<b>Keynotes</b>	<b>1</b>
Dynamic Environment, Adaptive Comfort, and Cognitive Performance (497)	1
Green Infrastructure and Urban Sustainability Recent Advances and Future Challenges (499)	7
Humans and Nature in the Loop (498)	17
Multiphysics Modeling of Materials, Assemblies, Buildings and Cities (496)	25
The Physics in Natural Ventilation of Cities and Buildings (501)	35
<b>BE-1 Diagnostics and Models for Building Performance</b>	<b>37</b>
A state-space based method to predict thermal performance of pipe-embedded double skin façade case study in Guangzhou (115)	37
Computer Tomography as a data acquisition tool for quantifying and modeling in-pore gypsum crystallization in building materials (84)	43
Determination of the input data for computational simulation of active glazing with changeable optical properties (92)	49
Predicting the thermal conductivity of porous building materials with nanopores or reduced gas pressures (80)	55
Rational selection of experimental readouts for hygric material characterisation (197)	61
Towards validation of a numerical model of a test cell laboratory (362)	67
<b>BE-2 Liquid Water in Buildings and Materials</b>	<b>73</b>
Adsorption and film forming of train of water droplets impacting porous stones (373)	73
Application of rain intensity dependent rain admittance factor (RAF) in hygrothermal performance assessment of wall systems (202)	79
Do interface resistances matter in historic masonries - analysis based on X-ray tomography and heat, air and moisture modelling (33)	85
Drainage and retention of water in small wall drainage cavities experimental assessment (253)	91
Rain-tightness of door sill sealing (95)	97
Water uptake in masonry effect of brickmortar interface (216)	103
<b>BE-3 Innovative Thermal Insulation Systems</b>	<b>109</b>
Aerogel-enhanced blankets state-of-the-art, market readiness and future challenges (106)	109
Hygrothermal analysis of a vapour-open assembly with vacuum insulation panels (440)	115
Measurements of temperature dependency on thermal insulation thickness in ventilated attics (199)	121
Prediction of the long-term performance of vacuum insulation panels installed in real building environments (342)	127
Super insulation material in district heating pipes (187)	133
Super insulation materials in the building sector field studies and future challenges (206)	139

<b>BE-4 Moisture in Buildings and Materials</b>	<b>145</b>
Effect of air pressure on moisture transfer inside porous building materials three-dimensional behavior of moisture and air (116)	145
Evaluation of the impact of phase change humidity control material on energy performance of office buildings (167)	151
Experimental analysis of micro-cracks on the change of moisture transport properties of AAC (37)	157
Moisture monitoring of wood-frame walls with and without exterior insulation in a Midwestern U.S. cold climate (428)	163
Psychrometer method to measure the moisture retention curves of porous building materials in the full humidity range (59)	169
Semi-permeable membrane experiment for unsaturated liquid permeability of building materials potential and practice (58)	175
<b>BE-5 Ventilation Systems for Buildings</b>	<b>181</b>
Experimental analysis on a solar air heating façade system (235)	181
Experimental validation of a model for naturally ventilated double-skin facades (465)	187
Hygrothermal assessment of north facing, cold attic spaces under the eaves with varying single sided passive ventilation strategies and infiltration rates, in a cool, temperate climate (223)	193
Hygrothermal performance of sealed attics in climate zone 3A (446)	199
Moisture robustness of eaves solutions for ventilated roofs – experimental studies (331)	205
Thermal performance of novel natural ventilation apertures in a high-performance single-family house (240)	211
<b>BE-6 Hygrothermal Performance and Mold Prevention</b>	<b>217</b>
Application of radiant floor heating in large space buildings with significant cold air infiltration through door openings (131)	217
Evaluating the hygrothermal performance of wooden beam heads in 19th century town houses using in-situ measurements (419)	223
Experimental investigations of wooden beam ends in masonry with internal insulation results contrasting three years of the experiment (405)	229
On the hygrothermal behaviour of brick veneer clad timber frame walls the role of the vapour diffusion resistance of the wind barrier (123)	235
Performance evaluation of a highly insulated wall to withstand mould (208)	241
Renovation with internal insulation and heat recovery in real Life – energy savings and risk of mold growth (93)	247
<b>BE-7 Energy Retrofits for Building Envelopes</b>	<b>253</b>
A sustainable approach to the adaptive reuse of historic brick buildings analysis of energy efficiency	

strategies for historic facade retrofits (433) .....	253
Experimental investigation of latent heat thermal energy storage for highly glazed apartments in a continental climate (13) .....	259
Interior insulation retrofit of a brick wall using super insulation materials design of a field testing in an industrial brick building (99) .....	265
Light transmissibility characterization of a new coating for window retrofit (444) .....	271
Monitoring and modelling of a prefabricated exterior envelope retrofit (474) .....	277
Retrofit of the existing buildings using a novel developed aerogel-based coating results from an in-field monitoring (277) .....	283
<b>BE-8 High Performance Building Envelope Systems .....</b>	<b>289</b>
Comparing exterior wall finishes using life-cycle assessment (372) .....	289
Experimental study of the performance of a double skin façade window under non-solar conditions (65) .....	295
Hygrothermal performance assessment of wall systems with various concrete and insulation configurations (194) .....	301
Preparation and thermal performance of diatomite-based composite phase change materials wallboard (175) .....	307
Study of the mechanical behavior of traditional Japanese mud wall on bamboo lath (272) .....	313
Thermal stability of lightweight frame partitions exposed to pulsed wind load (41) .....	319
<b>BE-9 Innovations in Wood .....</b>	<b>325</b>
Determination of lead dust fall rates during deconstruction of wood frame buildings in an urban region in the Northeastern United States. (317) .....	325
Hygrothermal performance of a hygroscopic and permeable wall assembly impact of a vented wall cavity (468) .....	331
Improving durability of wooden beam bearings in inside insulated walls by tempering the beam's heads (407) .....	337
Sorption hysteresis in wood and its coupling to swelling a new modeling approach (369) .....	343
The effects of production technologies on the air permeability properties of cross laminated timber (410) .....	349
Understanding swelling of wood through multiscale modeling (395) .....	355
<b>BE-10 Solar Energy Harvesting and Management .....</b>	<b>361</b>
A transparent insulation solar façade coupled with a selective absorber an experimentally validated building energy simulation model (300) .....	361
Power generation and visual comfort performance of photovoltaic toplighting technologies in transient spaces (255) .....	367
Solar and lighting transmission in complex fenestration systems with perforated solar protection	

systems (436).....	373
Solar efficiency index of building envelopes and load matching in low energy buildings (215) .....	379
Study on the design method of integration of roof and photovoltaic based on aesthetics, technology and energy-saving characteristic (130) .....	385
Thermal performance of PCM-glazing unit under moderate climatic conditions (38).....	391
<b>EC-1 Environmental Control Equipment and Systems .....</b>	<b>397</b>
A deep reinforcement learning method for model-based optimal control of HVAC systems (66).....	397
Air cooling and dehumidification with a zeolite coated heat exchanger regenerated by solar thermal energy (352).....	403
Evaluating the energy consumption and heat loss in the hot water supply and heating systems of a nursing home (177) .....	409
Extracting radiant cooling from building exhaust air using the Maisotsenko-cycle principle (276) .....	415
Periodic alternation between intake and exhaust of air in dynamic insulation (328) .....	421
The energy saving performance of ventilation-heat-recovery system in residential buildings in the summer of hot-summer and cold-winter zone in China (145) .....	427
<b>EP-1 Residential Energy Analysis and Management .....</b>	<b>433</b>
Characterisation of the flexibility potential from space heating in French residential buildings (172).....	433
Evaluation of the impact of weather variability on a net zero energy building advantage of sensitivity analysis for performance guarantee (192).....	439
Numerical analysis of a ground-source heat pump system in traditional Japanese “Kyo-machiya” dwellings (166).....	445
Offsetting peak residential cooling loads using a medium temperature chiller and sensible cold thermal storage (181).....	451
Prosumer cluster of single-family houses under the Danish net metering policy (473).....	457
Visualizing the quantitative comparison between exergy & energy analysis results with ExFlow (198)...	463
<b>EP-2 Urban Energy Generation, Analysis and Management .....</b>	<b>469</b>
A review of microgrid energy systems (431).....	469
Impacts of climate change and its uncertainties on the renewable energy generation and energy demand in urban areas (146).....	475
Multi-stage optimal design of energy systems for urban districts (399).....	481
Novel gas-driven fuel cell HVAC and dehumidification prototype (244) .....	487
Optimization of electric vehicle charging in a fully (nearly) electric campus energy system (259).....	

.....	493
Studying the impact of local urban heat islands on the space cooling demand of buildings using coupled CFD and building energy simulations (386) .....	499
<b>GB-1 Environmental Design, Sensing and the Built Environment .....</b>	<b>505</b>
An implementation for transforming a home energy management system to a multi-agent system (174) .....	505
Bioclimatic tools for sustainable design – uncertainty perspective (422) .....	511
Campus as a lab for computer vision-based heat mapping drones a case study for multiple building envelope inspection using unmanned aerial systems (UAS) (285) .....	517
Optimal control strategies for passive heating and cooling elements reduce loads by two-thirds in the adaptive reuse of a San Francisco Bay Area office (153) .....	523
Sensing and information technologies for the environment (SITE); hardware and software innovations in mobile sensing applications (430) .....	529
<b>GB-2 Green Roofs and Vegetation .....</b>	<b>535</b>
Experimental study on the stomatal resistance of green roof vegetation of semiarid climates for building energy simulations (104) .....	535
Greening rooftops to reduce heat islands how large is large enough (402) .....	541
Integrated vegetation model for studying the cooling potential of trees in urban street canyons (338) ....	547
.....	547
The use of a large, extensive green roof for multiple research objectives (447) .....	553
Thermal performance of a green roof based on CHAMPS model and experimental data during cold climatic weather (423) .....	559
Using rain and vegetation to improve thermal comfort in a hot street canyon with fully-integrated urban climate modeling (376) .....	565
<b>GB-3 Urban Microclimates and the Heat Island Effect .....</b>	<b>571</b>
An investigate on the quantitative correlation between urban morphology parameters and outdoor ventilation efficiency indices (429) .....	571
Effect of urban texture on building energy performance (287) .....	577
New microclimate monitoring method and data process for investigating environmental conditions in complex urban contexts (231) .....	583
Rapid cooling of urban surfaces during rainfall physical basis, dominant energy fluxes, and sensitivity to pavement and rainfall prop (400) .....	589
Using advanced urban canopy models to investigate the potential of thermochromic materials as urban heat island mitigation strategies (283) .....	595
<b>HF-1 Office Buildings .....</b>	<b>601</b>
A picture is worth a thousand words Smartphone photograph-based surveys for collecting data on	

office occupant adaptive opportunities (81).....	601
Benchmarking the energy efficiency of office buildings in Belo Horizonte, Brazil (52).....	607
Exploring occupants' impact at different spatial scales (147).....	613

### ABSTRACT

Since the invention of airconditioning over 100 years ago a central research challenge has been to define the indoor environmental temperatures best suited for occupants. The first scientific approach to this question was framed in terms of *optimising occupant thermal comfort*, commonly expressed as a U-function, symmetrical around a single optimum temperature for any given combination of the remaining comfort parameters (ISO, 2005). The inescapable conclusion drawn from such logic in the minds of risk-averse design engineers is that the only strategy able to reliably deliver occupant comfort is HVAC applied to sealed-façade architecture.

