada, 17% was found in residential sector, and 10% in commercial and institutional sectors (Canada, 2016). Therefore, it is important to thoroughly understand the interaction between energy consuming elements within a building, which requires hourly energy simulation. Performing an accurate hourly energy simulation requires having correct input boundary conditions available. Two important boundary conditions that could highly impact the simulation results are solar radiation and sky temperature values.

#### **Solar radiation**

Most available climatic weather data only contains global value for solar radiation, while direct and diffuse components of solar radiation as well as diffuse radiation on inclined surfaces are not always available (Burlon, et al., 1991). These three components are ultimately required to calculate the total solar radiation on a tilted surface. Many decomposition models for calculation of diffuse solar radiation are developed based on the terminology first studied by Liu & Jordan (1960). Performance of several previous solar radiation models are reviewed in this study, and results are compared with the measured data for validation purposes.

### **Sky radiation**

Measured sky radiation is not always available. Therefore, approximation models are being used to estimate the values.

There are several studies performed on sky radiation estimation. Most of the models are based on clear sky condition (Algarni & Nutter, 2015), while climates with high cloud coverage (i.e. Vancouver) require a certain correlation to account for sky condition. In this study, different models for cloudy sky temperature estimation are reviewed. Since no measured sky temperature values is available, only the impact of using different sky temperature models is reviewed on transient thermal modeling.

### **METHODS**

In this study, total of three hourly horizontal global solar radiation decomposition models, four hourly diffuse radiation on inclined surface models, and five sky temperature estimation models are reviewed.

### **Solar radiation**

The selected hourly horizontal global solar radiation decomposition models are Erbs, et al. (1982), Reindl, et al. (1990), and Orgill & Hollands (1977). Studied hourly diffuse radiation models on an inclined surface are Reindl, et al. (1990), Skartveit & Olseth (1986), Hay, (1979) and Perez, et al. (1990). These models are selected based on the climates that they have been developed based on, and extent of their use in energy modeling industry. Therefore, the combination of decomposition models and diffused radiation on tilted surface models would result in total of twelve models.

The above-mentioned models require extraterrestrial solar radiation, global solar radiation, cloud index, temperature and relative humidity, and sun position as inputs. Model inputs are imported from Engineering Climate Datasets (Government of Canada, n.d.). The model results (total of twelve combined models) are compared with 2013 one-year measured total solar radiation on a south-east oriented wall located at BCIT Burnaby Campus. Global solar radiation (Government of Canada, n.d.) is decomposed into direct and diffuse components using the selected three models. Fraction of diffuse solar components on south-east wall is then calculated using the four selected models. Lastly, results for total tilted solar radiation on south-east orientation wall (twelve models) are compared with 2013 measured data from BCIT Burnaby Campus.

In order to review the impact of different solar radiation models on hourly thermal modeling, solar radiation from different models are used to simulate the transient heat transfer in one-dimensional light-weight and mass-type walls (total of two walls). Errors caused by utilizing different models are presented.

### **Sky temperature**

In this study, selected sky emissivity models are Melchor (1982b), Clark & C. Allen (1978), Daguene (1985) (both England and Sweden), and Aubinet (1994). All these models are developed according to climates with relatively high chance of rain; therefore, they would be potential candidates for climates such as Vancouver.

The above-mentioned models require relative humidity, ambient temperature, atmospheric pressure, site elevation, sky cover and clearness index as inputs. Model inputs are imported from Engineering Climate Datasets (Government of Canada website).

Since measured data was not available for sky temperature, only impact of using different sky temperature on hourly thermal modeling is reviewed. Sky temperature results from different models are used to simulate the transient heat transfer in one-dimensional light-weight and mass-type walls (total of two walls). 2005 hourly Vancouver International Airport weather data is used for the purpose of this simulation. Deviation of the results from the reference case of “no sky temperature” is reviewed for each model.

### Simulation setup

For both solar radiation and sky temperature, light weight wall consists of ½” drywall, 5 ½” of batt insulation, ½” plywood sheathing, ½” air cavity and ½” hardie-siding, and mass-type wall consists of ½” drywall, 3” of XPS insulation and 8” concrete structural wall. Material properties are selected from 2013 ASHRAE Handbook – Fundamentals. Interior air film coefficient is assumed 8.33 W/m<sup>2</sup>K and exterior air film coefficient is assumed 33 W/m<sup>2</sup>K. No sky temperature radiation is considered for solar radiation simulation cases, and no solar radiation is considered for sky temperature simulation cases. Ground reflectivity is assumed to be 0.2 (dimensionless).

For all transient numerical simulations, COMSOL Multiphysics Modelling Software has been used. The software results are validated using the four benchmark cases from ISO 10211 (10211, 2007).

## RESULTS

### Solar radiation

Six days of hourly results for different solar radiation models on the south-east wall are provided in Figure 1. Discrepancy of results are calculated using seasonal and total Mean Absolute Error (MAE) for each model in Table 1. Figure 2 shows percentage of hourly solar radiation results corresponding to specified range of relative error, which reveals the reliability of each model.

Table 2 is provided to review the impact of different solar models on transient heat transfer simulation for light-weight and mass-type wall assemblies. This table contains seasonal and total heat transfer Normalized Mean Absolute Error (NMAE) compare with simulation results from measured solar values. The errors are normalized by dividing MAE by the average heat transfer results corresponding to measured values for the specified period of time.

## DISCUSSIONS

### Solar radiation

Table 1 and Figure 2 reveal that Erbs - Skartveit, Reindl - Skartveit and Orgill - Skartveit models result in the closest solar radiation values to measured data. Among these three models, Reindl - Skartveit model has the best performance with 42% of the results within  $\pm 10\%$  relative error, and has the lowest seasonal and total MAE (35.78 W/m<sup>2</sup>). This model also shows the least seasonal fluctuation in MAE values, which proves the stability.

Table 2 confirms the fact that Reindl - Skartveit model also results in the lowest seasonal and total NMAE (5.09% for light-weight and 4.31% for mass-type) hourly heat transfer for both light-weight and mass-type walls. Different solar models could result up to 2.26% additional discrepancy in total NMAE for the light-weight wall and 0.47% additional discrepancy in total NMAE for the mass-type wall. Similar pattern could be found for seasonal NMAE results.

### Sky temperature

Significant variation between sky temperature models' results is revealed in Figure 3, which mostly occurs during days with clear sky. Using different night sky models could result in total deviation (Table 3) in the range of 2.71% to 10.77% for light-weight wall and 6.09% to 15.33% for mass-type wall from the reference case (no sky radiation). Significant seasonal deviation is also shown in Table 3 for both light-weight and mass-type walls. This shows the great impact of utilizing different sky temperature models on transient heat transfer simulations.

## CONCLUSIONS

Several different horizontal global solar radiation decomposition models, hourly diffuse radiation on inclined surface models, and sky temperature estimation models are reviewed in this study. Solar radiation models' results are compared with one-year measured data from BCIT campus. With respect to solar radiation, combination of Reindl, et al. (1990) and Skartveit & Olseth (1986) models revealed the best result compare with measured values. Impact of using different solar radiation model on transient heat transfer modelling was reviewed, and 2.26% additional discrepancy on the light-weight wall and 0.47% on the mass-type wall were found. Using different sky radiation models could result in additional deviation of 8% in light-weight wall and 9.3% in mass-type wall compare with reference results.

Transient thermal simulation results reveal the fact that sky temperature models' estimation have more impact on total transient heat transfer compare to solar radiation models. Overall, in order to conduct an accurate building energy simulation, it is critical to diligently select the proper estimation model for both solar radiation and sky temperature if the measured values are not available.

## Roof Windows for Passive Houses – What Can Be Improved?

Jan Tywoniak<sup>1,\*</sup>, Kamil Staněk<sup>1</sup> and Vítězslav Calta<sup>1</sup>

<sup>1</sup>Czech Technical University in Prague, Czech Republic

### ABSTRACT

In general, skylights and roof windows in pitched roofs can be described as the critical components of buildings concerning heat losses, risk of surface condensation, increased risk of overheating of rooms behind etc. This is very sensible task especially for passive house solutions. The paper informs about studies analyzing the importance of these relatively small areas in the building envelope and more detailed in pitched roof of a passive house. One of the key problems is the position of roof window within the pitched roof construction.

Second part of the paper comments results of detailed analysis of thermal performance for different combination of frame type and glazing. These studies are performed hand in hand with development works. It is documented that such approach can lead to promising results, reducing the thermal transmittance of roof window to  $0.7 - 0.5 \text{ W/(m}^2\text{K)}$ . If we consider the real roof window quality including the thermal couplings due to window installation such thermal transmittance stays safely below  $0.9 \text{ W/(m}^2\text{K)}$ .

### KEYWORDS

roof window, pitched roof, thermal transmittance, passive house

### INTRODUCTION

It is known that roof windows are the weakest components of building envelope. Therefore they are quite unpopular by passive house designers. Nevertheless, they have to be used in some cases and the resulting increased heat transmission must be compensated in order to achieve the passive house criteria. The database of components certified for passive houses (PHI, 2018a) contains only 2 products (for comparison: there are 218 products of passive house suitable vertical windows in this database). The problem with roof window quality is rather complex and starts with the non-optimal position of such window in the pitched roof: Perimeters of window frames are more or less exposed to outdoor condition (Fig.1). Typically for passive houses, no heating body below the window is placed there. This can be a critical issue for avoiding the risk of surface condensation in some details. Even if the heating body would be used its temperature is controlled according to heating demand which does not guarantee the presence of warm air movement near to window surface. From both mentioned reasons only the very best roof windows should be used, carefully checked for very low thermal transmittance and for high enough surface temperature.

Figure 1. Schematic horizontal cross section of a typical position of roof window in a pitched roof. Dotted line represents the surfaces exposed to the exterior temperatures. (a typical pitched roof assembly (from interior): indoor gypsum board lining, OSB boards, mineral wool thermal insulation, protective membrane open to water vapor diffusion), b roof window (simplified): b1 glazing unit, b2 frame and sash, b3 possible additional thermal insulating shield), c roof covering)

### THERMAL TRANSMITTANCE

Thermal transmittance of the roof window installed in a pitched roof can be described in an extended way as follows (in accordance with PHI, 2018b):

$$U_{w,inst.} = \frac{A_g \cdot U_g + A_f \cdot U_f + \Sigma(\psi_g \cdot l_g) + \Sigma(\psi_w \cdot l_w)}{A_g + A_f}$$

where the  $\Sigma(\psi_w \cdot l_w)$  describes the effects of installation. It is illustrated in Fig.2 for hypothetical window of excellent quality: Assumed thermal transmittance of glazing  $0.60 \text{ W}/(\text{m}^2\text{K})$ , frame  $U_f$   $0.60 \text{ W}/(\text{m}^2\text{K})$ , thermal bridges of glazing edge expressed by linear thermal transmittance  $\psi_g$   $0.03 \text{ W}/(\text{mK})$ , thermal bridge due to installation in the roof ( $\psi_w$   $0.05 \text{ W}/(\text{mK})$ ), considering the reference window size  $1.14 \text{ m} \times 1.40 \text{ m}$ . It can be seen that for improvements of roof windows all parts are of a high importance: glazing, frame and installation method and overall geometry.

Figure 2. Result of a study for excellent roof window in typical position in pitched roof (see Fig.1). Heat transfer of window (left), heat transfer of window including installation in the pitched roof (right) based on 2D calculations for all relevant cross sections.

### IMPORTANCE OF ROOF WINDOWS IN HEAT LOSS OF BUILDING ENVELOPE

Two studies were performed to show the influence of roof window in the overall transmission heat loss of a building envelope for simple single family house. Thermal transmittances used here are based on standard requirements (CSN 73 0540-2, 2011) as well as on recommendations for passive buildings published there. First study (Fig.3, Tab.1) deals with the whole building envelope. The second one (Tab.2) is focused to pitched roof only – with or without windows, considering different thermal qualities. At the pitched roof of 140 m<sup>2</sup> for a passive house is the opaque part responsible for 77 % and the roof windows (6 pcs a 1 m<sup>2</sup>) for 23 % of heat losses respectively. This corresponds to and ¼ increase of heat losses compared to the roof without windows.

Figure 3. Distribution (%) of transmission heat loss for simple single family house with typical values needed for reaching passive house level.

Table 1. Data for case study – Effect of 6 roof windows in the building envelope.

	Thermal transmittance [W/(m <sup>2</sup> K)]	Area [m <sup>2</sup> ]
External walls	0.15	120
Windows in walls	0.8	46
Doors	1.0	2
Pitched roof	0.10	134
Roof windows (6pcs a 1m <sup>2</sup> )	0.8	6
Floor	0.25	100
Overall effect of thermal couplings between building components	+2 %	--

Table 2. Distribution of transmittance heat loss for a pitched roof of the family house with 6 roof windows. Alternative **A** corresponds to traditional solution around year 2000, alternative **B** for passive house quality roof with traditional roof windows, alternative **C** for passive house quality with high performing windows.

	Thermal transmittance	Heat transfer coefficient		Overall increase [%] (100 % = no windows)
		[W/K]	[%]	
<b>A</b>				
Roof	0.3 W/(m <sup>2</sup> K)	40.2	69	} 31
Roof windows	1.8 W/(m <sup>2</sup> K)	10.8	19

Thermal coupling by installation	0.02 W/(mK)	0.5	2	
Total		17.5	100	125

## DETAILED STUDY

A roof window in typical geometry, usual opening system (horizontal pivot casement) and typical installation in the roof was the subject of thermal analysis during our real development process (UCEEB, 2017) (Figure 5). Frame combining wood (assumed thermal conductivity 0.12 W/(mK)) and hard polymer parts (0.04 W/(mK)) together with two types of glazing (Ug 0.30 and 0.50 W/(m<sup>2</sup>K)) units were used. Installation is assumed to be carried out using thermal insulating installation frame in the roof (demonstrated here by block of extruded polystyrene thickness 100 mm) or traditionally without such additional frame. Two geometries of interior side lining are assumed: perpendicular to the window or symmetrically slanted (opened) to the interior with an angle of 45°. All data are based on 2D calculations of heat conduction for 4 typical cross sections of windows and related to the reference size 1.14 m x 1.40 m. The thermal transmittance of respective frames and linear thermal transmittance of glazing edges were calculated according to EN ISO 10 077-2. Adiabatic boundary layer was set according to EN ISO 12 567-2. The ratio of glazed area to full projected area of the window is 0.63.