A rigorous scientific rebuttal of the “single temperature optimum” model of comfort came 30 years after PMV/PPD was first floated (e.g. de Dear and Brager, 1998; 2001). Known as the *adaptive comfort model*, a clear implication is that passive design solutions are capable of delivering comfortable internal environments across a broad swathe of climate zones, throughout most if not all of the year. But recently the “single temperature optimum” model has resurfaced, this time with its justification shifting away from the thermal comfort requirements of occupants towards their cognitive performance.

Beyond the building science domain, in disciplines such as psychology and ergonomics, the prevailing wisdom regarding temperature effects on cognitive performance is an *extended-U* rather than an inverted U function. The gist of the model is that cognitive performance is relatively stable throughout the moderate temperature range, but it rapidly deteriorates at the boundaries of thermal acceptability where stress drains the performers’ attentional resources. The *extended-U* model has garnered broad acceptance across a range of disciplines with the notable exception of HVAC engineering and indoor air sciences. But the weight of research evidence tends to support the extended- rather than inverted-U model. In this paper the arguments regarding thermal effects on cognitive performance are critically evaluated.

### KEYWORDS

Cognitive performance, arousal theory, temperature optimum, adaptive model.

### INTRODUCTION

The effect of the thermal environment on performance and productivity has been a focus of interest among indoor environmental researchers for nearly a century, but most of that work has been conducted in relative isolation from the cognate disciplines of human performance evaluation. In his wide-ranging survey of the indoor environmental research domain Corsi (2015) observed that “... *indoor air scientists all too often work in narrow trenches, interacting primarily with those they have interacted with for years, content to dig more deeply into that of which they already have significant knowledge, and unaware of the*

*connections that their work may have to those who dig in other trenches.”* This insularity is clearly evident in cognitive performance research theme.

The range of indoor temperatures deemed acceptable has a strong bearing on building energy requirements because it constrains the geographic scope as well as the seasonal duration when *passive* designs are able to achieve acceptable indoor environments. Secondly, the design temperature range indoors directly impacts energy required by active systems (HVAC) to achieve them. Up until about the end of the last century the range of indoor design temperatures was mostly couched in terms of thermal comfort. Simple comfort models suggested that a range of  $\pm 1.5\text{K}$  around an invariant optimum temperature could ensure 90% occupant thermal acceptability (Fanger, 1970; ISO, 2005). However, more recent adaptive thermal comfort models have challenged these narrow temperature prescriptions with strong empirical evidence that indoor comfort temperatures are dependent on outdoor climatic conditions (e.g. de Dear and Brager, 1998, 2001). The adaptive comfort approach encourages warmer indoor temperatures in warmer climate zones and seasons, and *vice versa* in cooler climates and seasons. In response to this debunking of the comfort arguments HVAC peak bodies such as REHVA and ASHRAE have shifted their justifications for tight indoor temperature control away from occupant comfort towards occupant productivity (ASHRAE, 2013). Since these HVAC peak bodies exert a strong influence on air conditioning practices, HVAC-related energy and greenhouse gas emissions well beyond their European and North American jurisdictions, it behooves us to critically review the scientific evidence put forward in support of temperature effects on cognitive performance.

In this review we examine a broad collection of papers, all specifically examining the effects of thermal environment on cognitive performance, but from a variety of disciplinary perspectives *beyond* the indoor environmental sciences.

## LITERATURE REVIEW

Moderate indoor thermal environments are far from hyper- and hypo-thermic scenarios because they pose no threat to health and safety. Nevertheless they are still capable of exerting adverse impacts on building occupants' cognitive performance, although the literature remains conflicted on the significance of these impacts. Two distinct theoretical perspectives have emerged. The first posits a dose-response relationship between the indoor thermal environment and cognitive performance, with *any* deviation from thermal optimum leading to a decrement in performance and productivity. The second position asserts that, depending on the thermal intensity of exposure, type of cognitive activity, and other attenuating factors, externally imposed cognitive demands can be absorbed by the buffering capacity or “cognitive reserve” of the subject, with little or no deleterious effect appearing until those adaptive resources are depleted.

### The inverted-U model

*Arousal theory* (e.g. Duffy, 1962) has been ubiquitous in the stress literature. Alternatively known as the *Yerkes-Dodson law*, it postulates an *inverted-U relationship*. Performance of a particular task improves as arousal increases until reaching an optimal level for the task in question. Beyond this optimum, performance starts to decline when the arousal level continues to rise, and likewise with reductions below the optimal level of arousal. In regards to the effects of thermal environment on cognitive performance, the same inverted-U relationship has been assumed, substituting arousal level with the intensity of the environmental thermal load (e.g. Griffith and Boyce, 1971).

In the indoor environmental science domain, arousal theory and the associated inverted-U relationship, has held sway for several decades, judging by the number of citations it has received. Arithmetic relationships have been proposed by different researchers to quantify the performance decrement in percentage terms as room temperature (or thermal sensation) deviates from the single optimum. These functions have then been widely applied to cost-benefit analyses that trade off the costs of lost performance from the building's workforce against the costs of variations in building and building services design, retrofits, and operational facilities management practices. Seppänen and Fisk (2006) along with Seppänen et al. (2006) have emerged as the most influential studies in the indoor environmental science literature. Their meta-analysis collated 24 previously published studies, then fitted an inverted-U relationship to the summary data. The resulting model shows performance increasing as temperatures increased towards 21.6 °C, then decreasing in temperatures beyond 22 °C. The same inverted-U relationship is mirrored in the *American Society of Heating, Refrigerating, and Air-Conditioning Engineers' Handbook of Fundamentals* (2013), but instead of room temperature, as in Seppänen et al. (2006), the *ASHRAE Handbook* shows the x-axis as room temperature relative to the optimal comfort temperature  $T_c$  for the group. Despite the large variance in data points in the meta-analysis, *ASHRAE's Handbook of Fundamentals* graph shows a smooth parabolic curve for performance, peaking at the optimum comfort temperature (corresponding to “neutral” thermal sensation), and then tapering off as soon as room temperature deviates from neutrality (Figure 1).

Figure 1 Relative performance of office work vs. deviation from optimal comfort temperature  $T_c$  (adapted from *ASHRAE Handbook of Fundamentals*, 2013).

### The extended-U model

The extended-U model, initially proposed by Hancock and Warm (1989) and also known as the *Maximal Adaptability Model* contends that human performance remains relatively stable across a broad range, but rapidly deteriorates at the boundaries of thermal acceptability (Figure 2). Thermal stress exerts its adverse impacts on performance by consuming and ultimately depleting the performers' attentional resources (e.g. Kahneman, 1973). The normative zone falls in the middle of the continuum of input stress intensity, and it is here that zero compensatory effort is required of the participant in order for them to maintain optimal performance. The comfort zone encompasses broader conditions than the normative zone, but cognitive adjustments are easily accomplished within the comfort zone in order to maintain a

near-optimum level of performance. However, when the environmental stress exceeds the comfort zone, attentional resources begin to be depleted. At first, equivalent or even improved performance can still be achieved by psychological adaptive behaviours such as attentional focus. Because of the central role played by psychological adaptability this region is referred to as the psychological zone of maximal adaptability in Figure 2. When the stress level continues to increase, human performance deteriorates as attentional resources begin to be depleted, indicated by the dashed line at the boundary of the psychological zone of maximal adaptability.

The extended-U model has garnered broad acceptance and currency across a range of disciplines with the notable exception of HVAC engineering and the cognate indoor environmental sciences. It has been confirmed by several authoritative literature reviews on this topic, none of which were published in the HVAC engineering and building science outlets. For example, Ramsey (1995) performed a meta-analysis on 160 individual performance studies and concluded that mental or simple tasks would most likely undergo negligible performance loss in hot environments, and may even be enhanced, at least for exposures under two hours. For perceptual motor tasks other than mental tasks, performance decrements were discernible only beyond 30°C WBGT (approximately 32°C air temperature at 50% RH).

Figure 2 Extended-U model linking stress and performance (Hancock and Warm, 1989)

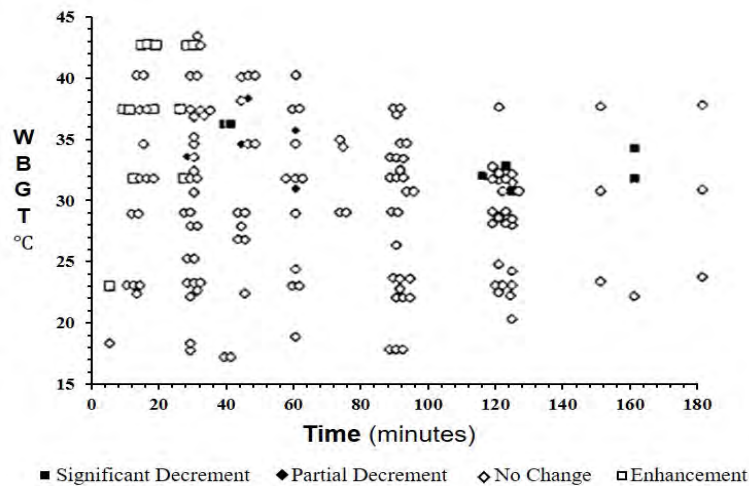

Figure 3 Mental or simple task performance under thermal stress (after Ramsay, 1995)

Another definitive meta-analysis by Pilcher et al. (2002) extracted 515 effects sizes from 22 original studies, and could find no effect of temperature on mental performance in the air temperatures ranging from 23-28.8°C at 50% RH. This meta-analysis provides some of the strongest confirmation of the extended-U model. In Hancock et al.'s (2007) meta-analysis of 49 separate studies providing 528 effect sizes, the original studies were classified into four effective temperature ranges: below 25.7°C, 25.7°C–29.4°C, 29.4°C–35.2°C, and above 35.2°C. It was found that, “... with the exception of the lowest temperature range, it is clear that the effect size variation sequentially increases across the three remaining categories. This gives rise to the proposition that performance is relatively stable over much of the temperature range but exhibits radical variation at the highest extreme ” (p.862) and this observation represents a core feature of the extended-U theory of stress and performance.

## CONCLUSIONS

Notwithstanding its overly simplistic concept and methodological flaws throughout its empirical bases, the inverted-U relationship has held sway in the indoor environment research literature on thermal environmental influences on cognitive performance and productivity. Moreover, it has permeated engineering practice, as reflected in design guidelines and handbooks published by HVAC peak bodies. The dose-response inverted-U model has been uncritically implemented across broad swathes of the world's commercial building sector. Enhancements in HVAC equipment and control technology over recent decades have facilitated ever-tighter tolerances on indoor temperatures around a speciously defined performance optimum. Scientifically illiterate tenants and their facility managers have begun specifying overly stringent temperature clauses in their commercial office space lease agreements under the mistaken belief that they will maximise productivity from their human resources. However, this multidisciplinary review conducted in this paper finds the evidence for the single-temperature optimum dose-response relationship between indoor environment and occupant performance less compelling, which calls into question the crude cost/benefit of productivity decrements prevalent in the indoor environmental and HVAC engineering

domains. Much stronger evidence in support of an extended-U relationship exists in literature published *outside* the usual for building science and indoor air fora.

## ABSTRACT

Although the majority of urban green infrastructure (GI) programs in the United States, and elsewhere, are being driven by stormwater management challenges arising as a result of the impervious nature of modern cities, GI is also believed to provide other benefits that enhance urban sustainability. This paper discusses the role that GI systems might play in urban climate adaptation strategies for cities like New York City, where increases in both temperature and precipitation are projected over the coming decades. Examples of work conducted by the author and colleagues in New York City to quantify the performance of urban GI are first presented. This work includes monitoring efforts to understand how extensive green roofs retain rainfall, reduce surface temperatures and sequester carbon. Next, a discussion of the advantages that a distributed, or neighborhood level, GI system might bring to a climate adaptation strategy is provided. The paper then concludes with an outline of some of the future work that is needed to fully realize the potential of urban GI systems to address future climate change impacts.

*Keywords:* Green infrastructure, distributed infrastructure, urban sustainability, stormwater management, climate adaptation

## 1. INTRODUCTION

The term *green infrastructure* (GI) was coined in 1994 as part of a greenway planning report that advocated for land conservation through a system of greenways, or *green infrastructure*, that were as well-planned and financed as traditional built infrastructure [1]. Since then, the term has been used by planners, designers, scientists, and engineers alike to describe networks of green space, including *natural areas* such as waterways and woodlands, and *built areas* such as parks and community gardens - all of which are widely considered to provide an array of services to humans and the environment [2], [3]. More recently, green infrastructure has gained attention as a means of improving urban stormwater management. This focus has given rise to a class of *engineered green infrastructure*, whose primary design purpose is to reduce urban stormwater runoff and pollution. Examples of *engineered green infrastructure* (GI) include green roofs, porous pavement, rain-gardens and rain cisterns. It is these green infrastructure types that are those most closely associated with GI programs to promote sustainable buildings, neighborhoods and cities. Examples of US cities where large investments in engineered GI are currently underway include Philadelphia (\$2.4 billion), New York City (\$1.5 billion), Chicago (\$50 million), and Cleveland (\$42 million) [4]–[6].

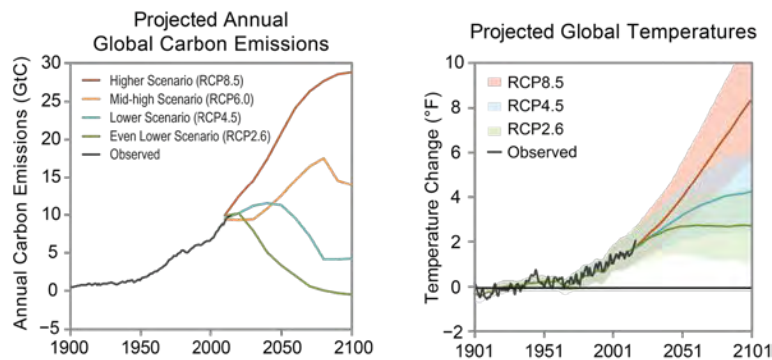

Although the majority of urban GI programs in the US, and elsewhere, are being driven by stormwater management challenges arising as a result of the impervious nature of modern cities, GI is also believed to provide other benefits that advance urban sustainability. By increasing vegetation and perviousness within city boundaries, it is claimed that GI can help cool urban environments, thus reducing urban heat island impacts [7], trap harmful air-borne

particulates [8], sequester greenhouse gases [9], increase and/or restore urban biodiversity [10], improve public health and well-being [11], [12] and even create so-called “green collar jobs” [13], [14]. Thus, many GI programs are promoted not only on the basis of their stormwater management goals, but also on the basis of these claimed co-benefits.

The goal of this paper is to examine some of the advantages and hurdles associated with green infrastructure programs for urban sustainability. The paper will do so by using climate adaptation as an example urban sustainability challenge. In order to focus the paper, New York City (NYC) will be used as a case study. Nonetheless, many of the discussions and conclusions reached in the paper are also relevant to other urban settings, as well as other sustainability challenges.

## 2. CLIMATE CHANGE IMPACTS

Current climate change projections involve significant uncertainty, not least because scenarios for future green-house gas emissions are unknown. For high emissions scenarios (RCP8.5), mean global temperature rise is projected to be about 4°C (~ 8°F) over the course of the 21<sup>st</sup> Century, Figure 1, while mean global sea-level rise is projected to be about 2.5 meters (~ 8 feet), Figure 2. Local sea-level and temperature rises are projected to be above or below the mean global levels shown in Figures 1 and 2, depending upon the region under consideration.

**Figure 1.** Past and projected changes in global mean temperature rise under different emissions scenarios, from [15].

**Figure 2.** Past and projected changes in global mean sea level rise under different emissions scenarios, from [15].

Nonetheless, despite uncertainties in the projected magnitude of climate change effects, there are general trends that climate scientists and others agree upon. These include a raise in sea-levels; an increase in temperatures; changes in the patterns and amount of precipitation; a decline in snow-cover, permafrost and sea-ice; acidification of the oceans; an increase in the frequency, density and duration of extreme events, and a change in eco-system characteristics. These effects will negatively impact water resources, infrastructure, food supplies and eco-systems, as well as human health and well-being. Given the rapid pace of urbanization, adaptation to climate change impacts is especially important for the world's cities, which are expected to house 66% of the world's population by 2050 [16].

### *2.1 New York City Temperature and Precipitation Changes*

In New York City, historic trends over the past 110 years indicate an increase in both the average temperature and annual precipitation, as recorded at the Central Park Meteorological Station [17]. From a baseline of the year 2000, projected climate change scenarios for a mid-range of emissions scenarios indicate temperature rises of up to 3°C and precipitation increases of up to 11% by the 2050s [18]. These increases will only intensify the present day challenges New York City faces with respect to its stormwater management issues [19] and mitigation of the urban heat island effect [20].

## **3. NEW YORK CITY GREEN INFRASTRUCTURE PLAN**

In 2010, New York City (NYC) released the NYC Green Infrastructure Plan, which is a multi-decade, multi-billion-dollar plan to improve water quality in the City via the introduction of engineered interventions such as green roofs, right-of-way bioswales, green streets and urban street-trees into NYC's impervious landscape [19], Figure 3. By increasing the amount of vegetation in the City, the NYC Green Infrastructure plan aims to allow precipitation to be soaked up locally, thereby reducing contamination of local water bodies and also incidents of rain induced flooding.

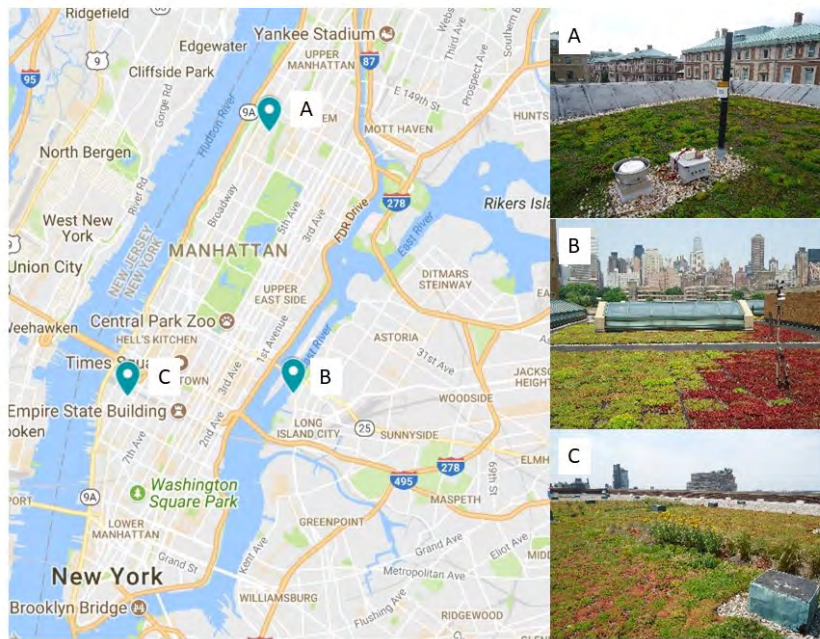

**Figure 3.** a) Green roof on a Columbia University building, and b) Right-of-way bioswale in the Bronx, New York City. Image (a) courtesy of Stuart Gaffin, Columbia University. Image (b) courtesy of Nandan Shetty, Columbia University.