Figure 5. Thermal transmittance of roof windows with the newly developed frame ( $U_f$  0.59 W/(m<sup>2</sup>K)) and two types of glazing ( $U_g$  0.30 and  $U_g$  0.50 W/(m<sup>2</sup>K) respectively). (P for perpendicular, S for slanted side lining, IMF for insulating mounted frame)

The results presented in Fig. 5 can be summarized as follows: Even with the (still un-usual) best glazing unit ( $U_g = 0.30$  W/(m<sup>2</sup>K)) and optimized window frame ( $U_f = 0.59$  W/(m<sup>2</sup>K)), the  $U$ -value of the window installed in typical configuration (P 0) is 0.72 W/(m<sup>2</sup>K). With a standard triple-glazed unit ( $U_g = 0.50$  W/(m<sup>2</sup>K)) the overall  $U$ -value rises to 0.88 W/(m<sup>2</sup>K).

The thermal coupling due to installation, which can be hardly avoided, plays a significant role in both cases ( $\psi_w \cdot l_w = 0.23$  W/(m<sup>2</sup>K)).

The additional thermal insulating frame (IMF) has effect only in combination with slanted interior lining (S), where it lowers the thermal transmittance of about 0.05 W/(m<sup>2</sup>K). The installation with slanted interior lining (S 0) has higher thermal transmittance of about 0.05 W/(m<sup>2</sup>K) compared to perpendicular case (P 0). However, this solution may still be preferable due to better distribution of daylight.

## RESULTS

The relative high influence of roof window for overall thermal transmittance was identified. In order to reach the passive house criteria the increased thermal loss even by the best possible roof windows has to be compensated. It is advantageous to combine the best glazing with a frame having the thermal transmittance in the same range. Best option seems to be the use of a high performing insulation material directly in the frame. In order to reduce the negative impact of the installation in the roof additional installation components (mounting frames) can be used or (better) the window frame itself should contain corresponding continuing thermal insulation material on its perimeter.

The geometry of side lining (widening to interior) has no significant negative influence on heat loss due to limited amount of thermal insulation there (UCEEB, 2017).

## CONCLUSION AND OUTLOOK

Consistent and complex application of building physic instruments can effectively accompany ongoing development works. All parts of future roof window should be optimized in order to achieve plausible results: Of critical importance is the frame in terms of material choice and shape. The form of installation has a big influence on the final result as well.

Based on these findings our research will continue in following directions:

- a) Developing and testing of a real solution together with industrial partner according to already performed theoretical and experimental studies (not published here). It is expected that the frames will be alternatively made of hard polymer with appropriate surface layer (high pressure laminate, veneer lumber etc.) or made of high quality wood profiles combined with hard polymer.
- b) Continuation in theoretical and experimental research concerning heat transfer at surfaces of windows in order to guarantee no condensation risk there, especially for situations without possible positive effects of heating bodies placed bellow.
- c) Continuation (UCEEB, 2017) in day-lighting experimental studies for optimum size and installation. The side lining widened to interior can support better distribution of daylight. In general, such measure can lead to sufficient daylight with smaller window areas which has an additional energy saving effect.
- d) Studies about optimum shading and estimation of overheating risks.

## ACKNOWLEDGEMENT

This work has been supported by the Ministry of Education, Youth and Sports within National Sustainability Programme I, project No. LO1605 and by Technology Agency of the Czech Republic, project No. TH01021120.

### **ABSTRACT**

Green roofs are a popular form of sustainable drainage infrastructure. They provide many environmental benefits, such as reducing peak urban stormwater runoff by enabling retention and evapotranspiration similar to natural conditions. Each green roof has unique hydrologic behavior based on physical properties of its growth medium, types of vegetation, structural design, and climate. To improve the application of green roof technology at a site, there is a need to predict stormwater mitigation for several designs before commencing green roof construction. The Storm Water Management Model (SWMM) includes a low impact development control module which makes it possible to model the hydrologic performance of a green roof by directly defining the physical characteristics of its layers. In this study we compare the outputs of the SWMM model with hydrologic performance data from a large extensive green roof in Syracuse, NY from April 2017 to October 2017. Our objectives are to evaluate the performance of SWMM as a long-term modeling software appropriate for predicting the hydrologic performance of a green roof, and to explore changing parameters that might improve hydrologic performance when designing future green roofs. It is expected that this work will help designers of green roofs in climates similar to those of Central NY. In the future, more extensive hydrologic data will be obtained to enable better assessment of SWMM as a tool to help design green roofs.

### **KEYWORDS**

Green roof, SWMM, Green roof modelling, Stormwater management, Green infrastructure

### **INTRODUCTION**

Urbanization contributes to an increase in impervious surfaces and a decrease in land area covered by soil and vegetation. This reduces ecosystem services such as infiltration and evapotranspiration, leading to an increase in urban stormwater runoff. Green infrastructure (GI), which is an important component of low impact development (LID), is being used in urban settings to restore ecosystem services. Green roofs, a form of GI, can restore ecosystem services by retaining and detaining stormwater runoff (Carson et al. 2013; Li and Babcock, 2014) and increasing urban biodiversity (Baumann, 2006; Francis and Lormier, 2011).

Monitoring studies have been conducted to understand the hydrologic performance of green roofs (Peng and Stovin, 2017). Since green roofs vary in configuration, they can range in retention and detention rates (Carson et al. 2013). Though many studies have aided in understanding green roof performance (Heusinger et al. 2018), this indicates the need for engineers to accurately forecast green roof performance through the application of modelling whenever a new green roof is built. The Storm Water Management Model (SWMM) is the most

commonly used commercial hydrologic and hydraulic model and provides a quick assessment tool for quantifying the hydrologic performance of GI (Li and Babcock 2014).

The first objective of this study is to assess the SWMM model as a tool for predicting hydrologic performance of a green roof by comparing model outputs with monitoring data from a full-scale, extensive green roof located in Syracuse, NY. The second objective is to perform a sensitivity analysis which will lead to future adjustment of the model parameters and verification. This research is still in an early phase.

## **METHODS**

### **Green Roof Test Site**

The study site is a 5550 sq. meter green roof located on the roof of the Nicholas J. Pirro Convention Center (the OnCenter) in downtown Syracuse, New York (43.04368N, 76.14824W). See Squier-Babcock and Davidson (2018) for a detailed description of the site, drainage design, and monitoring equipment.

Precipitation, runoff, and temperature data have been collected between 4/1/17 and 10/31/17 at 5-minute intervals. Common retention and detention metrics are used to quantify performance. Retention is calculated cumulatively for the entire monitoring period. For the purposes of comparison, rainfall and runoff are expressed as equivalent depth in mm.

### **EPA SWMM Model**

The EPA Storm Water Management Model (SWMM version 5.1.012) is a dynamic hydrology, hydraulic, and water quality simulation model that can be used for both single-event or continuous simulation (Rossman, 2015). The LID controls in SWMM are designed to specifically model GI, such as green roofs. The LID controls work by performing and tracking moisture balances between different vertical layers that are defined by parameters in the graphical user interface.

To model restoration of retention capacity, SWMM has five methods for calculating Potential ET (PET). In this study, following the methods of Peng and Stovin (2017), monthly PET values are calculated using the Hargreaves equation (Marasco et al. 2015) which is standard in SWMM. Note that SWMM models ET strictly as a constant proportion of PET and does not automatically account for the reduction in actual ET (AET) that occurs during moisture limited periods. The proportion can generally be used to account for crop variability or moisture limited months (Peng and Stovin, 2017). For this analysis, the proportion was initially set to 1.

The green roof is modelled in SWMM as a subcatchment that is 100% occupied by the green roof and has an outlet. The dimensions of the subcatchment are 111 m width by 50 m length since the water flow path is perpendicular to the width, which represents the actual flow path of the OnCenter roof. To test the accuracy of the ET component of the model for predicting long-term retention, SWMM is used to generate runoff for the period of 4/1/17 to 10/31/17 at an hourly temporal resolution, avoiding periods of freezing.

The long-term simulation used observed precipitation from the OnCenter green roof site. Monthly PET values were calculated with monthly temperature minimums, maximums, averages, and the geospatial location of the OnCenter. The initial green roof parameter values were estimated from field measurements by Squier and Davidson (2016), Yang and Davidson (2017), and CH2M who performed the initial modelling studies of the OnCenter green roof, and SWMM default values. The values and sources for each parameter utilized in the SWMM Bioretention Module are presented in Table 1.

Table 1. SWMM Parameters and Initial Values for Uncalibrated Simulations

Parameter	Initial Value	Data Source
<u>Subcatchment</u>		
ET coefficient	1	Default
Area	5600 m <sup>2</sup>	Squier and Davidson (2016)
Width	110.8 m	Squier and Davidson (2016)

Flow coefficient	0.075	CH2M Estimate
Flow exponent	0.5	CH2M Estimate
Offset Height	0	CH2M Estimate

### Sensitivity Analysis

To determine the parameters that would most effectively minimize the difference between observed and simulated results, a sensitivity analysis was performed using the long-term simulation results. The method suggested by Rosa et al. (2015) and Peng and Stovin (2017) was followed, where each single parameter is adjusted over a range of plus or minus 10 and 50 percent of its original value while holding the other parameter values constant. The difference in annual retention and annual runoff volume were determined for the long-term simulation. Sensitivity was calculated using Eq. (1) (Rosa et al. 2015; Peng and Stovin, 2017):

$$Sensitivity = \left( \frac{\delta R}{\delta P} \right) \left( \frac{P}{R} \right) \quad (1)$$

Where  $\delta R$  = the difference between the original and the new model output;  $\delta P$  = the difference between the original and the adjusted parameter value;  $R$  = the original model output; and  $P$  = the original value of the parameter.

### Validation

The Nash-Sutcliffe model efficiency (NSME) coefficient in Eq. 2 (Nash and Sutcliffe, 1970) was used to reflect the accuracy of the model results as compared to the collected data. An NSME value equal to 1 indicates that the model predicted the performance of the green roof

perfectly, while an NSME value greater than 0.5 is still an indication of acceptable model performance (Rosa et al. 2015, Peng and Stovin, 2017). The long-term simulation hourly results were compared in this study to determine an NSME value.

$$NSME = 1 - \left[ \frac{\sum_1^N (Q_m - Q_p)^2}{\sum_1^N (Q_m - Q_{Am})^2} \right] \quad (2)$$

where  $N$  = number of samples;  $Q_m$  = runoff observed;  $Q_p$  = modeled runoff; and  $Q_{Am}$  = mean observed runoff.

In the future continuation of this work, single events will be modelled and evaluated with NSME. The subsequent NSME values from this study and future studies will lead to evaluation of the model.

## RESULTS

### Uncalibrated Long-Term Simulations

Long-term simulations run with these initial parameter values show less than ideal agreement. The cumulative runoff predicted by SWMM totaled 345 mm while the cumulative runoff collected from the green roof totaled 451 mm, or about 100 mm difference. As Figure 1 shows, the model consistently underestimates the amount of runoff compared with the observations. The value of NSME is -0.07. One possible cause of the disagreement is that SWMM may be overestimating ET; work is underway to explore the reasons for the difference. These are the very first results using SWMM with this green roof, and we expect results will improve as we continue to measure roof characteristics rather than using default values and estimates.

### Sensitivity Analysis

The results of the sensitivity analysis are presented in Table 2. The negative sensitivity values indicate a decrease in corresponding runoff volume or annual retention, while positive values indicate an increase. The total runoff volume and annual retention were found to be influenced by the ET coefficient, the soil field capacity, and the soil wilting point. The surface slope, soil porosity, soil conductivity, conductivity slope, suction head, storage void ratio, drain flow coefficient, and drain flow exponent were found to have less impact on the model results. For one run, the values were not valid because porosity cannot be smaller than field capacity. Both the annual retention and the total annual runoff were most sensitive to a change in the soil field capacity, followed by the wilting point, and then the ET coefficient. Field capacity influences the retention capacity; wilting point and ET influence retention recovery. Both retention capacity and recovery are essential contributors to annual retention performance. The importance of both ET and field capacity in green roof performance have been cited in many studies (Peng and Stovin, 2017; Cipolla et al. 2016; Stovin et al. 2013).

## DISCUSSION

The SWMM bioretention module for a green roof with a drain has the potential to be an accurate model representation. However, the initial results of consistently underestimating runoff points to the way that a green roof's storage capacity is restored – ET. The sensitivity analysis identifies the importance of ET in green roof retention, which is well supported by many studies (Stovin et al. 2013; Peng and Stovin, 2017). The use of the Hargreaves equation, a temperature-based model for ET, and the standard option in SWMM, could contribute to overestimate ET during moisture limited conditions. Further examination of alternative options for ET modeling will be explored, specifically related to energy-based models and PET verses AET, in pursuit of model simulation and observed agreement with data.

Table 2. Sensitivity of Annual Retention and Annual Runoff Volume to SWMM Bioretention Parameters Adjusted  $\pm 10\%$  and  $\pm 50\%$ 

Parameter	-50%		-10%		10%		50%	
	Annual Retention	Runoff Volume	Annual Retention	Runoff Volume	Annual Retention	Runoff Volume	Annual Retention	Runoff Volume
ET coefficient	-0.343	0.369	-0.277	0.292	0.229	-0.247	0.187	-0.202
Surface slope	0	0	0	0	0	0	0	0

Figure 1. Uncalibrated long-term simulation. NSME calculated from hourly runoff. The rainfall is given in mm for each 1 hr timestep. The runoff is given as cumulative depth in mm.

## CONCLUSIONS

The initial comparison of the results obtained from the OnCenter green roof and the SWMM bioretention module needs further investigation before concluding that the model can represent the hydrology of a green roof. The concepts of accurate PET verses AET and antecedent dry weather period are important for green roof model representation. This study is merely a first step in validating SWMM as an accurate model for a green roof in Syracuse, NY.

## Simulation of Building Physics for Beginning Design Students

Alexander Timmer<sup>1</sup>

<sup>1</sup>University of Wisconsin – Milwaukee, Milwaukee

*\*Corresponding email: timmer@uwm.edu*

### ABSTRACT

Concepts such as heat transfer, stack effect, natural ventilation, and other problems related to building physics are taught to beginning design students through architectural examples, deterministic diagrams, and rules of thumb. Unlike the approach to teaching form, which involves exploration and iteration within a studio environment, often suspending disbelief to allow exploration, these exercises see architecture through the lenses of optimization, equilibrium, and objective outcomes. They are taught as steady state concepts. Instead of leaning on teaching techniques derived from an engineering standpoint, often technocratic and deterministic, it would serve beginning design students well to explore these concepts through experimentation and scaled built models that demonstrate the intended atmosphere effect. Can we ask the students to think compositionally about an architectural atmosphere in the way we ask them to think about form, proportion, sequence, and hierarchy? The goal then is to have students learn to think about atmosphere and energy from a design standpoint. As Kiel Moe notes, this point of view comes from an understanding of architecture and energy as one of magnificence and not of management. (Moe, 2017) With the help of students at the University of Wisconsin – Milwaukee, this research looks to explore reciprocal design techniques that allow students to iterate within an open system of their design. This ongoing investigation looks to grow the rigor and accessibility of scaled physical simulation of atmosphere and energy in buildings within a beginning design student studio.