### 3.1 Green Infrastructure Performance Monitoring in New York City

Over the past decade, the author and her colleagues have been researching the performance of green infrastructure in NYC from the vantage point of multiple sustainability metrics [21]–[32], including those relevant to climate adaptation. In the following paragraphs, some example findings are provided for the performance of a common building level GI intervention, namely green roofs.

The two major green roof categories include extensive green roofs, whose substrates are typically 15 cm thick or less and feature short rooting, drought resistant plants such as *sedum*, and intensive green roofs, whose substrates are greater than 15 cm thick and may be sowed with deeper rooting plants including shrubs and trees. Due to their lower cost, reduced maintenance requirements, and lighter weight per unit area, extensive green roofs are more frequently adopted than their intensive counterpart [27]. For this reason, the majority of green roof studies engaging the author and her colleagues involve extensive green roofs. Figure 4 provides the location of three of these extensive green roofs, each of which encompasses a popular construction type. W118 is a Xero Flor America XF301+2FL *vegetated mat system* with a substrate depth of 32 mm, ConEd is a GreenGrid-G2 *modular tray system* with a substrate depth of 100mm, while USPS is a Tecta Green *built-in-place system* with a substrate depth of 100mm. All three roofs are planted with *sedum* species. Monitoring of green roof performance began in 2009 and has been almost continuous since then. Further information on the characteristics of each green roof, monitoring equipment and set-up can be found in [21].

**Figure 4.** Locations and rooftop views of the W118 (A), ConEd (B) and USPS (C) green roofs, respectively. Map data retrieved from Google Maps (Google Chrome 2018).

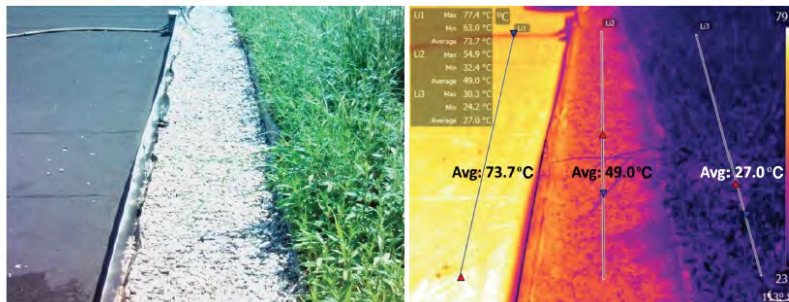

Figure 5 summarizes stormwater retention values by storm size category for the three extensive green roof types. As would be expected, green roof rainfall retention reduces with increasing storm depth. Nonetheless, even for largest of storms (50mm +), rainfall retention is

30% or more of incident rainfall. In general, the thinner W118 green roof under-performs with respect to rainfall retention in comparison to the thicker ConEd and USPS systems. Since July 2011, the date when vegetation on all three roofs was considered fully established, the observed annual retention of the W118, ConEd and USPS green roofs has been 45.9%, 50.7% and 56.5%, respectively.

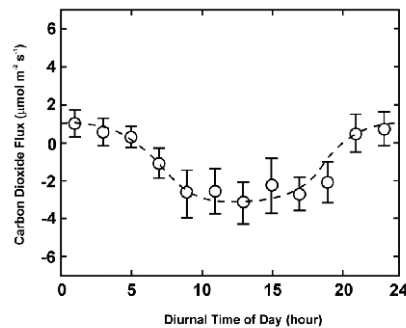

**Figure 5.** Green roof stormwater retention performance for the W118, ConEd and USPS *sedum* green roofs for different storm event categories.

Green roofs achieve air temperature reductions by transforming adsorbed sunlight into water vapor through evapotranspiration (ET), also termed latent heat loss. White or “cool” roofs, which achieve a high reflection of sunlight, are an alternative to green roofs for air temperature reduction. Temperature data collected over a period of a year from the ConEd green roof and nearby white and black roof treatments, show that white roof and green roof temperatures are actually fairly close, except during summer wet periods when the efficiency of latent heat loss lowers the green roof temperatures significantly below that of the white roof [33]. An illustration of the surface temperature differences that are possible between black, white and green roof areas are shown in Figure 6. It is the observation of large, surface temperatures differences like those shown in Figure 6 (e.g., a different of 46°C between the black and green roof surfaces) that has spurred interest in the use of vegetated GI to moderate extreme heat in urban spaces.

**Figure 6.** Standard (left) and Infra-red (right) photographs of an NYC based rooftop comprising black, white and green surfaces. Image courtesy of Stuart Gaffin, Columbia University.

Figure 7 provides measurements of diurnal surface-atmospheric CO<sub>2</sub> fluxes for the W118 green roof taken during the month of April. The data show the green roof to be a source of CO<sub>2</sub> during night-time hours (0 – 5am, and 9pm to midnight) and a sink during daylight hours. Overall, the calculated net ecosystem exchange (NEE) of CO<sub>2</sub> for the measurements shown in Figure 7 is -116.5 g CO<sub>2</sub> m<sup>-2</sup> month<sup>-1</sup>, or -31.8 g C m<sup>-2</sup> month<sup>-1</sup>. This value is very similar to values reported for an extensive sedum green roof located in Berlin, Germany during the Spring growing season [34]. The authors of [34] report an annual, cumulative NEE of -313 g CO<sub>2</sub> m<sup>-2</sup> year<sup>-1</sup>, equivalent to -85 g C m<sup>-2</sup> year<sup>-1</sup>, for the green roof that they studied. For comparison [35] estimate a NEE value of -7.33 kg C m<sup>-2</sup> year<sup>-1</sup> associated with carbon storage and sequestration of the NYC urban tree cover, where area refers to the canopy area, which was obtained from aerial photographs taken during a leaf-on state.

**Figure 7.** Measured values of CO<sub>2</sub> surface-atmospheric exchange during the Spring growing season for W118.

### 3.2 Green Infrastructure and Climate Adaptation

Like many other municipal green infrastructure plans, the NYC Green Infrastructure Plan is targeting the construction of thousands of GI interventions, located on both public and private property, to achieve the City's stormwater management goals. The plan is therefore relying on a distributed, or neighborhood scale, infrastructure approach to realize a city-wide objective.

Unlike centralized infrastructure approaches, which usually comprise a smaller number of large investments, distributed infrastructure approaches can be incorporated into urban fabrics at a range of densities and scales. These approaches can thus evolve as performative systems over space and time as needed. Given current uncertainty in climate change projections (see Figures 1 and 2), strategies for climate change adaptation need to be able to change as projections improve over time and/ or impacts are better quantified. Given the flexibility with which a distributed infrastructure system can evolve, the use of distributed infrastructure as part of an urban climate adaptation strategy has many advantages.

Although the NYC Green Infrastructure Plan was not developed as a climate adaptation strategy for NYC, the Plan's promotion of green infrastructure could help mitigate the projected effects of increased precipitation and temperatures in the City, as well as augment local carbon sequestration (refer to Figures 5, 6 and 7). Thus the Plan, inadvertently, encourages a climate adaptation strategy that relies on a distributed infrastructure approach in the face of ill-quantified climate impacts.

## 4. CHALLENGES AND FUTURE NEEDS

As discussed above, distributed GI appears to have promise as a strategy for climate change adaptation in urban environments. Nonetheless, as discussed below, there are still hurdles that need to be overcome in order to fully realize the actual potential of this promise.

Despite significant progress in documenting the performance of an individual GI intervention, an understanding of how thousands of GI interventions perform as a system of interventions remains lacking. Developing this understanding is essential to advancing system level optimization of multi-component GI schemes for climate adaptation, or other urban sustainability goals. Modeling approaches might be one way to make the necessary progress. However, even in the well-studied area of stormwater management, process-based predictive models have had limited success in forecasting the behavior of an individual GI installation [23], let alone a multi-component GI system. One reason for this, is poor parameterization of evapotranspiration processes for engineered GI. An alternative to systems level modeling is systems level monitoring. This approach has the advantage of providing direct, possibly real-time, information on neighborhood or city-wide GI performance. Furthermore, with enough data collection, it might be possible to create data driven models to inform future system design, optimization and operation strategies. Nonetheless, advancement of this approach will require the development of appropriate sensor networks as well as accompanying data-management and support systems: In other words, a “smart-cities” type approach to urban GI programs.

Improved understanding of the role of engineered GI in mitigating urban heat island effects is also needed. While it is true that large patches of greenery, such as NYC’s Central Park, have measureable effects on air temperatures within the park boundary, the cooling effects exerted by smaller areas, such as the green roofs or right-of-way bio-swales shown in Figure 3, are less clear. Thus, more research is needed to define the scale and spatial patterns of urban vegetation required to significantly lower air temperatures in dense urban environments like NYC.

Different from larger-scale climate adaptation strategies, such as the installation of massive underground stormwater storage tanks, distributed GI systems are not only comprised of many more elements, they are also more likely to interface with urban social systems and communities. This can add complex facets of public acceptance and stewardship to the equation of GI performance, which are not always accounted for in GI design, siting and maintenance. Public acceptance and stewardship lessons learned to date from NYC’s Green Infrastructure program indicate the importance of greater public dialogue regarding infrastructure placement in the public right-of-way (e.g. Figure 3b). In general, public acceptance of right-of-way GI in NYC has been mixed, with many residents not embracing this vegetative intervention due to concerns about loss of parking, accumulation of trash in the GI, dislike of GI plant palettes – especially native grasses, and general dis-satisfaction about perceived lack of public consultation prior to implementation. In some instances, right-of-way GI has been vandalized in ways that actually compromise its physical performance. Survey work by the author and colleagues indicate that the public places more value on the cultural, social and aesthetic services provided by GI, than the environmental services. Thus, GI designs that account for public value systems, might have better long-term performance and stewardship outcomes than present-day designs.