### KEYWORDS

Buoyancy Ventilation, Simulation, Physical Models, Early Design Education, Design Process

### INTRODUCTION

This research is focused on the physical simulation of building physics. This ongoing research attempts to balance a desire for the visual representation of building physics for use in the architectural design studio with a repeatable and measurable outcome. While the primary purpose of the model is not measurement, the various inputs of heat and matter are scaled appropriately. Using the concept of similitude, this model is scaled to allow for the building of a representational section, which can then be heated to demonstrate the flow of fluid through the section. While focusing primarily on the simulation of buoyancy ventilation in two dimensions, this project develops a working methodology that encourages iteration. Students design parts within Rhino 3D, print them with a 3D printer, test them in the rheoscopic fluid bath, document them with a long exposure camera, evaluate the results and then repeat the process. This work was completed as part of an exhibition and workshop at the University of Wisconsin – Milwaukee.

### METHODS

This design exercise asked students to work through a fixed loop. Students design a section within Rhino 3D, print them with a 3D printer, test them in a rheoscopic fluid bath, document them with a long exposure camera, evaluate the results and then repeat the process. The first

step is the design of an initial section in Rhino 3D, a NURBS modelling software. Students are asked to produce sectional models in which the wall thickness is fixed at .8mm. While the first section is a guess on the student's part, the next model made will be informed by the process to come. The second step is the printing of the student's design. Students print their sections 6mm thick out of PLA plastic. For the third step students place their prints into a heated bath. The parts are pinched between a piece of glass and the milled aluminium back which heats that fluid. The medium of the bath is a rheoscopic fluid that makes the flow visible. (Figure 3) A heating element is mounted to the back of the aluminium half of the tank. After this, students document the sections with a camera, make changes to their design and repeat the process. The models were scaled using similitude and the Galileo Number. (Etheridge, 2011)

## RESULTS

Figure 1. Iterations produced by the students.

The students produced a wide range of examples. (Figure 1,2) The studies often led to a series of variations in which each student explored the role of shape, form, and proportion in the flow of fluid by buoyancy ventilation. The more successful explorations used simple forms to better understand the effects of their design decisions. While the models are essentially two dimensional, they offer a way into the process of natural ventilation from the point of view of

a designer. The work was exhibited and functioned as a workshop to introduce the students to the concept of buoyancy ventilation. (Figure 4, 5, 6)

Figure 2. Long exposure documentation of rheoscopic fluid.

Figure 3. Rheoscopic fluid tank with section.

Figure 4. Exhibition and workshop.

Figure 5. Exhibition and workshop.

## Equations

$$Ga_M \equiv \left[ \frac{\Delta T_0}{T_0} \right]_P \left[ \frac{\Delta T_0}{T_0} \right]_M Ga_P \quad (1)$$

Using dimensionless analysis similarity between the model and prototype can be achieved by increasing the  $\Delta T_0$  in the model. This equation assumes a simple single cell enclosure in which ventilation is achieved with buoyancy only. (Etheridge, 2011)

## Names and units

Ga	Galileo Number
T	Temperature, C°

## DISCUSSIONS

The most problematic aspect of these models is the lack of three dimensionality. While the two-dimensional model allows students to understand some of the basic concepts of buoyancy ventilation, it lacks the complex reality of a three-dimensional model. The appropriate application of this pedagogy to the design of a building, not merely proto architectural objects, requires more research. In general, though the next steps in this research will require a transition to three dimensions. Additionally, while this modeling technique allows for the visual approximation of heat driven flows, it does not at this time allow for the measurement of the rate of flow. Although, the appropriate scaling of the model and its heat input should allow for a measurable rate of flow through the openings by mathematical means. As mentioned before, the intended goal of this exercise is the development of a pedagogy that encourages design students to explore building physics as an opportunity for design and spatial innovation.

## CONCLUSIONS

When we think of architectural models, we think of them as objects, representational at best, a stand-in for a larger construct. While this has not always been the case historically, new digital measures seek to reduce the physical model further to merely the output of a printer: a stereotomic afterthought. Renaissance model makers, for example, used the model as a stand-in for construction documents that were intended to assist the builders with complex geometry, calculating structural loads, and testing the quality of light. These models participated in the construction of buildings. At the Bauhaus, making was integral to the introductory design exercises, asking students to fold the paper and imagine the spatial and sculptural qualities. The paper though was not a stand-in for another material but the material of study itself. With the advent of the digital model, and more recently the BIM model, the physical artifact has been pushed out. In its transformation, it has lost its material intelligence and its active role in the design process. It has been reduced to a representational artifact and an imperfect imitation of its digital doppelganger. What then is the role of the contemporary physical model, what could its role be in contemporary design practice?

These new operative artifacts find themselves between a study model and a finished representational model. They hang ambiguously between these two states. They are far from pristine, but they are highly rigorous and intensely participatory. They are objects that both represent a complete thought and speak to a possible future. These objects develop out of an understanding of design as an open system, a series of inputs and outputs, in which the model is understood as an active participant in the design process rather than passive byproduct.

### **ACKNOWLEDGEMENT**

I would like to acknowledge the students at University of Wisconsin – Milwaukee and specifically Max Rodencal who helped in the development and initial testing of this pedagogy. This ongoing research was supported through the UWM SURF Grant program.

### **ABSTRACT**

At present, the widespread existence of haze phenomenon has a serious impact on indoor air quality. Indoor particulate pollution has been paid more and more attention by the society. However, the correlation and diffusion mechanism of indoor and outdoor particulate matter are still controversial. In order to explore the correlation between indoor and outdoor particulate matter of different building types in heating season and non-heating season, the indoor and outdoor particulate concentrations and meteorological parameters of 110 stations in severe cold area of China were monitored by experiments. The analysis shows that indoor and outdoor temperature, humidity, air velocity, wind direction and atmospheric pressure are the main factors affecting indoor and outdoor particulate concentration. And based on these factors, it can model the indoor predicted particulate concentrations by multivariate regression. It also shows a significant difference in the relationship between the concentration of particulate matter and factors of indoor and outdoor particulate matter. Therefore, this study provides a good premise for exploring the health risks and control measures of particulate matter.

### **KEYWORDS**

Particulate Matter, Severe Cold Area, Correlation Analysis, Regression Model

### **INTRODUCTION**

Human inhalable particulate matter (PM<sub>10</sub>, PM<sub>2.5</sub>) is the primary pollutant in most cities in China, especially for fine particulate matter (PM<sub>2.5</sub>). More and more epidemiologists show that there is a positive correlation between human morbidity, mortality and mass concentration of particulate matter (Dockery et al. 1993; Zhao et al. 2015; Tseng et al. 2015; Cohen et al. 2017; Klemm R J et al. 1996). People spend 90% of their time indoors, so indoor air quality plays an important role in human health. The study showed that the outdoor pollution components can enter into the indoor air through natural ventilation, mechanical ventilation and infiltration ventilation. There is a significant correlation between the indoor and outdoor particles. The proportion of indoor PM<sub>2.5</sub> from outdoor is 30~75% (Dockery and Spengler, 1981; Koutrakis et al., 1992; Ozkaynak et al. 1995; Xiong et al. 2004).

The situation of indoor and outdoor particulate matter in severe cold area of China is different from that in other regions because of geographical location, climatic condition and building type. This paper will via the long-term monitoring of indoor and outdoor particulate concentrations to analyze the correlation between indoor particles concentrations and indoor and outdoor influencing factors of different building types in Daqing, which will provide parameters and basis for indoor particulate matter exposure assessment.

## METHODS

### Selection of measured objects and sampling points

The sampling points were located in five districts of Daqing which were total of 110 sampling points, including 30 classrooms, 30 offices and 50 residences, among which were divided into urban and rural residences. To get the seasonal variations of particulate pollution, we collected data of summer and winter from November 2016 to April 2017 and June to August 2016, respectively. A sampling point was sited in and out of each room, measured simultaneously. Each point was collected seven days of valid data. To analyze more accurately, the hourly average value of each sampling point was calculated. The measuring instrument includes QT50 particulate online monitor ( $\pm 1 \mu\text{g}/\text{m}^3$ ). The measurements contents include indoor and outdoor temperature, relative humidity and  $\text{PM}_{2.5}$  mass concentration. The monitoring time was set to start every 15 minutes, and the data were collected for 5 minutes each time.

### Data analysis and processing method

In this paper, the analysis data is mainly based on the hourly average of each parameter. With the SPSS software, the statistical analysis of sampling data was completed, and finished the multiple analysis such as bivariate correlation analysis and multiple linear regression.

Bivariate correlation analysis is an important method to evaluate the relationship between two of variables. Pearson coefficient ( $r$ ) could measure the extent of correlations, which could be expressed as:

$$r = \frac{\sum (X - \bar{X})(Y - \bar{Y})}{\sqrt{(\sum (X - \bar{X})^2)(\sum (Y - \bar{Y})^2)}} \quad (1)$$

Where  $X$  and  $Y$  - variables,  $\bar{X}$  and  $\bar{Y}$  - the averages of variables. In this part, Pearson coefficient ( $r$ ) is used to express the relationship between indoor particulate concentration and indoor and outdoor influencing factors (such as outdoor particulate concentration, temperature and humidity, etc.).

Multivariate linear regression is a regression with one dependent variable and two or more independent variables, each of which is a single term. It is one of the most commonly used statistical methods in the measurement of microenvironment or exposure of particulate matter. The mathematical model of multivariate linear regression can be expressed as follows:

$$y = a + b_1x_1 + b_2x_2 + \cdots + b_nx_n \quad (2)$$

Where,  $y$  is a dependent variable;  $x_1, x_2 \dots x_n$  are independent variables;  $b_1, b_2 \dots b_n$  are coefficients of independence variables;  $a$  is a constant term. To ensure the accuracy of the regression model, the errors between the observed and predicted values of five performance

indexes are used in this paper: the normalized absolute error (NAE), the root mean square error (RMSE), the prediction accuracy (PA), the determinant coefficient ( $R^2$ ) and the index of agreement (IA).

## RESULTS AND DISCUSSIONS

### Correlation Analysis between Indoor PM<sub>2.5</sub> concentration and factors

There are many factors affecting indoor particulate concentration, such as indoor particulate source strength, settling rate, air exchanges rate, penetration coefficient, building types and meteorological conditions. The results show that there is a certain relationship between indoor particulate concentration and them above, while little attention has been paid to this aspect in the present researches. By the method of bivariate analysis, Pearson correlation coefficient ( $r$ ) was used to express the extent of the linear correlation between the indoor particulate concentration and these factors. The probability distribution value ( $P < 0.05$ ) was considered to be statistically significant.

Table 1. The correlation analysis between indoor PM<sub>2.5</sub> concentration and affecting factors

Note:  $r$ -Correlation,  $P$ -Significance,  $N$ -Sampling times,  $T$ -Temperature,  $RH$ -Relative humidity,  $P$ -Atmospheric pressure,  $WD$ -Wind direction,  $WS$ -Wind speed

Table 1 compares the correlation analysis between indoor PM<sub>2.5</sub> concentration and indoor and outdoor factors of four building types in summer and winter, statistics of which have significant correlation has been bold. On the whole, it can be found that outdoor PM<sub>2.5</sub> concentration has the strongest correlation with indoor PM<sub>2.5</sub> whether it is summer or winter. Indoor PM<sub>2.5</sub> concentration is positively correlated with indoor and outdoor temperature, humidity and outdoor wind speed, negatively correlated with outdoor atmospheric pressure, and both positively and negatively correlated with outdoor wind direction. However, all these factors are significantly related to indoor particulate concentration for summer. For winter, the main factor of indoor PM<sub>2.5</sub> concentration is outdoor particulate concentration, the influence of other factors is relatively little. The primary explanation is that the main ventilation mode of the measured buildings is natural ventilation during summer, outdoor particulate matter can enter into the indoor environment which is vulnerable to wind pressure and hot pressure. Outdoor wind speed and atmospheric pressure will affect the indoor and outdoor air exchange rate and the concentration of indoor particulate matter. For the season of winter, the indoor temperature is constant due to the use of heating equipments, which has little effect on the diffusion and transfer of particulate matter. At the meanwhile, doors and windows are always closed and the impermeability of enclosure structure is well, the change of outdoor atmospheric pressure has little effect on the permeation process of indoor particulate matter.

#### Multivariate regression model fitting

According to the correlation analysis above, it found that all the factors mentioned could affect indoor particulate concentration. Based on these factors, a multivariate linear regression model of indoor PM<sub>2.5</sub> concentration prediction was proposed. In order to ensure the reliability of the results, the data is divided into two groups, one composed of 70% of the original data for regression, and the other 30% is used to verify the regression model. Table 2 shows the regression model between indoor particulate concentration and factors of four building types in summer and winter. The simulation results are standardized to ensure the comparability among the model parameters, which can be found that the range of determining coefficient  $R^2$  obtained by calculation of four building types in summer and winter is 0.57 ~ 0.85, indicating that the model has a strong fitting.

Table 2. The regression model between indoor particulate concentrations

	Season	$R^2$	model

	Winter	0.69	$y=0.20x_1+0.06x_2+0.83x_3-0.03x_4-0.09x_5+0.11x_6-0.05x_7-0.02x_8$

Note:  $x_1$ - Indoor temperature;  $x_2$ -Indoor humidity;  $x_3$ -Outdoor PM<sub>2.5</sub> concentration;  $x_4$ -Outdoor temperature ;  $x_5$ -Outdoor humidity;  $x_6$ -Outdoor atmospheric pressure;  $x_7$ -Outdoor Wind Direction;  $x_8$ -Outdoor air velocity

Table 3. The results analysis of performance indicators

	Office		Classroom		Urban residence		Rural residence	
	Summer	Winter	Summer	Winter	Summer	Winter	Summer	Winter
NAE	0.290	0.344	0.341	0.306	0.271	0.385	0.269	0.527
RMSE	10.250	20.540	8.420	9.710	10.730	14.510	16.890	32.230
$R^2$	0.740	0.868	0.684	0.664	0.773	0.743	0.876	0.756
PA	0.537	0.834	0.820	0.630	0.122	0.661	0.405	0.628
AI	0.719	0.680	0.724	0.682	0.699	0.997	0.700	0.556

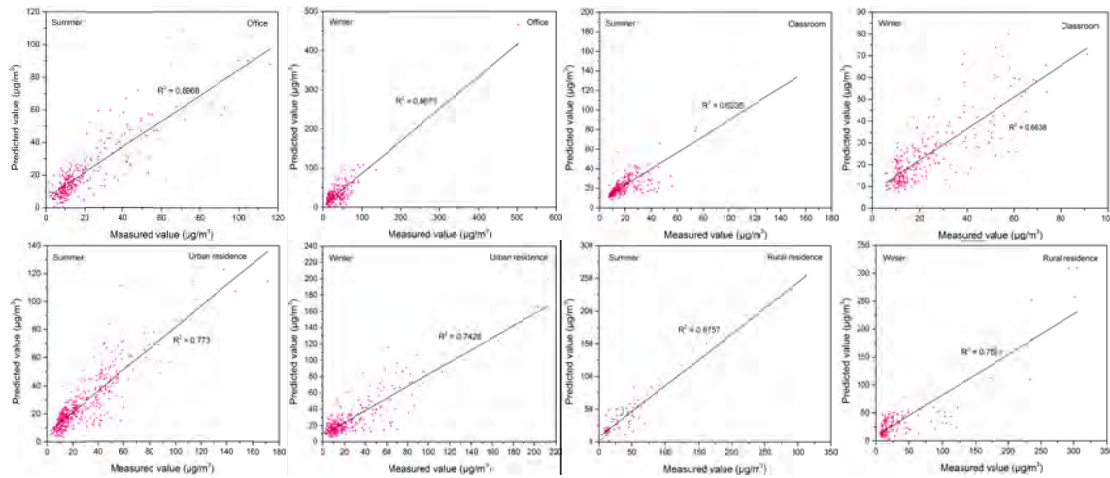

Figure 1. The comparison between predicted and measured values of regression model

According to the results of regression model in Table 2, the predicted value of the model is compared with the measured by 30% test data. Figure 1 is the result of comparison of each model. It can be found that there is a strong correlation between the measured and predicted values of indoor  $PM_{2.5}$  concentration. Table 3 shows the analysis results of the errors between the measured values and the predicted values of five performance indexes, the values of NAE, RMSE are relatively small and  $R^2$ , PA and IA are close to 1, which indicates that the prediction model and the method are practical to some extent.

### Comparative analysis of model parameters

Table 2 shows the regression results of the model parameters standardization. According to the comparative analysis, it can be found that the outdoor  $PM_{2.5}$  concentration plays a leading role in the model, whether it is summer or winter, air velocity and wind direction are relatively weak, while the other parameters have their diversities respectively. For heating season, the influence of indoor temperature and humidity account for a large proportion of the model, while small in the non-heating season. Therefore, the correlation between indoor particulate concentration and all the parameters has significant seasonal differences, while no for different building types.

### CONCLUSIONS

In this paper, the indoor and outdoor particulate concentrations of four building types were monitored to analyze the correlation and factors of indoor and outdoor particulate concentrations and establish the prediction model of indoor particulate concentration. Specific conclusions are as followed:

- (1) Outdoor temperature and humidity, air velocity, wind direction and atmospheric pressure are the main factors affecting indoor particulate concentration. According to the results, indoor  $PM_{2.5}$  concentration is positively correlated with indoor and outdoor temperature and humidity as well as outdoor air velocity, negatively with outdoor atmospheric pressure and both positively and negatively with outdoor wind direction.
- (2) Based on these factors, the study uses multivariate linear regression to establish the indoor  $PM_{2.5}$  concentration prediction model. No matter in summer and winter season, outdoor  $PM_{2.5}$  concentration plays a leading role in the model, the outdoor air velocity and wind directions are relatively weak, while the other parameters have their diversities respectively.

### **ABSTRACT**

Sustainable construction and in particular the sustainability of materials is a global issue with legislation on material properties and product performance at the forefront. In traditional constructed buildings however, it can be extremely challenging to get accurate data on performance. The variability of building materials design, manufacture and construction from different eras is substantial, even within local areas due to the vernacular nature of construction from these periods. Material properties testing can be expensive and is not always readily available when required and is therefore often ignored, particularly in the retrofitting of historic buildings. This can have major adverse effects on the building fabric and for its inhabitant’s health if the appropriate material interventions are not chosen. An inexpensive environmental chamber for testing such materials has been designed and built at the Dublin Institute of Technology, (DIT) Ireland, adopting comparable standards from EN ISO 8990 and ASTM C1363. This paper describes the design requirements for the construction of an affordable and mobile calibrated hot box (CHB) for the testing of historic materials. A characterisation panel has been used to carry out early calibration testing and the results of this are discussed. Improvements and tweaking of the first test are also discussed.

### **KEYWORDS**

Calibrated hot box, Historic materials, Characterisation panel, Data acquisition.

### **INTRODUCTION**

Buildings’ energy consumption accounts for approximately 40% of total energy use in developed countries. The legislation on energy efficiency in buildings, such as the EU Directive 2010/31 has tried to raise minimum energy efficiency standards, for both the single components and the entire building. The building fabric plays a fundamental role in its energy balance, particularly the thermal properties when exposed to moisture and often generic values are used in ideal situations when modelling. In solid walled structures these values are, expensive and difficult to accurately ascertain due to the inconsistency of materials.

To establish accurate and reliable data on structures with different materials used in the one homogenous unit requires different approaches such as numerical simulation, but this is only as accurate as the accuracy of the inputs which often tend not to be validated. Hot boxes have been used to establish accurate properties with guarded hot boxes used mainly for commercial use and calibrated hot boxes used in laboratory work, where often it is necessary for greater levels of refinement and accuracy be achieved. The design of the hot box produced at the DIT was motivated by the need for such testing of small building elements from historic buildings primarily. These material dimensions influenced the design and construction of the whole apparatus and in particular the dimensions of the panel which hosts the sample.

Hot boxes require two closed rooms kept at constant, individual temperatures: a metering chamber, which is warm and the environmental chamber that is cold. A test wall typically containing the specimen under test, divides the two chambers. The overall thermal resistance

is evaluated from the heat flux between the two chambers including that of the internal and external air resistances. This research paper looks at the design, build and calibration of a calibrated hot box (CHB) constructed in the Dublin Institute of Technology, incorporating guidelines from EN ISO 8990 and ASTM C1363-05 with the primary aim of designing and constructing an affordable dynamic environmental test chamber. The construction of the facility was carried out in the Dublin Institute of Technology (DIT) workshops and Labs.

### Objectives

a) Design and construct a dynamic environmental hot box to meet the input requirements for a later hygrothermal simulation, establishing thermodynamic properties b) Calibrate a small-scale, affordable apparatus for thermal testing of non-conventional materials using a characterisation panel of known thermal conductivity and c) Analyse and compare measured versus theoretical data to establish % error.

### Literature review

Typical thermal testing of multilayer wall systems is conducted using a hot box apparatus according to standards comparable to ASTM C1363 [2] and EN ISO 8990 [4]. The properties of non-conventional materials can create challenges when conducting thermal tests using apparatus designed for conventional materials. For example, past tests conducted on historic brick varied in reliability due to poor fit inside conventional testing frames (Baker, 2011). EN ISO 6990 & ASTM Standard C1363-11 details the requirements for design and operation of a test apparatus for evaluating thermal performance of building materials and envelope assemblies by means of a hot box apparatus. The sensors measure the surface-to-surface heat transfer rather than the overall thermal resistance, and the initial performance is evaluated using heat transfer calculations.

Ulgen (2002) measured the time lag and decrement factor using wall compositions of opaque materials in a hot box simulation. Sala et al., (2008) conducted dynamic testing of insulated brick walls using a calibrated guarded hot box. The two types commonly used are the: Guarded hot box : In the guarded hot box, the metering box is surrounded by a guard box in which the environment is controlled to minimize lateral heat flow in the specimen. The total heat flow through the specimen will then be equal to the heat input to the metering box. In practice, there will be a limit in detecting imbalance in each test. (EN ISO 8990) [4]

Calibrated hot box : The calibrated hot box is surrounded by a temperature-controlled space not necessarily at the same air temperature as inside the metering box. The heat losses through the box walls are kept low by using a construction of high thermal resistance. The power input shall be corrected for the wall and flanking losses. The correction for chamber and flanking losses are determined by tests on specimens of known thermal resistance. For flanking loss calibration, the calibration specimens should cover the same thickness and conductivity range as the specimens to be measured and the temperature range of intended use. (EN ISO 8990) Schumacher, et., al.,(2013) constructed a hot box and concluded that the thermal performance of wall assemblies is complex and heavily influenced by factors such as insulation level, air leakage, thermal bridging, operating conditions, moisture content and installation defects and argue that simple R value calculation is not sufficient to address the above factors. They contend that more sophisticated testing is required before a new metric for testing is established. They used finite element programme analysis for the flanking losses.

International Standards lays down the principles for the design of the apparatus and minimum requirement that shall be met. It does not, however, specify a particular design since requirements vary, particularly in terms of size, and also to a lesser extent in terms of operating conditions. This International Standard describes also the apparatus, measurement technique and necessary data reporting.

The air exchange rate (AER) is not often measured in hot box construction and three methods using tracer gases exist for its determination. These are the concentration decay method, the constant injection method, and the constant concentration method (Laussman et al. 2011). The primary function being to establish additional heat losses at junction interfaces.

## **METHODOLOGY**

All thermal bridge calculations were carried out according to EN ISO 10211. Numerical simulations were performed using the 2D and 3D finite element program Psi Therm. The U-value of the metering chamber was calculated according to EN ISO 6946:2007

### **Design for construction**

Concept: It was determined that a calibrated hot box would be the most suitable for the testing requirements within the DIT. The limiting factors in design and dimensioning of the apparatus were the size of the door openings in different buildings as it was constructed in the Bolton street campus, 4-5 Km away. Transportation also determined the overall weight and mobility of the unit and had to be factored into the design and construction. The maximum specimen area achieved was 715mm (L) by 715 mm (H) by 200mm (T). 200mm was chosen as being capable of testing a panel of representative material to achieve accurate results. Bricks from a historic building have been prepared to a test standard size of 180 x 80 x 55mm for testing in the chamber. The following items were addressed: Identification of experiments to be carried out, Comply with standards, Capable of testing historic elements, Self-contained unit, Logging capabilities/ dynamic, Humidifier capacity and location, Highly insulated, Thermal bridge free or as low as practicably possible, Constructible in DIT and mobile, Good compactness ratio, Robust but adaptable specimen holder panel, Cost effective, Compliance and Practical implications re; budget, size, mobility.

### **Construction of CHB**

The hot box, shown in Figure 1 was constructed using a 45 mm medium density fibreboard (mdf) outer structural layer, with one layer of 200mm EPS insulation glued to the inside surfaces with PVA glue. Air leakage was prevented by using a brush-on waterproof tanking layer, this also ensuring that the insulation and mdf thermal properties do not change due to moisture uptake from within. A 100mm wide mdf strip was glued on internally to provide fixings for the heaters/fans thus ensuring no fixings penetrated the eps. Heating is produced by a single 60W resistance heater located as far as is practicably possible away from the specimen. Cooling is provided by the environmental chamber on the other half of the apparatus, -a insulated box identical in size and construction to the metering box. The cooling is provided by a chiller unit placed on top of the unit with the evaporator connected internally. The identical dimensioning of the hot box ensures that air circulation and velocity across the sample face should be almost identical as they are placed in the same position in both boxes. Both boxes were designed to accommodate a 6mm mdf baffle painted matt black, installed 200mm from the face of the test specimen. Air circulation is provided by 2 computer fans per box placed behind the baffles in identical positions. Each specimen prepared for testing, is fitted with insulation plugs around its perimeter, identical to the layers insulating the hot box.

Four castors per box allow for easy opening and closing of the units. External threaded bars are used to tighten the two chambers together during testing, minimising air leakage. A humidifier has been fixed to the outside of the chamber and each chamber is equipped with a humidity probe and 8 thermocouples. All data is acquired and managed by the use of a single National Instruments cRio datalogger using Labview programming.

**Calibration:** The accuracy of each individual apparatus shall be estimated with reference to homogeneous specimens of thermal conductance extending over a range of temperatures, close to what the final testing conditions are likely to be. The metering chamber was set up to keep steady-state conditions: the set point was 30 °C, with an air flow rate of 3.8 m/s measured and RH that ranges in average between 30% - 47% with the environmental (cold) chamber value 'set point' changing at 5 °C intervals from 25, 20, 15, 10, and 0 °C, until steady state environment was reached at each.

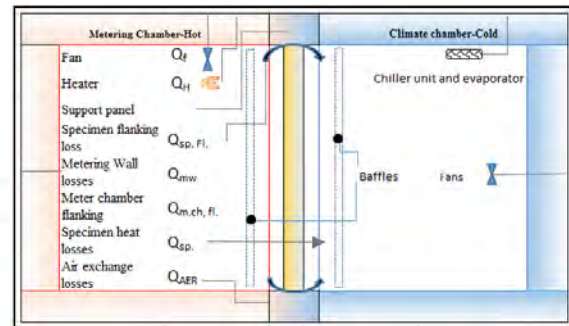

Figure 1. Horizontal section through apparatus. Figure 2. Components and Heat Pathways

### Air Exchange Rate (AER)

The air change rate (ACR) through the box as a whole was determined through standard tracer gas measurement. After CO<sub>2</sub> was released into the chamber, its concentration decays exponentially, if no further CO<sub>2</sub> supply occurs and if the driving forces for air exchange remain constant. After introduction of the CO<sub>2</sub> into the sealed enclosure, the concentration of the gas decreased as air entered and exited. Plotting the natural logarithm of this exponential decay curve against time normally result in a straight line, the slope of which is the (AER) air changes per unit time. The mass balance equation is used to describe the relationship between the concentrations of gas in a space as a function of time. The general form of the equation for calculating air exchange per unit time is given as follows:

$$N = [\ln(C_{int} t_0 - C_{ext}) - \ln(C_{int} t_1 - C_{ext})] / (t_1 - t_0) \quad (1)$$

where N= number of air changes,  $C_{int} t_0$  = internal concentration of tracer gas in enclosure at start,  $C_{ext}$  = external concentration of tracer gas in room,  $C_{int} t_1$  = internal concentration of tracer gas in enclosure at end,  $t_0$  = time at start (days),  $t_1$  = time at end (days) and ln = natural logarithm.