Currently, efforts to design GI to maximize performance beyond stormwater management remain limited. For example, [34] note that carbon uptake by the sedum green roof they monitored in Berlin, Germany declined when substrate moisture content fell below  $0.05 \text{ m}^3\text{m}^{-3}$ , while [33] observed that high substrate moisture contents were linked to lower green roof temperatures. Yet, the active management of substrate moisture content to enable optimal rainfall capture, carbon uptake and the lowering of surface temperatures is neither a design nor

operational feature of most extensive green roofs. Going forward, more attention needs to be paid to the design and operation of GI interventions that maximize as many sustainability benefits as possible.

Finally, questions still remain as to how to define “acceptable” performance for a distributed GI system, whether for the purpose of climate adaptation or not. For example, with respect to performance redundancy, questions remain as to what is an acceptable factor of safety for a distributed system? And should a factor of safety be applied to each individual component of a GI system (i.e., each component has a built-in factor of safety) or the entire system itself (i.e., the system has redundant components)? In addition, there are questions regarding system resiliency. For example, are distributed systems more resilient because they are comprised of very, many components (so if several components fail the overall system performance is not compromised) or are they less resilient because it is hard to manage and secure a system of very many components? Furthermore, with respect to funding, what is the model for financing distributed GI systems that are installed on private land to perform public good? These, and other, questions will need answers if distributed GI systems are to become viable elements of urban climate adaptation strategies.

## 5. CONCLUSIONS

Distributed, or neighborhood level, systems of green infrastructure can contribute to urban sustainability goals in multiple ways. This paper discussed climate adaptation as one such example. Because GI can be incorporated into urban fabrics at a range of densities and scales, the performance of GI systems can evolve over space and time as needed. Given current uncertainty in climate change projections and impacts, the flexibility of an adaptation strategy whose performance can continually evolve has many advantages. Nevertheless, there are a number of challenges that need to be overcome to advance the use of GI for climate adaptation.

Despite the fact that significant progress has been made in documenting the performance capacity of individual GI interventions, an understanding of how thousands of GI interventions perform as a system remains lacking. Developing this understanding is essential to designing multi-component GI interventions for climate adaptation, or other urban sustainability goals. In addition, better understanding of the scale and patterns of urban vegetation required to mitigate urban heat island effects is needed, as are new designs for GI that optimize different performance attributes and improve public acceptability and stewardship outcomes for GI sited in the public-right-of way. Finally, fundamental questions regarding what defines acceptable performance for a distributed GI system still need to be addressed.

## Humans and Nature in the Loop: Integrating occupants & natural conditioning into advanced controls for high performance buildings

<sup>1</sup>Center for Building Performance & Diagnostics, Carnegie Mellon University

### ABSTRACT

Post Occupancy Evaluation plus Measurements (POE+M) has revealed that thermal, visual, acoustic and even air quality standards derived through controlled experimentation alone does not ensure comfort or health in buildings. Introducing human input into environmental standards and into user centric controls is critically needed for a sustainable future. For over a decade, CMU's Center for Building Performance & Diagnostics has been gathering POE+M data from over 1500 workstations around the world and testing the benefits on innovative environmental control systems. The separation of ambient and task conditioning, the provision of task controls, the introduction of occupant voting and bio-signal inputs into ambient and task set-points, offers major gains in comfort, task performance, energy savings, as well as health and wellness.

### KEYWORDS

Humans in the Loop, Internet of Things, Task and Ambient Conditioning, Bio-signals, POE

### INTRODUCTION

Addressing the seriousness of climate change and resiliency necessitates breaking out of the control impoverished, reflective, sealed commercial buildings of today. These buildings are often driven by first least cost, treat humans as a liability by hiding sensors and controllers, and treat nature as a liability by blocking natural solar heating and sealing out natural ventilation and cooling. These buildings are not intelligent and not resilient. Next generation buildings will embrace the Internet of Things (IoT) to make every point of service – every air diffuser, light fixture, heating or cooling unit, window, shade and plug point - a point of sensing, control and intelligent feedback (figure 1). Sensor and control rich environments will engage humans and nature as assets for ensuring indoor environmental quality, organizational flexibility, individual health and productivity, as well as ecological sustainability.

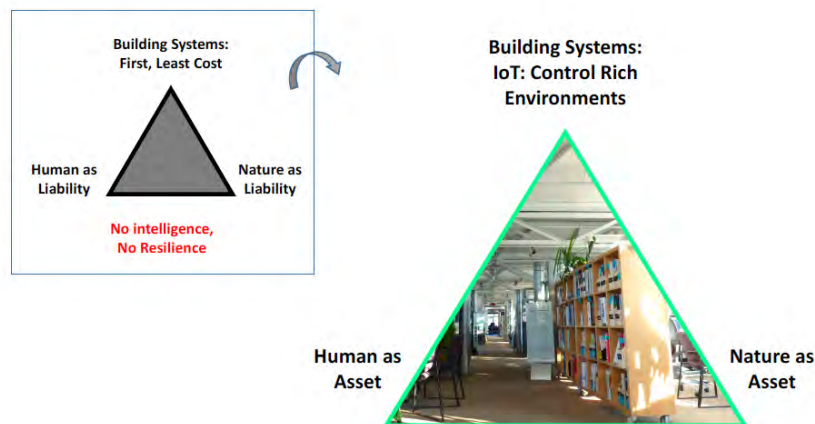

figure 1. Next generation buildings will be IoT control rich, treating humans and nature as assets

## Post Occupancy Evaluation plus Measurement (POE+M) in 70 Federal Facilities

Over the past 20 years, The Center for Building Performance and Diagnostics (CBPD) at Carnegie Mellon University and the U.S. General Services Administration (GSA) launched a nation-wide effort to complete post occupancy evaluations in federal facilities before and after the investments to improve the quality of the federal workplace. A National Environmental Assessment Toolkit (NEAT) was developed that critically merged user satisfaction surveys (long term and right now surveys) with physical measurements of environmental conditions and expert walkthroughs and interviews to capture the technical attributes of the building systems that supplied the thermal, air quality, lighting, acoustic and spatial performance (Loftness 2009, Aziz 2012, Choi 2012). Armed with national and international IEQ standards & thresholds, teams of Carnegie Mellon faculty and graduate students surveyed, measured and recorded conditions in over 1600 Workstations in 70 GSA buildings to build the NEAT data base, completing studies with recommendations, and leading to numerous Masters and PhD dissertations. The term POE+M was coined to emphasize the importance of simultaneously recording user satisfaction at given environmental conditions and given physical configurations of the building systems.

$$\text{CMU POE+M} = \text{User Satisfaction (COPE)} + \text{Environmental Conditions (NEAT)} + \text{Technical Attributes of Building Systems (TABS)}$$

For example, comparing field measured air temperatures with “right now” satisfaction Reveals: that US buildings are unacceptably and unnecessarily cold in summer (figure 2); that highest user satisfaction with air quality is achieved at CO<sub>2</sub> thresholds of 600 ppm ( $p < 0.05$ ) not the 1000 ppm presently used; that the highest satisfaction with lighting quality is achieved at less than 250 lux, given the computer intensive tasks in the office today. POE+M data bases offer a wealth of environmental learning and innovation (CBPD 2013), and should be the basis of both educational and professional commitments to field studies.

figure 2. Comparing field measured air temperatures with “right now” satisfaction reveals that US buildings are unacceptably and unnecessarily cold in summer.

### “Are Humans Good IEQ Sensors? Using occupants as sensors for thresholds that matter.”

With measurements in 1600 workstations in 64 buildings in the POE+M database, the 2014 CMU Dissertation of Jihyun Park used a rich array of statistical methods to definitely answer the research question ‘Are Humans Good IEQ Sensors’. The thermal, air quality, lighting and acoustic findings are both critical to building operation and future design, and statistically significant (Park 2015). The dissertation identified five building environmental conditions (NEAT) or physical conditions (TABS) significantly impacted thermal satisfaction: Air temperature at 0.6 m from the floor; Radiant temperature asymmetry with façade; Size of Zone; Window Quality; and Level of Temperature Control. These findings challenge existing design and engineering practices as well as existing comfort standards. For example, in 391 perimeter workstations, satisfaction with thermal conditions (-1 to +1) cannot be achieved unless horizontal radiant asymmetry is contained below 3.4°F ( $p < .001$ ), not the 18°F presently in the code (see figure 3). The highest user satisfaction with thermal conditions in summer is achieved at 76.5°F ( $p < 0.05$ ), not the 72°F so prevalent as a year round set-point in the field, and occupants in spaces with hidden or locked thermostats will be 20-40 % less satisfied with air temperature in their work area ( $p < 0.01$ ). Beyond thermal satisfaction, the research continued to identify the building environmental (NEAT) or physical (TABS) conditions that significantly impacted satisfaction with air quality, lighting quality and acoustic quality.

figure 3. Comparing measured horizontal temperature asymmetry with “right now” satisfaction suggest ASHRAE standards need to reduce acceptable delta’s from 18°F to <5°F (Park 2015).

### The CMU Intelligent Workplace: A Living Laboratory of Systems Integration for Performance

The Intelligent Workplace is one of the most sensed and controllable workplaces worldwide, shifting from traditional settings with one control for every 20 occupants to 20 controls for every occupant. With the emergence of wireless sensors and controllers and the Internet of Things (IoT), the IW is a testbed for the engagement of occupants as both sensors and controllers for the improvement of environmental quality and energy conservation.