### CHARACTERISATION AND ESTIMATION OF LOSSES

A characterization panel of known thermal resistance (wood fibre board  $\lambda$  0.04 W/mK) is used in a number of tests, over the expected operating temperature range. Each test determines the difference between the measured heat input to the metering chamber and the heat transfer through the characterization specimen, calculated from the measured temperature drop across it and its known resistance.

Calculations: A significant difference in temperature across the specimen is suggested. The air velocity on both sides was held constant and the heat flow across the sample was measured.

EN ISO 8990 and ASTM C1363-05 requires the following heat balance equation be verified. A schematic showing the heat transfer pathways is given in Figure 2.

$$Q_{\text{Source}} = Q_{\text{Heater}} + Q_{\text{Fans}}, \quad \text{Specimen} = U_{\text{Specimen}} \times A_{\text{Specimen}} \times \Delta T \quad \text{and} \\ Q_{\text{metering chamber losses}} = U_{\text{Chamber}} \times A_{\text{Chamber}} \times \Delta T + Vc_p\rho\Delta T + Q_{\text{flanking}}(W) \quad (2)$$

Where:  $A_{\text{Specimen}}$  = Sample area ( $\text{m}^2$ ),  $Q_{\text{Heaters}}$  = Heat input from heaters (W),  $Q_{\text{Fans}}$  = Heat input from fans (W),  $Q_{\text{m ch}}$  = Heat transfer rate through metering walls, floor and ceiling (W),  $Q_{\text{flanking}}$  = Heat transfer rate at junction of specimen to frame (W),  $U_{\text{chamber}}$  = Thermal conductivity of the chamber ( $\text{W/m}^2\cdot\text{K}$ ),  $A_{\text{chamber}}$  = Area of chamber walls where losses occur ( $\text{m}^2$ ),  $\dot{V}$  = Air exfiltration rate  $\text{m}^3/\text{s}$ ,  $c_p$  = A Specific Heat Capacity of  $1007 \text{ J/kg}\cdot\text{K}$  at  $30^\circ\text{C}$  is used,  $\rho$  = Air density between  $1.16 - 1.27 \text{ kg/m}^3$  used,  $\Delta T_{\text{air}}$  = Inside to outside temperature difference ( $^\circ\text{C}$ ),  $\Delta T_{\text{surfaces}}$  = Temperature difference between hot and cold surfaces ( $^\circ\text{C}$ ),  $U_{\text{Specimen}}$  = Thermal conductivity of the sample ( $\text{W/m}^2\cdot\text{K}$ )

## RESULTS

The results of the  $\text{CO}_2$  analysis are shown in Figure 3, where the air exchange rate equals the slope of the line at 0.087 ach and this is multiplied by the chamber volume to get a volume per second time of  $1.313\text{E-}05$  to be used in the heat balance equation. The test was conducted at ambient temperature only and accounted for less than 2% of the overall energy input, however further tests at different temperatures should further verify this figure.

Figure 3.  $\text{CO}_2$  results for air leakage of the chambers.

## Characterisation results

Table 1 shows the inputs for the heat balance equation measured over five delta T's during the testing of an 80mm woodfibre board. The stated manufacturer's lambda value for this panel is  $0.04 \text{ W/mK}$  and is used in the U value component (Table 1) of the  $U \cdot A \cdot dT_{\text{specimen}}$ . As the balance equation should read 0, the percentage error shown in the last row is just under 5%.

The theoretical and experimental results are plotted in Figure 3 and can be seen to have good correlation with the distance between the lines representing the gap to be identified.

Figure 3. Theoretical versus Experimental losses of wood fibre board over 5  $\Delta T$ 's

### ANALYSIS AND DISCUSSION

The limitations of this CHB are its relatively small size and also the fine levels of accuracy of some of the equipment but these have been counteracted by the extra care taken in the construction and calibration process. The maximum size of 715mm by 715mm sample area size requires that the thermal bridge calculation needs to be extremely accurately identified.

The advantages of reduced dimensions over more traditional hot box systems however, provides a reduced mass and, thus, reduced thermal inertia of the overall system. First tests on a wood fibre board of an accepted conductivity (0.04 W/mK) shows very close relationship between theoretical and experimental data. The percentages of error varies by approximately 5%. The average temperatures in both chambers were steady throughout the testing period. Investigation is required to establish the cause of the slight non-linearity at  $\Delta T$ , of 15 °C.

Finally the CHB built in the DIT set out to design and build an affordable testing chamber for establishing the material properties of historic building materials with the first step of calibrating a panel thickness of 80mm of known thermal conductivity. This was satisfactorily achieved and the percentages error of approximately 5% is acceptable for this apparatus. The next steps of testing historic building materials from a case study building is currently underway, with the results being inputted to a hygrothermal simulation.

### **ABSTRACT**

In modern society, house dust particulate matters pollution had become serious. Ventilation is an important method for removing house dust particulate matters and it is very important to explore the removal efficiency of house dust particulate matters under different ventilation modes. This study analyses the removal effect of house dust particulate matters under the two typical ventilation modes called ceiling exhaust and slit exhaust strategy through experiments and date analysis. In the process of experiments, riboflavin particles were used as the house dust particulate matters, instantaneous microbial detection (IMD) was used to measure the house dust particulate matters. Walking test was carried on after the ventilation system running for some time, which aimed to explore the influence of human behaviour on the house dust particulate matters distribution under two different ventilation modes. It is concluded that larger size particles had larger sedimentation velocity and sedimentation velocity of particles would be faster significantly after the ventilation system working. After walking experiment, particles concentration returned to background concentrations due to the effect of the ventilation system. Particles concentration in slit exhaust strategy was lower than ceiling exhaust so that the effect of slit exhaust strategy is superior to the ceiling exhaust.

Ventilation strategy; House dust particulate matters; Experiment; Concentration distribution; Walking test

### **INTRODUCTION**

In modern society, people spend 80% of the time in indoor environment (Peggy et al., 1992; Robinson and Nelson, 1995), thus indoor air quality is particularly important. With the worsening of atmosphere particle pollution, indoor particle pollution has become increasingly severe due to the infiltration by building exterior and other reasons. US Environmental Protection Agency had conducted an investigation for 5 years, which found that indoor pollution was serious in residential and public building (Zhu, 2002). Due to the limitations of various factors in China, indoor air environment can't build a more comprehensive monitoring network, resulting to indoor air quality is even more worrying.

Epidemiological studies showed that short or long-term exposure to dust particle would lead to widespread adverse effects on human multiple systems. "Global Environment Outlook" published UNEP pointed out that nearly 2 million premature deaths were related with particulate matter pollution. There was a positive correlation between the particle mass concentration with human mortality and morbidity, even the concentration lower than the

national limits standards (Yang, 2014). Dockery (1993) conducted a prospective study in six cities, and it found that particle pollution was related with cardiovascular diseases. With the increase of the annual average concentration of particulate matter, all-cause mortality, cardiovascular mortality and lung cancer mortality was significantly increased after controlling confounding factors (Pope et al., 2002). Under the same concentration, house dust particulate matters pollution was more harmful to the human body (Dockery et al., 1993; Pope et al., 2002; Guo et al., 2010; Tinker and Roberts, 1999). House dust particulate matters can enter the lungs to made greater harm to human body (Wang et al., 2013; Wang et al., 2007; Nikasinovic et al., 2006; Neas et al., 1994; Delfino et al., 2006; Zhu et al., 2015).

A growing number of epidemiological studies had shown that population incidence and mortality were associated with the particle mass concentration, especially significantly the indoor particulate matter concentrations (Yang, 2014; Dockery et al., 1993; Pope et al., 2002; Guo et al., 2010; Tinker and Roberts, 1999; Wang et al., 2013; Wang et al., 2007). Thus, the distribution characteristics of indoor particles and the health risks have been common concern in environmental science and engineering. Zhang and Chen (2006) studied particle transportation and distribution in ventilation chamber using experimental and numerical methods, who found that different ventilation forms had a great impact on indoor particle concentration distribution. Munat (2001) investigated and analysed the influence of different airflow forms on particle suspension, and the results showed that displacement ventilation system had small resuspension harm. Zhao B (2004) compared the diffusion characteristics of indoor particulate matter in displacement ventilation and mixing ventilation using numerical simulation method.

Many indoor air environment-related research study have been carried out, but it's not clear how indoor human behaviour affects indoor particle distribution under different ventilation. To solve this problem, the study made a research to figure out the effect of indoor human behaviours' influence to house dust particle distribution under different airflow. It will improve the prevention and control level of indoor air pollution and provide scientific basis of human health.

## **METHODS**

### **Selection of particles**

In the experimental study of house dust particulate matters, Japan used JIS-11 as experimental particles (Liu et al., 1996). JIS-11 test powder is non-biological particles produced by volcanic ash. The concentration of non-biological particles was high in the air, and its impact on the health is not clear, so in this study, riboflavin particles were used as the test particles because it is harmless for biological particles (Kurihara et al., 2010). Riboflavin is a special kind of biological particles which can emit fluoresce when it is exposed to light sources with certain specific wavelength. And it can be detected by particle detector (IMD) based on optical sensors and fluorescence detection techniques as biological particles. Studies have shown that value of riboflavin powder is low in the air, so it doesn't affect experimental results (Kurihara et al., 2010).

### **Ventilation systems and experiment process**

Figure 1 shows experimental room ( $L \times W \times H = 5.37\text{m} \times 2.74\text{m} \times 2.25\text{m}$ ) and ventilation systems. The window is sheltered by aluminum foil corrugated board to prevent solar radiation, and the walls are insulated by expanded polystyrene board. This study analyses the effect of the human walk activity on indoor particles distribution under two typical ventilation modes including ceiling exhaust and slit exhaust. Ceiling exhaust is the traditional ventilation way. For the slit exhaust strategy, delivery outlet was located in the center of the ceiling (In this study, delivery outlet of two ventilation system was same), the exhaust port is located at

the junction of walls and floors. Delivery outlet size of two ventilation systems were  $0.05\text{m} \times 0.10\text{m}$ . The exhaust port size in ceiling exhaust was  $0.05\text{m} \times 0.10\text{m}$ . As for the slit exhaust system, exhaust port size in the east was  $4.2\text{m} \times 0.005\text{m}$ ,  $4.53\text{m} \times 0.005\text{m}$  in the west. Figure 2 shows ceiling exhaust and slit exhaust system. Ventilation time was 0.75 times/h during the experiment

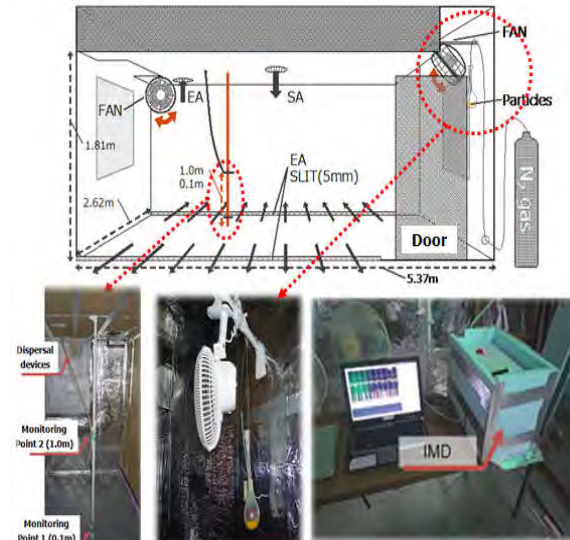

Figure 1. Experimental room and ventilation systems.

Figure 2. Two ventilation system. a) ceiling exhaust, b) slit exhaust

Indoor particles distribution was shown in Figure 1. The house dust particles were put in a measuring flask, which was fixed at the corner near the ceiling of the room. Nitrogen gas was blown into the measuring flask to disperse the house dust particles. Nitrogen gas flow rate was set as 10 L/min. To make the distribution of house dust particles as evenly as possible in the room, the house dust particles were mixed by an electric fan which was fixed close to the flask. Taking into the account of the height of the child, the position of the monitoring point was set at 0.1m and 1.0m. IMD (instantaneous microbial detection; IMD-A 200-1, BioVigilant Systems) was used to measure the particles, which is based on optical fluorescence sensor technology and is capable of detecting the size of biological or non-biological particles in the environmental air. Particle sizes were classified as the following six levels:  $0.5\text{--}1.0\text{ }\mu\text{m}$ ,  $1.0\text{--}3.0\text{ }\mu\text{m}$ ,  $3.0\text{--}5.0\text{ }\mu\text{m}$ ,  $5.0\text{--}7.0\text{ }\mu\text{m}$ ,  $7.0\text{--}10.0\text{ }\mu\text{m}$ , and  $10.0\text{--}15.0\text{ }\mu\text{m}$ . Experimental procedure (total 42 hours): the first hour - indoor particles spreading; 2 to 9 hours – indoor particles free settling; 10 to 42 hours - the ventilation system running. Indoor people started walking test from 27th hours. The purpose of the walking test was to explore the impact of walking behaviour to indoor particle concentration distribution under two different ventilation modes. Research was determined according to Liu Yu's experimental

methods from Japan's National Public Health Institute (Lu et al., 1982). In the study, male experimenter entered to room doing walk test, and walked in the room for 10min according to designated route (60 steps/ minute, 60 cm/step, a total of 600 steps). Figure 3 shows the walk test details.

Figure 3. The walk test details

## RESULTS AND DISCUSSIONS

### The results in the ceiling exhaust strategy

Figure 4 shows the variation of particles concentration (0.5-1.0  $\mu\text{m}$ , 1.0-3.0  $\mu\text{m}$ , 3.0-5.0  $\mu\text{m}$ ) in two different measuring points (from the ground 0.1 meters and 1.0 meters) in the ceiling exhaust strategy. It shows that: ① Before spreading powder (-6-0h), all size particles' background concentration was low in air (about 10 P/L). ② When powders walked for 1 hour (0-1h), indoor particles concentration increased rapidly; After 8 hours (1-9h), different size particles (0.5-1.0  $\mu\text{m}$ , 1.0-3.0  $\mu\text{m}$ , 3.0-5.0  $\mu\text{m}$ ) exhibited different settlement curve because of gravity; The larger particle size, the faster fall velocity. ③ After running the ventilation system (9h ~), all size particles accelerated subsidence (settlement curve sudden steep in figure 6); When did walk test (27h-), particles concentration increased significantly, which may be due to suspended caused by disturbance of human walking; After the walk test, particles concentration returned to background concentration under the action of the ventilation system running continuously. Two measuring points showed above trend.