In addition to field POE+M studies, the faculty and graduates in the Center for Building Performance have been testing the performance of innovations in component and integrated systems in the Intelligent Workplace at CMU. In collaboration with Siemens Corporate Research, Siemens Building Technology and the U.S. Department of Energy (DOE), this living and lived in laboratory supported two years of research on “Advanced, Integrated Controls for 40% Energy Savings in Building Operations” (figure 4) (Siemens 2012). A combination of seasonal controlled experimentation and computer simulation revealed that up to 75% of the ventilation energy, 36% of the heating energy, 25% of the cooling energy, and 70% of the lighting energy could be saved in cool and temperate climates through learning, occupant and nature responsive controls.

For example, the 36% in heating energy savings from the 2010 Baseline of US commercial buildings with limited sensors, limited controllers and sloppy 7x24 operation could be cumulatively reduced:

- 7.7% through updated sensors, time of day operation, and no over/under start up times;
- 15.5% through night setback  $\Delta 5^{\circ}\text{F}$  and weekend setback  $\Delta 2\text{--}7^{\circ}\text{F}$ ; and
- 36.1% through lower ambient settings & occupant controlled low watt task heating.

The 70% in lighting energy savings from the same 2010 baseline could be cumulatively reduced:

- 40% savings by daylighting when it met space requirements alone;
- 64% savings by adding occupant scene control to daylighting; and
- 71% total savings by Daylighting + Occupant Scene Control + Daylight Harvesting (possible through dimming controls).

#### Intelligent Workplace Lighting/ Daylighting/Shading Systems

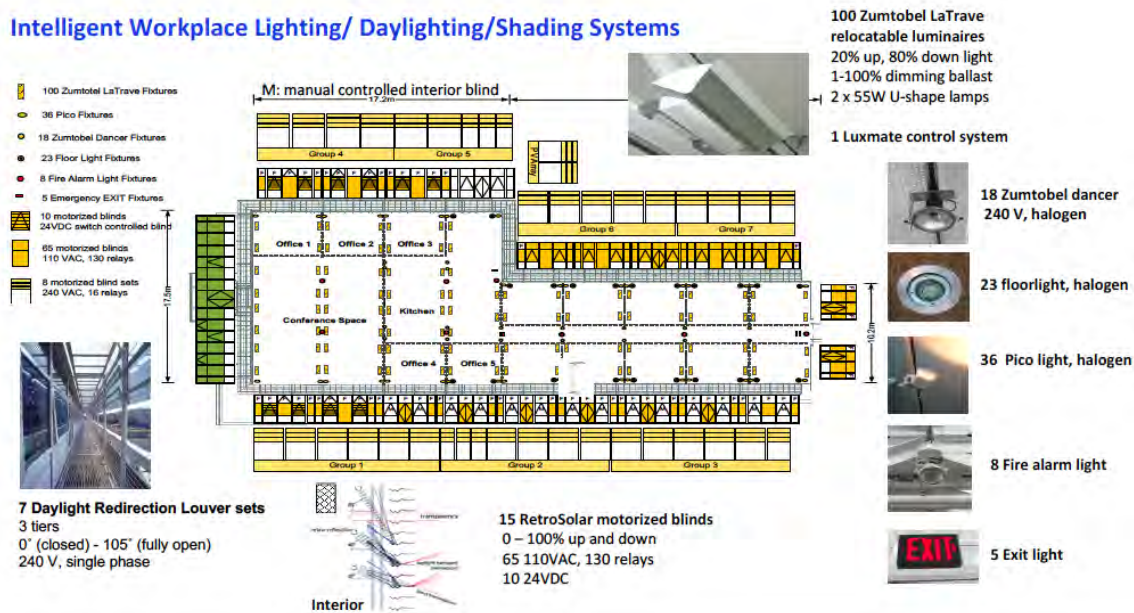

figure 4. The CMU Intelligent Workplace is a living and lived in laboratory for high performance building systems, the IoT, and human and nature responsive controls

The research also demonstrated that “control density is far more important than sensor density” and that the Internet of Things (IoT) offers a future where every node of service – every light fixture, air diffuser, heating or cooling coil, every plug – would support control optimization that

integrates across environmental conditioning systems, and includes occupant & natural conditioning strategies. These advances are key to net zero energy, resiliency, as well as human health and performance.

### **CoBi: Bio-Sensing Building Mechanical System Controls for Sustainably Enhancing Individual Thermal Comfort**

The CMU Intelligent Workplace has also been the testbed for numerous Master and PhD thesis projects including the path-breaking work on human bio-signals completed by Joonho Choi (Choi 2010, 2012). With IRB certified human subject testing of a host of bio-signals to control thermal conditions - skin temperatures from ten body locations, heart rate, heart rate variability, and sweat rate – the research identified the wrist as one of the most responsive body location relative to thermal sensation and comfort, given variations in seasons, BMI, MET and CLO conditions. When each individual's variation in wrist temperature is correlated to their thermal sensation votes and enabled to control air temperature, over 93% neutral sensation votes can be achieved, with 5.9 % energy savings for office cooling. This thesis helps to illustrate the importance of distributed controls for environmental systems and engaging occupants as sensors and controllers for energy savings and maximum user comfort, health and task performance.

### **Smart Phone Controls for the Internet of Things (IoT)**

The potential of micro-zoning, of separating thermal and ventilation, of layering ambient and task conditioning, and of controlling every plug - is unlocked by the Internet of Things (IoT). Every node of service – every light fixture, air diffuser, heating or cooling coil, window, window shade, and even every plug – will support control optimization that integrates across environmental conditioning systems, and includes occupant and natural conditioning strategies. In 2010, the IW faculty began a long term collaboration with the students of Dr. Bernd Bruegge in the Institut for Informatik at the Technical University of Munich. Through this collaboration, the IW has been the laboratory for Bachelor, Masters and PhD thesis projects exploring the capabilities of smart phones to provide communication, expert feedback and consulting, and intuitive control (Peters 2012, 2016). These efforts have introduced wifi triangulation for IoT locations, gesture and voice control, innovative smart phone based occupancy sensors, environmental sensing, geo-fencing, smart plug data analytics and more (figure 5).

*figure 5. Smart phones support intuitive gesture control of every fixture (left 2), provide energy use information (center) and readings of individual sensors and set points (right), (Peters, 2016)*

## Persistent Workplace Energy Savings and Awareness through Intelligent Dashboards

The importance of communication, feedback, expert consulting, and multiple levels of control are the basis of CMU's research into Intelligent Dashboards for Occupants (ID-O). The PhD thesis of *Ray Yun* explores the impact of nine critical interventions for behavioral change, structured in three sets: Instructional interventions – education, advice and self-monitoring; Motivational interventions – goal setting, comparison and engagement; and Supportive interventions – communication, control and reward (figure 6). With a focus on controlling plug loads, the fastest growing energy end use in commercial buildings, the nine-month controlled field experiment with 80 office workers at a leading green corporation in Pittsburgh revealed that occupant dashboards for controlling desktop technology, with ongoing energy communication and expert consulting generated by the occupants own data set, can generate up to 40% energy savings in plug loads (Yun, 2014).

Figure 6 Desktop energy feedback and control dashboards for occupants yielded as much as 40% sustained savings from an already efficient workstation (Yun, 2014)

## Occupant-oriented, mixed-mode, Energy+ predictive controls

In addition to engaging occupants directly, the power of occupancy and nature responsive building energy management (BEM) is also a critical development for the Internet of Things. The CBPD has been developing dynamic life-cycle building information models (DLC-BIM) into building energy models (BIM to BEM) focused on total building performance to ensure best practices in sustainable and green architecture. Jie Zhao completed a dissertation in 2015 demonstrating “Design-Build-Operate Energy Information Modeling for Occupant-Oriented Predictive Building Control”, moving from controlled experimentation in the IW to a partnership with a newly awarded Living Building in Pittsburgh. This dissertation developed and demonstrated the concept of design-build-operate Energy Information Modeling infrastructure (DBO-EIM), which can be used at different stages of the building life-cycle to improve energy and thermal comfort performance (figure 7). Given the Pittsburgh weather context and current operation, the Occupant-oriented Mixed-mode EnergyPlus predictive control (OME+PC) system provided a 29.37% reduction in annual HVAC energy consumption. In addition, OME+PC enables building occupants to control their thermal environment through an internet-based dashboard, updating a design stage EnergyPlus model for use through the entire DBO-EIM process.” (Zhao, 2015)

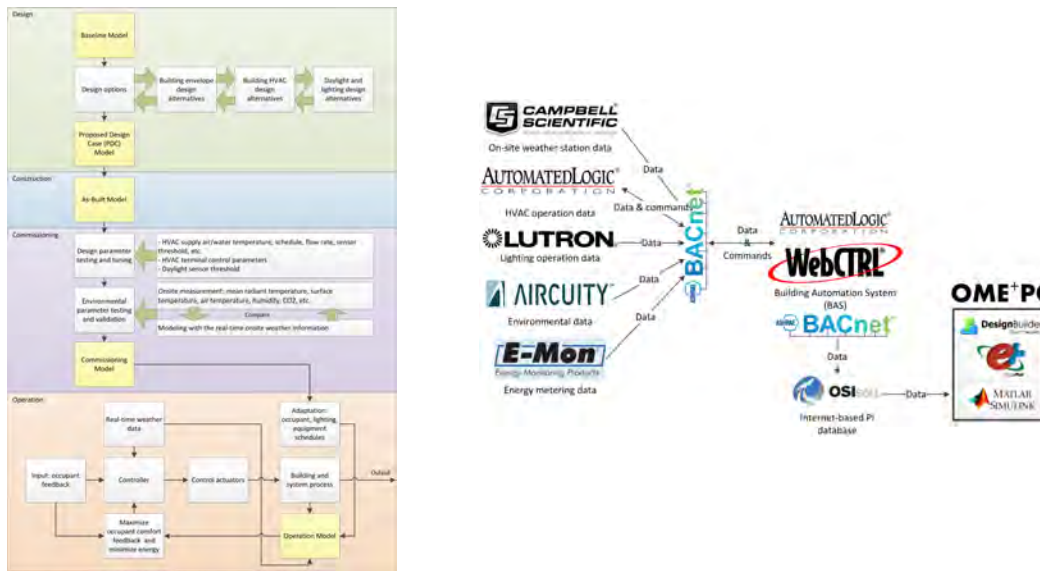

Figure 7 Design-build-operate Energy Information Modeling (DBO-EIM) infrastructure (left), and data collection and system integration architecture (Right) (Zhao, 2015)

## Embracing Natural Conditioning

Erich Fromm used the term ‘biophilia’ to describe the psychological orientation of being attracted to all that is alive and vital. EO Wilson and Stephen Kellert, in their book ‘The Biophilia Hypothesis’ described biophilia as the links that human beings instinctively seek with other living systems (Kellert 1993). For those of us in the bricks and systems that define buildings, biophilia must include a passion for natural conditioning. Yet we know that advances in conditioning systems, sensors and controls are equally invaluable to our goals of intelligence, resiliency, health and productivity – especially in the warming and wildly fluctuating changes in our environment. Our future is in the marriage of the high tech and the low tech. First, we must pursue every possible hour of natural conditioning through environmental surfing for daylight, natural ventilation, night ventilation cooling, time lag cooling, passive solar heating, evaporative cooling and more. Then we must lightly introduce mechanical and electrical conditioning through mixed mode design. This demands no more heavy handed, pervasive overlighting or overcooling, and no more over-sealing, over-darkening our building facades. Instead, we must fully design for:

- Mixed Mode: Daylight & Electric Light
- Mixed Mode: Natural Cooling & Mechanical
- Mixed Mode: Natural Ventilation & Mechanical
- Mixed Mode: Outdoor & Indoor Work/Learn/Play/Heal

For each of these mixed mode solutions, the disciplines must collaborate from the earliest stages of design – to integrate structure, enclosure, mechanical, lighting, interiors and control systems that fully engage nature and the building occupants in a sustainable future.

## CONCLUSION

Several decades of field and lab experiments at the Center for Building Performance and Diagnostics at Carnegie Mellon University have demonstrated that humans are good environmental sensors and humans are good environmental controllers, especially when given information, recommendations, and rewards. Occupants contribution to both energy savings and the highest level of individual satisfaction and delight is even greater when natural conditioning opportunities are introduced – daylighting, natural ventilation, night ventilation cooling, passive solar heating and more. Nature offers abundant, albeit variable, free energy sources for environmental conditioning. The future of intelligent buildings for resiliency, health and productivity depends on building systems that engage humans and nature to save energy and increase environmental quality.

### ABSTRACT

There is growing evidence that heat waves are becoming more frequent under increased greenhouse forcing, associated with higher daytime temperatures and reduced night-time cooling, which might exceed the limits of thermoregulation of the human body and affect dramatically human health. Especially urban areas are affected, since these regions in addition experience an urban heat island (UHI) effect characterized by higher air temperatures compared to the surrounding rural environment. A necessary breakthrough is a shift away from a fragmented approach towards an integrated multiscale urban climate analysis. This type of research is a rather new domain of research and might be based on an all-physics understanding and modeling of the urban climate ranging from the scales of material and buildings, to the scales of a group of several buildings, street canyons, neighbourhoods, cities and urban regions, referred to as multiscale building physics. To adequately cover global and local urban heat island effect, regional and mesoscale climate analyses have to be downscaled to sub-kilometer resolution and linked with urban climate models at neighborhood and street canyon scales. Such a multiscale urban climate model allows to analyze the influence of urban and building parameters on thermal comfort and the building cooling demand. The importance of accounting for the local urban climate when quantifying the space cooling demands of buildings in an urban environment is demonstrated. The heat-moisture transport model for building materials allows the design of new building materials, which can help in the mitigation of local heat islands. With respect to evaporative cooling materials, we need to optimize their water retention and evaporative cooling by tailoring their pore structure. The understanding and information obtained from pore-scale investigations enables to understand macro-scale transport processes, and enabling us to explore the potential of new evaporative cooling materials at local urban scale.

IBPC 2018, building and urban physics, multiscale modelling, building energy demand, pore scale modelling

### THE BROAD VIEW: URBAN CLIMATE AND CLIMATE CHANGE

There is growing evidence that heat waves are becoming more frequent under increased greenhouse forcing (e.g. Seneviratne et al. 2012, Hartmann et al. 2013, Schleussner et al. 2017). Climate simulations project an increase of the number and intensity of heatwaves and hot extremes in many regions in the world (Sillmann et al. 2013, Fischer et al. 2014) even for moderate scenarios of global warming of 1.5°C or 2°C (Seneviratne et al. 2016, Wartenburger et al. 2017, Dosio et al. 2018). In future, heat waves associated with higher daytime temperatures and reduced nighttime cooling might exceed the limits of thermoregulation of the human body and affect dramatically human health. Switzerland experienced important heat waves during the 2003 and 2015 summers, which were the two warmest summers over more than 150 years. For these summers, an excess mortality of 6.9% and 5.9% respectively

was estimated corresponding to 975 and 804 extra deaths for these years, see Figure 1a (Vicedo-Cabrera et al. 2016).

Urban areas are especially affected, since these regions, in addition, experience an urban heat island (UHI) effect characterized by higher air temperatures compared to the surrounding rural environment (Oke 1987, Moonen et al 2012b ). Urban heat islands in cities have been reported for more than 400 cities around the world (Santamouris and Kolokotas 2016). The magnitude of UHI is found to vary from place to place with urban heat island intensities up to 6 - 7°C (Santamouris and Kolokotsa, 2016). For Zurich, we found an urban heat island intensity of around 4.5 degrees during the heat wave of 2015 (see Figure 1b-c, Mussetti et al. 2016). Li and Bou-Zeid (2013) showed that the combined effect of UHI and heat waves is larger than the sum of the two individual effects.

The UHI leads not only to a reduction of urban thermal comfort, but also to an increase in building energy demand, especially in space cooling demand during warm periods. Due to local and global climate change and growth of world's population and economic, the world global space cooling demand for buildings is expected to strongly increase in future. In 2010 the global cooling consumption of the residential sector represented 4.4 % of the total space conditioning of buildings. This number is expected to increase to 35 % in 2050 and 61% in 2100 (Santamouris 2016, Isaac and van Vuuren 2009). Not only the annual but also the peak cooling demands will strongly increase. This means that also the power capacity for cooling, and thus electricity, may have to be strongly increased to satisfy future peak energy needs (Santamouris 2016). Santamouris (2016) proposed three main actions to face the problem with the increase in cooling demands: (1) mitigation of the global and local climate change, (2) adaptation of the building sector and improvement of its energy performance and (3) improvement of mechanical air conditioning and alternative cooling technologies.

In addition to the global UHI effect, heat waves are accompanied with local hot spots in cities, called local heat islands (LHI), see Figure 1d (Allegrini and Carmeliet, 2016). Certain city quarters or zones between individual buildings may show much higher air temperatures compared to neighboring urban areas, due to lower wind speeds by wind sheltering leading to less removal of heat. On the other hand, at low wind speeds, higher urban surface temperatures due to solar radiation may lead to more buoyancy enhancing heat removal. As a result, the origin of LHIs is a complex phenomenon depending on a set of parameters such as lack of urban ventilation, lack of vegetation, densification and urban morphology.

The continuing spread of urban areas and the growing fraction of people living in cities direct nowadays a particular spotlight on urban climate and urban heat islands, and the corresponding effects on thermal comfort and heat stress during heat waves. As a result, many research teams worldwide aim at formulating adequate measures to adapt to and/or mitigate these threats, but most approaches remain fragmented focusing on specific scales or topics of the urban climate.

A necessary breakthrough is a shift away from a fragmented approach towards an integrated multiscale urban climate analysis. This type of urban climate research is a rather new domain of research and might be based on an all-physics understanding and modeling of the urban climate ranging from the scales of material and buildings, to the scales of a group of several buildings, street canyons, neighbourhoods, cities and urban regions. The final aim is to propose adequate urban adaptation measures for climate change (CC) at regional scale in view of different CC scenarios and to develop adequate UHI mitigation measures. Such an approach for urban heat island mitigation allows communities to identify spots of local heat islands, reduced urban comfort and increased health risks, to pinpoint the causes for the appearance of local urban heat islands, and to propose possible mitigation measures using high-resolution urban mapping techniques.