Remarks: ①background values;②powder spreading;③free settling;④ventilation;⑤walk test;⑥ventilation  
Figure 4. Variation of particle concentration in the ceiling exhaust strategy

Remarks: ①background values;②powder spreading;③free settling;④ventilation;⑤walk test;⑥ventilation  
Figure 5. Variation of particle concentration in the slit exhaust strategy

### The results in the slit exhaust strategy

Figure 5 shows the particles concentration variation of two different measuring points (from the ground 0.1 m and 1.0 m) in the slit exhaust strategy. The variation trend of particles concentration in two measurement point was basically same with Figure 4, but there were some differences in concentration distribution.

### Comparison of indoor particles concentration distribution in both ventilation systems

Figure 6 shows the different size particles concentration after ventilation system running (9h-) under two ventilation modes. Figure 6a shows the results in the height of 1.0m, and Figure 6b shows the results in the height of 0.1m. The results indicate that particles concentration in slit exhaust was lower than that of ceiling exhaust in the two measurement points. The lower the height, the more obvious of the effect for slit exhaust. The exhaust outlet was located at the junction of walls and floors for the slit exhaust, thus indoor particle gathered in the corner and excluded.

Figure 6. Particles concentration after ventilation system running in two ventilation systems.

### CONCLUSIONS

This paper clarifies the effect of human walk behaviours on house dust particle distribution under different ventilation modes (including ceiling exhaust and slit exhaust). The following conclusions have been drawn:

- 1) Riboflavin was used to indoor house dust particles and IMD was used to measure the riboflavin particles concentration.
- 2) Larger size particles had larger sedimentation velocity and sedimentation velocity of particles accelerated significantly after the ventilation system working. Comparison of the number of particle in experimental monitoring point shows that the number of house dust particles in the ceiling exhaust was higher than that of the slit exhaust after house dust particles decreased as same level as background.
- 3) At the beginning of walking test, particles concentration increased significantly. After the walking test, particles concentration returned to background concentration under the action of the ventilation system running continuously.
- 4) Particles concentration in slit exhaust strategy was lower than that of the ceiling exhaust, thus the effect of slit exhaust is superior to the ceiling exhaust.

### ABSTRACT

This paper introduces the results of a one-year research, to gather and analyse data on the traditional housing buildings in Kukes region, Albania. The energy performance and the thermal comfort conditions in five different buildings were examined. The Design Builder Energy simulation software was used to analyse the thermal performance of the selected typologies. Detailed construction activity and weather information was applied in modelling the houses. Simulation results showed that these buildings require only heating during the winter. As for the first villa, seven improvement scenarios were applied and examined. The same scenarios incorporate the use of thermal insulation of the walls and the roof as well as the use of double glazing. The results suggest that improvements and insulations in building fabrics could reduce the annual energy consumption up to 35 %.

### KEYWORDS

Thermal performance, Traditional building, Parametric simulation, Design Builder

### INTRODUCTION

Adaptive reuse contributes to the sustainability of the urban generation, as it extends the life cycle of the buildings, avoids demolition waste, encourages energy efficient solutions, and provides significant social and economic benefits to the society (Resuli and Dervishi, 2015). Due to the difficulty of finding maintained buildings, very few researches analyze the energy efficiency of traditional buildings in Albania (Rexhepi and Mahdavi, 2010). Previous studies have identified effective ways for the energy conservation in the existing buildings (Kaleci and Dervishi, 2014). The renovation of the existing buildings is one of them, consisting of interventions on improving the functionality and sustainability of traditional buildings. This study consists of five traditional buildings located in Lume village, in the Region of Kukes, Albania, on which, records on thermal conditions and the energy use were gathered over a period of one year.

This paper is specifically related to five case studies of traditional houses in the villages of Kukës and identifying their sustainable potentials. The selected houses have been historically exploited as a shelter for the locals, guests, and foreigners. Nowadays their conditions have deteriorated and a large amount of energy is used for heating. Increase of energy consumption is caused by the low temperatures of this area, and the absence of insulations in old buildings, specifically the wall insulation, roof insulation, and double glazing. In most case studies, the building design does not consider orientation, glazing ratio, shading devices, or thermal mass. The sustainable environment is achieved using natural resources (sun, wind, temperature variation) in sustainable approaches, which directly affect the quality of the inner space (comfort, energy efficiency, and lighting) (Rashani and Mahdavi, 2015), and hence, this study is concerned with the following objectives: i) analyzing the energy consumption and

how it affects thermal conditions; ii) evaluating the thermal performance; iii) analyzing the comfort of inner spaces; and iv) developing strategies towards improvement.

## METHODS

The five selected buildings diverge in terms of construction period, location, orientation and occupancy. Table 1 summarizes general information regarding the concerned houses such as area, function, construction year, presence of Kulla, and the materials used.

Table 1. Overview of the selected houses (year of construction, area, interventions, material used).

## Indoor thermal Condition and Energy Used

Indoor climate parameters (indoor air temperature and relative humidity) and the energy use were simulated for all houses (living room and in the entire building over a period of one year (Jan 1<sup>st</sup>- Dec 31<sup>th</sup>). In order to evaluate the existing indoor thermal conditions, the ratios of air temperature and relative humidity are diagrammed in psychometric charts. Based on the questionnaires' and gathered information, building performance simulation models were generated and secondarily used to test various improvement scenarios by means of parametric simulation software [Design Builder 2013], (see Table 2).

Table 2. Questionnaire output (thermal insulation, heating equipment, cooling equipment, lamps, thermal comfort)

Questions	H1-Results	H2-Results	H3-Results	H4-results	H5-Results

## Simulation study

Five buildings, respectively H1, H2, H3, H4, and H5 were simulated over a period of one year. The gathered geometry and the construction records were used to generate the base case simulation models. Assumptions were made based on in situ observations, historical documents, and questionnaires'. Simulation assumptions regarding actual construction data

are summarized in Table 3. To run the simulations, weather files were generated based Meteoronorm (2007) software platform.

Table 3. Base case construction materials and respective U values for all houses (H1-H5).

Code	Scenario	U-Values	Description
BC 1	Base case- H1	$U_{\text{Walls}} = 1.31 \text{ W.m}^{-2}.\text{K}^{-1}$ $U_{\text{roof}} = 1.95 \text{ W.m}^{-2}.\text{K}^{-1}$	Wall- 60 cm stone wall Roof- Uninsulated pitched roof, Heavy weight
	Base case- H2	$U_{\text{window}} = 2.6 \text{ W.m}^{-2}.\text{K}^{-1}$ $U_{\text{Walls}} = 1.46 \text{ W.m}^{-2}.\text{K}^{-1}$ $U_{\text{roof}} = 2.11 \text{ W.m}^{-2}.\text{K}^{-1}$	Window- Double glazing, Clear, Argon filled Wall- 60 cm stone wall Roof- Uninsulated pitched roof, Medium weight
BC 2	Base case- H3	$U_{\text{Walls}} = 1.61 \text{ W.m}^{-2}.\text{K}^{-1}$ $U_{\text{roof}} = 2.11 \text{ W.m}^{-2}.\text{K}^{-1}$	Window- 4 mm Single glazing, Clear Wall- 50 cm stone wall
	Base case- H4	$U_{\text{Walls}} = 1.22 \text{ W.m}^{-2}.\text{K}^{-1}$ $U_{\text{roof}} = 1.95 \text{ W.m}^{-2}.\text{K}^{-1}$	Window- 4 mm Single glazing, Clear Wall- 60 cm stone wall
BC 3	Base case- H5	$U_{\text{Walls}} = 1.38 \text{ W.m}^{-2}.\text{K}^{-1}$ $U_{\text{roof}} = 1.95 \text{ W.m}^{-2}.\text{K}^{-1}$	Roof- Uninsulated pitched roof, Heavy weight Window- Double glazing, Clear, Argon filled
		$U_{\text{window}} = 2.6 \text{ W.m}^{-2}.\text{K}^{-1}$	Wall- 70 cm stone wall Roof- Uninsulated pitched roof, Medium weight Window- 6 mm Single glazing, Clear

### Improvement scenarios

To demonstrate thermal improvement possibilities a number of seven improvement scenarios (S1-S7) were introduced only for the first typology (H1) for parametric simulations in a 2 day interval (1<sup>st</sup> and 2<sup>nd</sup> of July). The first scenario (S1) explores the impact of the thermal insulation on the external walls. The second scenario (S2) involves the thermal insulation of the roof. The third scenario (S3) involves the use of double glazing as a replacement for of single glazing. The fourth, fifth, sixth, and seventh scenarios (S4-S7) comprise the combination of the aforementioned scenarios. The purpose is to achieve a more stable temperature in the indoor environment and to reduce energy consumption. Table 4 summarizes improvement scenarios for one selected representative house.

Table 4. Improved scenarios for H1 (WI, RI, DG, WI+RI, WI+DG, RI+DG, WI+RI+DG)

Code	Scenario	U-Values	Description
WI	Wall Insulation	$U_{\text{Walls}} = 0.26 \text{ W.m}^{-2}.\text{K}^{-1}$	Inner Insulation PVC= 12 cm
RI	Roof insulation	$U_{\text{roof}} = 0.151 \text{ W.m}^{-2}.\text{K}^{-1}$	Glass Wool 8 cm
DG	Double glazing	$U_{\text{window}} = 1.07 \text{ W.m}^{-2}.\text{K}^{-1}$	Replacement of Single Glazing with Double Glazing
WI+RI			
WI+DG			
RI+DG			
WI+RI+DG			

## RESULTS AND DISCUSSION

Figure 1 shows an indication of the existing thermal performance only in the first house (H1) based on the simulation results in a course of a 2 day interval (1<sup>st</sup> and 2<sup>nd</sup> of July 2017). Taking into account the weather conditions in Kukes, no cooling took place during simulation, and ventilation was considered during day and night hours with altered recesses (see Table 5). Figure 2a shows the assessment of indoor temperatures of all selected houses, compared with the outdoor temperature for a 2 day interval measurements (1<sup>st</sup> and 2<sup>nd</sup> of July 2017). As indicated in the relevant figures, the indoor temperature is more constant during day and night, compared to the outdoor temperature. Owing to that stone is the material that

was used in outer walls its conductivity directly brings about a stable room temperature. A considerable difference is shown between indoor temperatures of occupied houses (H1, H4, and H5) and unoccupied houses (H2 and H3), as the absence of activity affects the sustainability of internal temperatures in H2 and H3. Figure 2b compares the humidity measurements of all houses in the 2 day interval (1<sup>st</sup> and 2<sup>nd</sup> of July 2017). Based on the results, the amount of humidity is lower in the occupied houses (H1, H4, and H5) because the unoccupied houses (H2 and H3) are unventilated. Additionally, Figure 3a shows the comparison of energy between five houses in one year interval, while Figure 3b,c shows the ratio of indoor temperatures and relative humidity for one month (July 2017) for H1 (occupied) and H2 (unoccupied) represented by psychometric charts. As it is shown in the charts, the houses are positioned differently related to the comfort zone. The first typology (H1) is the most comfortable one, since its construction belongs to more recent years whilst the second typology (H2) is out of the comfort zone, since it is unoccupied and the amount of humidity is bigger. Figure 4a,b and shows that energy and temperature are changed based on improvement scenarios for the first typology (H1). As shown in the figure 4b the lowest value consists the first typology (H1) due to its recent interventions and insulation system. The second lowest value consists of the fifth typology (H5) which has the same material as the fourth typology (H4) but its activity takes place only during the summer period. For the unoccupied houses (H2 and H3) the results show relatively low performance. The implementation of all scenarios together reduces the amount of energy consumption (yearly) and decreases the indoor temperature in the 2 day interval (1<sup>st</sup> and 2<sup>nd</sup> of July). As expected, interventions in the external wall, roof and windows affect directly the indoor temperature and energy consumption. The combinations of the all scenarios (WI + RI + DG) decrease the average of the indoor temperature from 25°C to 22°C during summer period and reduce the annual amount of energy consumption from 74 kWhY.m-2 to 45 kWhY.m-2.

## CONCLUSIONS

The paper is about a study conducted on the comfort and energy consumption of five traditional housing conditions in Northern Albania, using one year simulation measurements. Given the climatic conditions in Kukes, traditional houses require only heating during the winter and no cooling in summer. The simulation results establish that thermal comfort is

directly connected to the climate conditions, manufacture fabrics, dwelling shape, and occupants' activity. Altered involvements to the building's fabrics can bring about better performance. Certain combinations of improvement measures (such as insulations in walls, roof, and double glazing) have the ability to recover the thermal performance of the buildings in the climatic context of Kukes, Albania. Wall insulation and other related arrangements have significantly increased the temperatures and condensed the energy consumption, compared with the other scenarios (30 to 35%). Replacement of glazing and roof insulation affects less the thermal comfort (2 to 10%). Future studies may address the impact of the change of the structure and activity on the energy consumption of the building.

### ABSTRACT

Characterization of building energy performance indicators such as the Heat Loss Coefficient (HLC) based on in-situ measurement data calls for thorough building physical insight, a well-designed measurement set-up to collect sufficient, qualitative data and adequate data analysis methods. On-board monitoring may be an alternative for dedicated experiments to perform the data collection task. This paper analyses the sensitivity of the end-result of the characterization, the HLC estimate, to flaws in the monitoring data set. More specifically, the impact of not installing submeters to disentangle the gas consumption for space heating and the production of domestic hot water is evaluated. Hereto, multiple gas decomposition methods are applied on a case study monitoring data set, after which the HLC is assessed. The results show deviations up to 33% for the mean estimate and non-overlapping 95% confidence intervals.

Characterization, Heat Loss Coefficient, On-board Monitoring,  
Gas Consumption Decomposition, Sensitivity Analysis.

### INTRODUCTION

Building energy performance (BEP) characterization based on in-situ measurements has recently been gaining much attention in the framework of IEA EBC Annex projects 58 and 71. Furthermore, Bauwens (2015), Deconinck (2017) and Farmer et al. (2017) demonstrate how the thermal resistance of building elements and the HLC of building envelopes can be estimated through application of statistical modelling techniques on data collected in on-site steady-state and dynamical measurement experiments. The HLC hereby describes the amount of heating power needed to maintain a temperature difference of 1 degree Kelvin over the entire building envelope [W/K]. The case studies investigated to date, however, mainly focus on mock-ups or unoccupied dwellings. Not only because the measurement conditions can be better controlled, but also because the measurement set-up can be perceived as intrusive and costly.

On-board monitoring, using sensors to collect data of an occupied, in-use building, is put forward as a solution to the issues of cost and intrusiveness (Saelens and Reynders, 2016). However, much uncertainty still exists about the optimal sensor set-up, the way disturbances induced by occupants should be handled, etc.

The present paper aims to address a particular data related challenge that researchers, aspiring to estimate the HLC, might have to face; namely that the same type of fuel has been used for both space heating (SH) and the production of domestic hot water (DHW), and that no submeters can or have been installed to differentiate between both end uses.

The dynamic heat balance for a single zone (Eq.1), which forms the framework for both the

monitoring campaign and the data analysis model, stipulates that the HLC at each timestep  $t$  depends on the effective heat capacity  $C_i$  [J/K] of the zone, the difference between the interior and exterior temperature ( $T_i$  and  $T_e$  resp. in [K]), the heat flow rates due to mechanical ventilation with heat recovery, internal and solar gains ( $\varphi_{vent,hr}$ ,  $\varphi_{int}$  and  $\varphi_{sol}$  resp.), and the net power supplied by the heating system  $\varphi_H$  [W]. This final term not only implies that the gross fuel consumption has to be converted in net energy use on the basis of the system efficiency, but also that the energy use for SH should be separated from that for DHW production and that the latter should be eliminated from the analysis for as far that it does not induce internal gains.

$$C_i \cdot \frac{dT_i}{dt} = HLC \cdot (T_{i,t} - T_{e,t}) + \varphi_{vent,hr,t} + \varphi_{int,t} + \varphi_{sol,t} + \varphi_{H,t} \quad (1)$$

Not decomposing the fuel consumption results in an overestimate of the HLC. However, disentangling it incorrectly might just as much lead to an erroneous estimate. This paper will therefore evaluate the sensitivity of the HLC estimate to the approach used to determine the not-monitored fuel (gas) consumption for space heating.

The first part of the methodology section describes the case study dwelling and on-board monitoring campaign used to this end. Next, three different ways to decompose the gas consumption and thus approach  $\varphi_H$  are discussed. In the final part of the methodology section, the data analysis procedure used to estimate the HLC is delineated. In the results section, differences between the decomposition outcomes are shown, and, more importantly, their impact on the characterization of HLC is demonstrated. Finally, conclusions are drawn on the present study and recommendations are given for future research.

## METHODOLOGY

### Case study dwelling and on-board monitoring campaign

The object of this study is a semi-detached, two-story house built in 2012 in Gainsborough, UK. A theoretical HLC of 47 W/K is calculated based on the target U-values and surface areas of the building envelope parts, the average result of three blowerdoor tests, and the assumption that the efficiency of the mechanical ventilation heat recovery unit equals 100 %. SH and DHW are provided by a gas fired combi boiler. Together with the other dwellings in its terrace, the house has been the subject of a monitoring campaign conducted from October 2012 until November 2015. During this period, the dwelling was inhabited by three persons. The interior temperature of the living room and bedroom (both from the studied and neighbouring dwelling), the exterior temperature, the gas, water and electricity consumption and the PV production were monitored with a 5 min sample frequency. Hourly averaged values of the global horizontal solar irradiance (GHR) were obtained from a RAF weather station located 30 km from the site. A detailed description of the dwelling and performed monitoring campaign can be found in (Sodagar and Starkey, 2016), in which the dwelling is referred to as 'House 1'.

### Gas consumption decomposition methods (DMs)

Classifying all gas consumption for the production of DHW as internal gains and thus assessing HLC based on the total gas consumption ('No decomposition') is incorrect since the hot tap water directly leaves the dwelling through the sewage system.

A first decomposition method to disentangle both end uses ('DM1') could therefore be the application of a default distribution. In this case study there will be opted for a 76/24 distribution for the end uses SH/DHW, as reported by Menkveld (2009). A major drawback of this method is that it does not take the actual consumption, SH demand or occupant behavior into account.

The second decomposition method ('DM2') is fully based on the assumptions that (1) in the case of the combi boiler, the production of DHW and SH do not occur at the same time and (2)

the gas consumption for DHW production perfectly coincides with the DHW consumption. It involves the implementation of two rules on the 5min-interval monitoring data. The first rule stipulates that the gas consumption for DHW production must be set to 0 when mains water consumption is 0, else gas consumption for the production of DHW must be set equal to the total monitored gas consumption. The second rule states that the gas consumption for SH must be set to 0 when mains water is consumed, else gas consumption for SH must be set equal to the total monitored gas consumption.

This DM is straightforward and easy to implement. However, a number of potential flaws can be identified. First, the assumptions imply that all cold water tapplings occurring while gas is used for SH are classified as DHW usage. The fact that grey water is used to flush the toilets though makes this assumption more reasonable. Secondly, the hot water tapplings could be significantly shorter than the 5 min sampling time. Yet, from the moment water consumption is observed, however small, the full gas consumption for that 5 min period is allocated to DHW production. Higher frequency logging could solve this issue. Thirdly, small time delays between starting and stopping of water and gas consumption will create some error.

The third approach, 'DM3', which was demonstrated by Bacher et al (2016), uses a robust, zero order, Gaussian kernel smoother to estimate the 'gas consumption for SH'-profile underlying the noisy 5 min gas consumption data. Next, all spikes of the total gas consumption significantly above this kernel (smoother) estimate are classified as DHW heating spikes and their values are obtained by subtraction of the kernel estimate. Finally, subtraction of the estimated heat load for the production of DHW from the total heat load gives an estimate for the heat load for SH. The parameters of the kernel smoother procedure were tuned with an eye on limiting the gas consumption classified as 'gas used for space heating' during the summer months. The final model parameter values are as follows: kernel window: 1 h, bandwidth: 0.5 h, threshold for bisquare robust estimation  $\gamma$ : 7 MJ/h, separation threshold  $q_{tres}$ : 1.1.

Just like DM2, this decomposition method has not been verified on a case study where the total gas consumption and the consumption for the production of DHW and SH were measured separately. In contrast with the previously described approach, this method assumes that gas consumption for both end uses can occur simultaneously. It should furthermore be noted that all peaks are classified as DHW heating, although the start-up of the space heating might also result in a similar peak in the fuel consumption.

### Determination of HLC

For the characterization exercise, four periods were selected from the entire data set: a relatively long model training period, extending from the 1st of October 2014 till the 31st of March 2015, and three different shorter model validation periods, in January, February and March 2014. With the heat balance equation (Eq.1) in mind, the following variables were selected from the monitoring data; the exterior temperature  $T_e$ , the interior temperature of the dwelling itself and the neighbouring dwelling ( $T_i$  and  $T_n$ , resp). Both  $T_i$  and  $T_n$  are approximately determined as the arithmetic mean of the sensor data collected in the living room and bedroom. In the absence of data on the incident radiation on the different facades, the GHR will be used to represent  $I_{sol}$ . After adaptation with the calorific values published by National Grid (2017) and decomposition through one of the above-mentioned decomposition methods, the gas consumption data will be used as  $\varphi_H$ . The system efficiency is thus assumed to be equal to 100 %. Although this value is uncertain and in reality not even constant, this will not pose an issue for this study, which focuses on the relative differences caused by DMs used for gas consumption. The same holds for the other assumptions made. Finally, the internal gains  $\varphi_{int}$  are neglected in a first run ( $\varphi_{int} = 0$ ) and assumed to equal the total electricity consumption in a second run ( $\varphi_{int} > 0$ ). The latter variable is hereby approximated as the mains electricity consumption plus half of the PV

production to account for the not-submetered electricity that is directly fed to the grid. Next, an Auto-regressive with eXogenous input (ARX) model is fitted on the selected time series data, utilizing the 'lm' function in R-Studio:

$$\varphi_i(B) \cdot T_{i,t} = \omega_e(B) \cdot T_{e,t} + \omega_n(B) \cdot T_{n,t} + \omega_{sol}(B) \cdot I_{sol,t} + \omega_H(B) \cdot (\varphi_{H,t} + \varphi_{int,t}) + Int + \varepsilon_t \quad (4)$$

with  $T_i$ ,  $T_e$ ,  $T_n$ ,  $I_{sol}$ ,  $\varphi_H$  and  $\varphi_{int}$  the previously determined variables, resampled to hourly values, and  $\varphi_i(B)$  an input polynomial of order  $p_i$  in the backshift operator  $B$ . Likewise, the  $\omega_x(B)$ 's are output polynomials of order  $p_x$ .  $Int$  is a constant intercept term and  $\varepsilon_t$  the residual (error) (Madsen, 2016).

To decide on the model order, a backward elimination procedure is followed, starting from a model including 24 lags for each of the considered polynomials. After every run, the significance of the fitted model coefficients is verified using a t-test (threshold of  $p < 0.05$ ), starting with the highest available order. When coefficients of a certain order prove insignificant, their variables are eliminated from the model description and the model is refitted. The iterative process ends when all model coefficients present are significant.

To validate the developed models, it is verified whether their residuals resemble white-noise in plots of the autocorrelation function (ACF) and cumulated periodogram (CP). By comparing the normalized RMSE (nRMSE) [%] between the measured interior temperature and its one-step-ahead prediction for both the training and a validation period, it is checked whether the model is not overfitted.

If the model is accepted, HLC is calculated as the quotient of steady-state gains  $\omega_e(1)/\omega_H(1)$ . Finally, the models are compared based on (1) their score for the Akaike Information Criterion (AIC) and (2) the nRMSE between the observed and simulated interior temperature for the cross-validation periods. For both criteria, a lower value indicates a better model.

## RESULTS ANALYSIS AND DISCUSSION

### Differences between the gas consumption for SH estimated by the DMs

Table 1 compares the decomposition of gas consumption for SH and DHW production obtained through the different approaches. The default method (DM1) almost always results in a higher gas consumption for SH than DM2 and DM3. The method with the robust kernel smoother (DM3) uses a certain threshold instead of selectively classifying the gas consumption as either gas consumption for SH or production of DHW as DM2 does. This way it appears to systematically obtain a lower gas consumption for SH.

Table 1: Total gas consumption [kWh] and the gas consumption for SH as estimated by the four approaches [expressed as a percentage of the total gas consumption], per month.

	Oct 2014	Nov 2014	Dec 2014	Jan 2015	Feb 2015	Mar 2015
Total gas consumption	188 kWh	286 kWh	486 kWh	526 kWh	428 kWh	267 kWh
No decomposition	100 %	100 %	100 %	100 %	100 %	100 %
DM 1	76 %	76 %	76 %	76 %	76 %	76 %
DM 2	58 %	69 %	74 %	77 %	74 %	59 %
DM 3	44 %	55 %	62 %	63 %	59 %	45 %

### Validation of developed ARX models

Given the applied model selection procedure, all finally included parameters of the 8 models (4 variants for  $\varphi_H$  times 2 scenarios for  $\varphi_{int}$ ) are significant. Except for the models with  $\varphi_H$  based on DM2 or DM3 and  $\varphi_{int}=0$ , the interior temperature of the neighboring dwelling appeared to be an insignificant model input, probably because of a nearly constant profile of  $T_n$ . For the

other validation tests, the results were positive for all models: the nRMSE did only increase with about 1 % for the one-step-ahead cross-validation test, and the ACF and CP plots indicated white noise residuals. All models thus appear to be statistically valid.

### Comparison of resulting HLC

Figure 1 shows the impact of the applied gas decomposition method on the HLC estimate, and this for the two different  $\varphi_{int}$  scenarios. The models appear to yield fairly different results, with 95 % confidence intervals that do not all overlap. In the case of  $\varphi_{int} = 0$  the mean estimates range from 47 to 71 W/K, which is a difference of 33 %. The assumption that the internal gains equal the (approximated) total electricity consumption not only slightly reduces the uncertainty on the outcomes, but also lowers the impact of the choice for a certain DM (maximal difference of 25 % between the means). Nonetheless, the mean outcomes for DM2 and DM3 still differ with 14 %. Notably, the observed deviances are dwelling and occupant specific. In the case of a less-insulated dwelling with a lower DHW consumption and higher setpoint temperature of the heating system, the sensitivity of the characterization result to the applied DM may be lower.

The majority of the estimates fall above the calculated reference value, suggesting that the actual HLC is higher. As neither DM2 nor DM3 has yet been validated and the information available on the boiler is limited, it is impossible to claim that one of the HLC outcomes

Figure 1: Overview of the HLC estimates and their related 95 % confidence intervals for the different models. The dashed line indicates the theoretically calculated reference value.

Table 2: Comparison of the different models based on the AIC and nRMSE between the measured ( $T_i$ ) and simulated ( $\hat{T}_i$ ) interior temperature.

	AIC	nRMSE( $T_i, \hat{T}_i$ ) [%] for validation periods in:		
	Training period	Jan '14	Jan-Feb '14	Feb-Mar '14
$\varphi_{int} = 0$				
No decomposition	-4319.60	24.52	18.59	33.62
DM 1	-4316.53	24.51	18.62	33.69
DM 2	-4585.14	14.07	10.13	14.72
DM 3	-4515.00	18.10	17.25	16.76
$\varphi_{int} > 0$				
No decomposition	-3415.77	35.74	28.44	43.49
DM 1	-3390.58	43.01	34.22	48.54
DM 2	-3558.96	22.05	16.04	23.96
DM 3	-3548.66	26.94	26.75	30.34

is correct. However, some conclusions can be drawn from a statistical point of view. When comparing the models' AIC and their nRMSEs for the simulation validation periods (Table 2), we see that the models with  $\varphi_{int}=0$ , and the models where DM2 (and DM3) are applied, are better capable of predicting the interior temperature. The more accurate predictions on cross-validation data may indicate more correct input data and a more accurate model structure, and are therefore argued to be a reason for favoring the outcome of those models.

## CONCLUSION

The present paper explored how the HLC of a building envelope can be characterized based on on-board monitoring data. The focus was on the sensitivity of the characterization outcome to the preciseness of the knowledge on the supplied net heating power. This way the paper aimed to address the common problem that the two end-uses of gas (SH and DHW) are not submetered. By means of a case study, diverse approaches to approximate the unknown gas consumption for SH were illustrated. It was uncovered how, depending on the approach used, the HLC outcome can be 33 % apart. Uncertainty regarding other variables involved, e.g. the internal gains, furthermore influences this result. Since the applied gas decomposition methods have not yet been validated, the 'correct' characterization outcome could not be identified. However, based on statistical model comparison tests, suggestions on the trustworthiness of the outcomes were given. Submetering the gas consumption would, however, clear all doubts and increase the accuracy of the outcome. In next steps the applied decomposition techniques should be validated and the sensitivity of the HLC estimate towards assumptions on other variables (e.g. the system efficiency, interior temperature, incident solar radiation) should be explored.

## Ventilation Potential Assessments for Residential Building Arrangements Based on Exceedance Probability Analysis

Wei You<sup>1</sup>, Lian Tang<sup>1</sup> and Wowo Ding<sup>1,\*</sup>

### ABSTRACT

In this study, the building ventilation potentials were assessed at building group level. Exceedance probability analysis was applied to estimate the uncertainties associated with the influence of climate on wind environment. The criterion was proposed based on building facade pressures. Two typical residential building arrangements were investigated. Simulation results show that facade pressure based exceedance probability are efficient in assessing the natural ventilation potentials of building groups and building height variations are important for improving building natural ventilation potentials.

### KEYWORDS

Residential buildings, Ventilation potential, Exceedance probability, Facade wind pressure.

### INTRODUCTION

Natural ventilation is a common adopted passive building design strategy. It can improve indoor thermal comfort and air quality by removing excess heat and airborne contaminants. Optimizing building natural ventilation design is not only related to building façade opening size and location, but also refers to the arrangements of buildings. Thus, the assessments of natural ventilation potentials require an investigation at building group level.

For building natural ventilation, wind pressure distribution of building facade is an important boundary condition, as wind is the driving force. Many studies had investigated the indoor natural ventilation in terms of wind pressures for building groups. Tsutsumi et al. (1992) experimentally studied the wind pressure on a building surrounded by a group of buildings. The relations between average wind pressure coefficients and various layouts of buildings are discussed under different wind conditions. Similar studies were also carried out by Kim et al. (2012) and Shirzadi et al. (2018). In addition, Asfour (2010) investigated the effect of building layout patterns on ventilation potential of these buildings. Six hypothetical arrangements of buildings were assessed by calculating wind pressure difference. Bady et al. (2011) carried out wind tunnel experiments to study wind pressure characteristics on groups of buildings located within high density building arrays. The results all show that buildings configuration and wind direction are important factors in determining urban ventilation. However, most studies had investigated single building under typical wind directions.

For wind environment evaluation considering the uncertain upper wind parameters, some researches introduced the probability analysis into wind performance studies. This method estimates the probability of ventilation performance satisfying certain criteria. In past researches, probability analysis had most been applied in investigation of pedestrian-level wind environment, generally focusing on wind comfort/safety issues (Blocken and Persoon, 2009; Du et al. 2017). Recently, several researchers had introduced the probability concept into other wind performance area. Pietrzyk (2008) developed a probabilistic model and

studied the problem of air infiltration in low-rise buildings. Bu et al. (2009) analyzed the exceedance probability of local air change rate and local kinetic energy for investigating the ventilation performance and thermal comfort within urban street canyons.

This study attempted to introduce probability concept into wind-driven natural ventilation area for valuating natural ventilation potentials of building groups. Exceedance probability was calculated in terms of wind pressure on building facades. Two typical residential building arrangements, namely multi-story buildings and high-rise buildings, were adopted as the evaluation objects. The cases were located at a typical southeast monsoon wind city - Nanjing. And residential building units were investigated for natural ventilation potentials. To calculate building facade pressures, computational fluid dynamics (CFD) method with ANSYS-Fluent was adopted. The exceedance probabilities were post-processed by MATLAB and ArcGIS.

### RESIDENTIAL BUILDING GROUP CONFIGURATION

A 3 x 3 building group were built for building arrangement analysis. The central group (CG) was the analysis unit, and surrounding units (SG) were arranged around the studied area as environmental conditions, as shown by Figure 1a. Road widths (Sr1, Sr2) were determined as 30m according to design code. Two residential building types were established for case comparison (Figure 1b-c). Case A was multi-storey building group (building height  $H=18\text{m}$ ), and Case B was high-rise building group ( $H=36\text{m}$ ). Building widths  $L$  and depth  $D$  were determined as 72 and 12m, respectively. Lateral spacing  $S$  were 12m, and north-south spacing was 24m and 48m for multi-storey and high-rise building group. Figure 1d shows the data extracted zones for probability calculation and comparison. W1-W6 numbered the south and north facade of living units. W0 and W7 numbered the east and west facade of living units. For vertical partition, multi-storey building was divide into three part, which represent the living unit at low, middle and high levels, and high-rise building was divide into six levels.

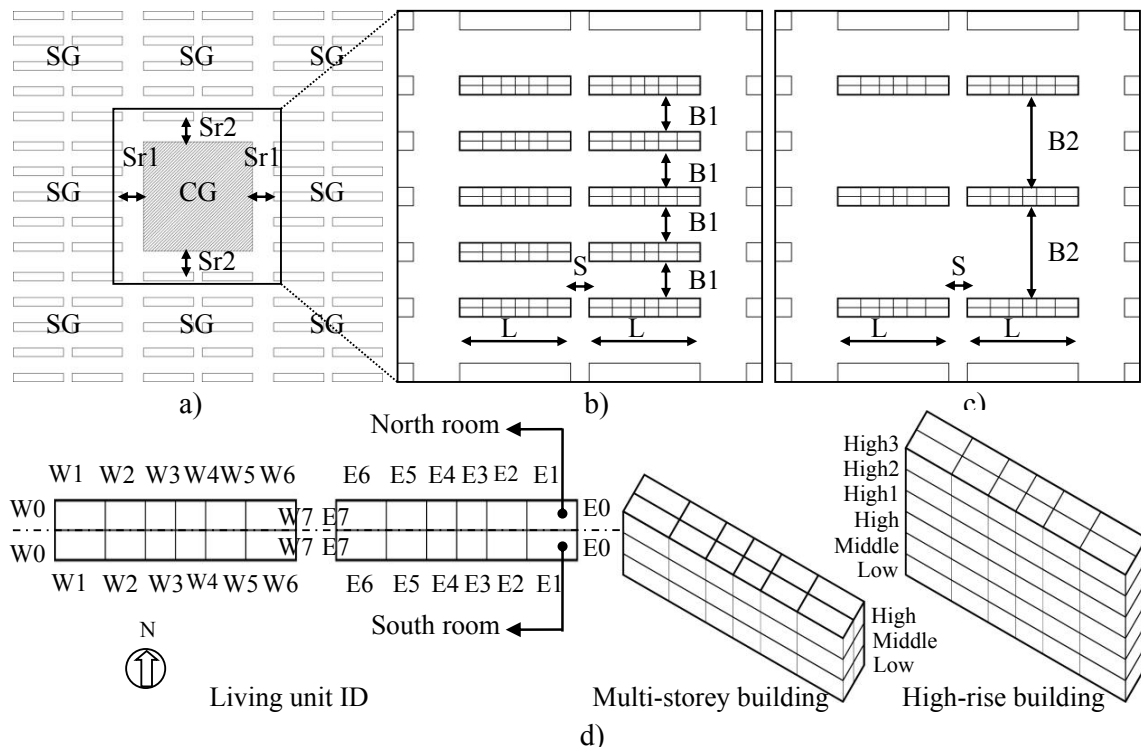

Figure 1. a) Building groups setting, b) Case A, c) Case B, d) Data extracted zones

### EXCEEDANCE PROBABILITY CALCULATION FOR VENTILATION POTENTIALS

The exceedance probability based building ventilation assessment consisted of three parts, as shown in Figure 2. The first part was the base data collection, which include weather data, building geometry data and wind flow data. The second part was MATLAB based data processing. In this step, wind data and façade pressure data were extract from the weather file and simulation results. Exceedance probability for each building façade were calculated by processing façade pressure data. At last, building façade geometry and the corresponding probability data were linked and by ArcGIS's spatial join tool for further ventilation potential analysis. The probability distributions were also visualized for each studied surface.

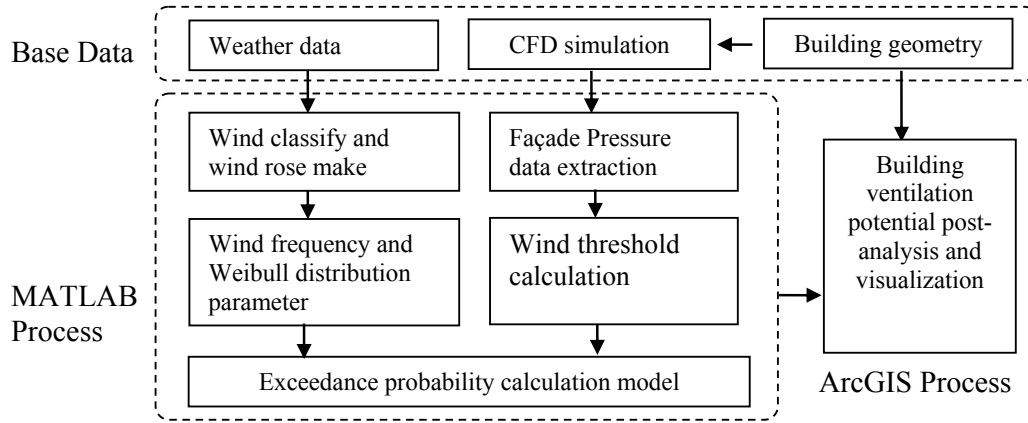

Figure 2. Flow chart of exceedance probability calculation

#### Base data obtaining

The wind climate of Nanjing was obtained from calibrating the hourly wind data of the solar and Wind Energy Resource Assessment (SWERA) weather file, which were download from EnergyPlus Weather Data (EPW) website. Building façade pressure data were obtained from CFD simulation results. The study referred to the AIJ (Architectural Institute of Japan) guidelines (Tominaga et al. 2008). For turbulence model selection, the Reynolds-Averaged Navier-Stokes (RANS) approach with standard  $k-\varepsilon$  model was adopted in this study due to its less time consumption and less complexity in boundary condition setting.

#### Exceedance probability calculation

The pressure based exceedance probability ( $P_g$ -EP) at each point above building facade was assumed to follow a two-parameter Weibull distribution in this study. And the  $P_g$ -EP for 12 azimuths was calculated as follow:

$$P(P_g > P_g^*) = \sum_{i=1}^{12} A(i) \exp \left[ - \left( \frac{\sqrt{P_g^*}}{R \cdot C(i)} \cdot \left( \frac{H_{met}}{\delta_{met}} \right)^{\alpha_{met}} \right)^{k(i)} \right] \quad (3)$$

$$R = \frac{\sqrt{\text{abs}(P_g)}}{V_{ref}} \cdot \left( \frac{H}{\delta} \right)^{\alpha} \quad (2)$$

Where  $P(P_g > P_g^*)$  is the probability of exceeding the specified  $P_g^*$ .  $i$  is the wind direction number, and  $A(i)$  is the occurrence frequency, and  $K(i)$ ,  $C(i)$  are two parameters of Weibull distribution.  $P_g$  is the façade pressure extracted from CFD simulation results.  $V_{ref}$  is the

reference up wind speed at the height  $H$ .  $\alpha$ ,  $\alpha_{\text{met}}$ ,  $\delta$  and  $\delta_{\text{met}}$  are the wind speed profile exponent and boundary layer thickness of the studied building located terrain and the weather station located terrain.  $H_{\text{met}}$  is the wind measured height at the the weather station.

## RESULTS AND DISCUSSION

Figure 3 showed the distributions of exceedance probability percentage ( $P_g$ -EP) on building facade for multi-story and high-rise buildings. In subplot (a)-(b), the facade  $P_g$ -EP distribution were viewed from southeast and in subplot (c)-(d), the  $P_g$ -EP distribution were viewed from northeast. The natural ventilation potentials of the building groups were clearly revealed by the  $P_g$ -EP distribution on each building facades. High-rise buildings obviously improved the building natural ventilation potentials, comparing with that of multi-story buildings. The variation range of  $P_g$ -EP was between 30% and 70% for high-rise buildings, while between 20% and 60% for multi-story buildings. For high-rise building group, the more ventilation living units were located at the first (south) and third (north) row, which the  $P_g$ -EPs of first row building's south facade (Figure 3b) and the third row building's north facade (Figure 3d) were almost above 60%. It was because the surrounding buildings were multi-story buildings, which wind can directly reach the up part of the high-rise building facades. For the multi-story building group (Figure 3a) and the middle row high-rise buildings (Figure 3b), the more ventilation living units were located at the building's eastside. It was due to effect of southeast monsoon in summer. Due to the recirculation flow phenomenon, the middle level  $P_g$ -EPs of the multi-story buildings' north facade increase (Figure 3c). It revealed the ventilation potentials of north living units at the third and fourth storey building are improved.

Figure 3. Distributions of the exceedance probability percentage on building facades.

More detailed quantitative analysis of natural ventilation potentials of the building groups was shown in Figure 4 and Figure 5. Figure 4 were the  $P_g$ -EP comparison of different height level residential units for multi-story and high-rise buildings. From the figure, it can be found that for the multi-story building group, the  $P_g$ -EPs were all below 50% (Figure 4a). And the natural ventilation potentials of low, middle and high levels of high-rise building units all increased, with  $P_g$ -EP around 50% (Figure 4b). It was due to the strengthen of air flow by the

upper facade of the high-rise building. The natural ventilation potentials of higher levels (high1 high2 and high3) of high-rise buildings were improved greatly due to the less effect of surrounding buildings. The  $P_g$ -EPs of these areas were all generally above 50% (Figure 4c). In terms of the positions of residential units at one storey, ventilation potentials of side units are better than that of middle units, and ventilation potentials of east side units are better than that of west side units. It is more obviously reflected within the multi-story building group. Figure 5 shows the  $P_g$ -EPs of south and north units for multi-story and high-rise buildings. The simulation results showed that  $P_g$ -EPs of north units were slightly better than that of south room for multi-story building. It was due to the turbulence flow, which acted on the north facade of the multi-story residential building, which discussed above.

Figure 4. Comparison of different living-unit levels for multi-story and high-rise buildings.

Figure 5. Comparison of living-unit facade directions for multi-story and high-rise buildings.

## CONCLUSIONS

This paper provided a simple method to assess building group's natural ventilation potentials considering the effect of local wind climate. The cases studies show that, by calculation the exceedance probability of wind pressure on building facades, the natural ventilation potentials of building group can be revealed for each living units. Two typical residential building arrangements were investigated using the façade pressure based exceedance probability. Simulation results show that high-rise buildings could obviously improve the building's natural ventilation potentials by increasing  $P_g$ -Eps of around 20%, comparing to that of the same levels (1-6 storey) of multi-story buildings. In southeast monsoon regions, the ventilation potentials of eastside living units is indeed improved especially for multi-story buildings. The  $P_g$ -Eps could increase by about 10%. And the ventilation of north façade living units could also be beneficial by the turbulence flows.

This study is a preliminary test of using façade pressure based exceedance probability as an indicator for assessing of building natural ventilation potentials. Only two typical residential building groups were investigated. In the following study, more building arrangement cases will be evaluated to provide design strategies for architects.

## ACKNOWLEDGEMENT

The project is supported by the National Natural Science Foundation of China (Nos.51508262 and 51538005).