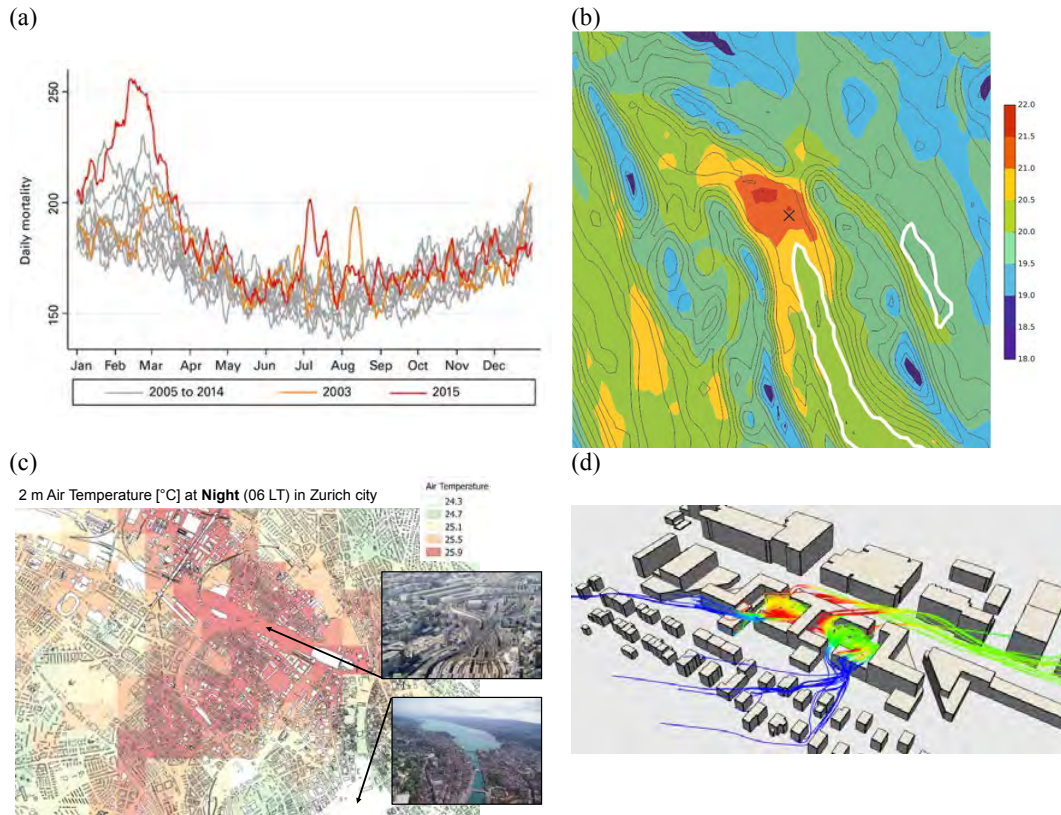

Figure 1. (a) All-cause daily mortality (number of deaths) in Switzerland in 2003, from 2005 to 2014 and in 2015. Two prominent mortality peaks in the summer months, July 2015 and August 2003. (b) Global heat island in Zurich during the heat wave of 2013: map of air temperatures at 2 m height at 12 pm averaged over 5 consecutive days. (c) Urban mapping of air temperatures at 2 m height at 6 am in city of Zürich showing higher air temperatures during the night. (d) Local climate at a neighborhood in Zurich determined with coupled Building Energy - CFD simulations. Selected streamlines where colours indicate local temperature increase due to new buildings (Allegrini and Carmeliet 2016).

### WHY MULTISCALE BUILDING PHYSICS ? WHICH SCALES TO CONSIDER?

Traditional building physics focusses on the scales of materials towards building components and buildings systems, and finally whole buildings. The aim of building physics is assuring a correct indoor comfort with minimal building energy consumption, while guaranteeing a correct hygrothermal and acoustic performance, maintenance and durability. Urban physics focusses on physical processes from the scales of urban materials, to the scales of a group several buildings, street canyons, neighbourhoods and total cities. Urban physics can be seen as a complement to building physics, filling the missing link between studies at meteorological and climate scales and building physics. There is nowadays not only a high need of integrating urban and building physics, but also to develop a new discipline, called multiscale building physics. The challenge for multiscale building physics is not only to broaden its field over different scales from material to city scale, but also to link up with other fields. From one side urban climate scientists and planners generally consider only UHI mitigation measures to limit the negative impact of local heat islands. Climate model scientists on the other hand mainly focus on the effects of greenhouse gas mitigation to limit the climate change impact globally. A necessary breakthrough consists in the combination of regional climate modeling combining the effects of greenhouse gas forcing on larger scales with the assessment of UHI mitigation measures on smaller scales for local heat islands during heat waves, and the analysis of their interaction. Such a global approach allows the

formulation of more general UHI mitigation measures integrating the use of materials, energy and water on different scales, which can be considered in climate change projections and climate change adaptation.

### Scales in urban climate analysis

To adequately cover global and local urban heat island effects, regional and mesoscale climate analyses have to be downscaled to sub-kilometer resolution and linked with urban climate models at neighborhood and street canyon scales. The scales to be considered are represented in Figure 2. We start from global climate models and scale them down to the European (~25 km resolution) and further to the regional scale (entire Switzerland and a portion of central Europe at 1-2 km resolution) using a regional/mesoscale climate model. The regional climate model is further downscaled for selected cities to resolve small-scale thermal circulations and intra-urban variability at sub-kilometer resolution (~200 m). At the urban level, we consider city, neighborhood and street canyon scales.

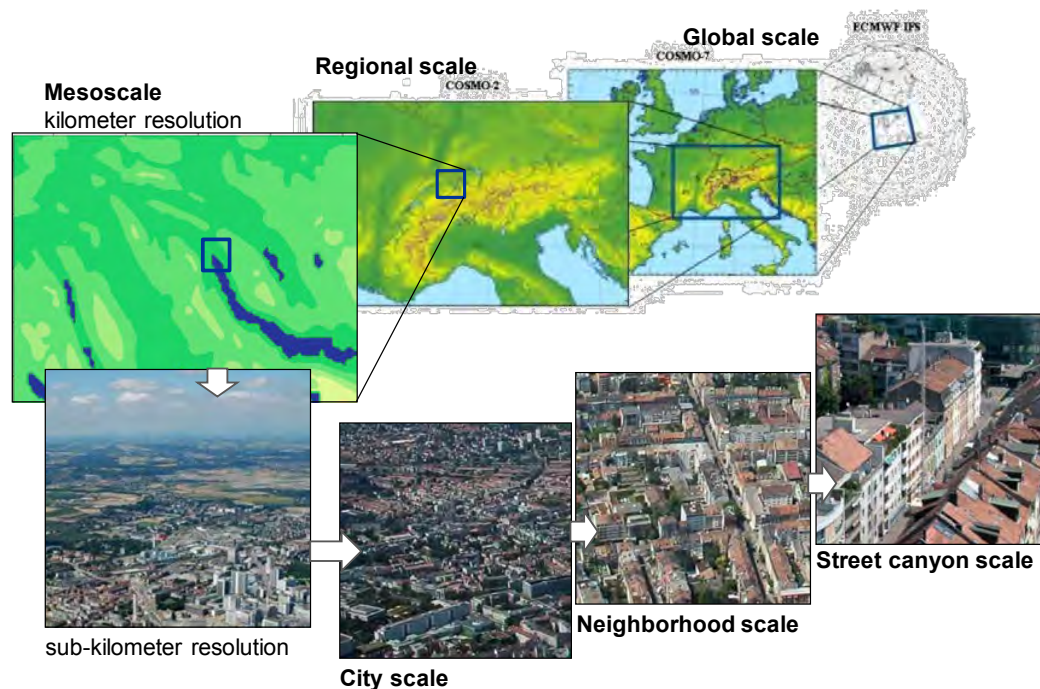

Figure 2. Different scales in urban climate modelling and multiscale building physics (photos from Christen 2005).

### MULTISCALE MODELING?

#### Regional and urban climate interactions

Urban surfaces interact with mesoscale meteorology and climate in several different ways (Roth 2000; Masson 2006; Martilli 2007). Their roughness exerts enhanced drag on the flow and they alter the surface energy balance by trapping radiation, storing heat in urban materials, changing the ratio between sensible and latent heat fluxes, and releasing additional heat due to human activities. These interactions motivated the development of urban canopy parameterizations in atmospheric models enabling a better representation of the mesoscale forcing of urban weather and climate. These models describe the sub-grid scale effects of buildings and urban surfaces on the flow and on surface heat exchange in a parameterized fashion, for example by representing buildings within a grid cell as a statistical ensemble of

street canyons of different orientations and dimensions and calculating radiative transfer (including multiple reflections between surfaces) and energy and water vapor exchange between atmosphere and building and street surfaces in each canyon separately.

As an example, the urban heat island effect in Zurich was simulated with the climate version of COSMO in order to capture the local atmospheric circulation influenced by the orography and the presence of Lake Zurich, see Figures 1b-c (Mussetti et al. 2016). The model has currently been extended with the representation of street trees and a detailed representation of short- and long-wave radiation in the street canyons by ray tracing.

### **From urban to building scale: building-resolved analysis**

At city scale, a CFD based urban climate model is used which, in contrast to mesoscale models, also resolves the physical phenomena at street canyon scale. These models take into account accurately the building and street geometry, where buildings are geometrically resolved in computational fluid dynamics (CFD) (figure 3a). They also take into account the used urban materials, particular weather conditions (wind, sunshine, rain, temperature, relative humidity), shadowing, as well as the local urban water cycle.

The influence of higher scales such as the global urban heat island are modeled via appropriate boundary conditions (wind velocity and orientation, surface temperatures) from simulations at sub-kilometer resolution using a nesting approach (Vonlanthen et al. 2017). In order to solve the mismatch between different scales and physics involved in the two models, we apply a blending layer. Transpirative cooling and shadowing effects from trees as well as the evaporative cooling effects of water bodies or absorbed water (by rain or spraying) can be considered. Figure 3b gives an example of the air temperatures at 3 m height in downtown Zurich during a heat wave day.

These models at city scale are further downscaled to neighborhood and street canyon scales for selected parts of a city. At this scale, an all-physics model is used considering solar and longwave radiation, three-dimensional turbulent wind flow and buoyancy, temperature and relative humidity in the air domain and heat and moisture transport in the porous domains of urban surfaces (see Figure 3c, Kubilay et al. 2016). The surface temperatures are determined by a thermal balance of solar and longwave radiation, convective heat transport at surfaces, heat conduction and storage of heat in the building materials and soil, and evaporative cooling effects. The urban climate model is extended with vegetation using a porous media approach with sink and source terms for moisture and heat to model the transpiration and the related transpirative cooling effect. The vegetation model includes moisture transport within the soil/roots, tree, stem, branches and leaves, allowing the consideration of the complete water cycle at street canyon scale between air, soil and tree. A multiphase Eulerian model for wind driven rain has been developed and validated in order to accurately determine the wetting of the building surfaces and soil, see Figure 3d (Kubilay et al. 2013). The wind driven rain model is able to predict the rain load and wetting of all urban surfaces including roofs, facades, pavements, streets, soils and other surfaces. The porous heat-moisture transport model allows the determination of the heat and moisture transport and storage in these materials. When evaporation occurs, evaporative cooling is considered.

The urban climate model is further integrated with an urban water cycle model including rain and drainage systems at city scale in order to explore the potential of using urban water resources locally for UHI mitigation, especially during heat waves. This enables the assessment of when stormwater can be used to reduce the local heat island effects via evaporative cooling. A thorough analysis on stormwater availability and storage potential in cities can then be performed. This provides answers to questions such as: Is the stormwater volume sufficient and available when required to mitigate urban heat island effects? How does

dedicated stormwater storage solutions compare with other existing urban water infrastructure in terms of city infrastructure retrofitting possibilities and costs?

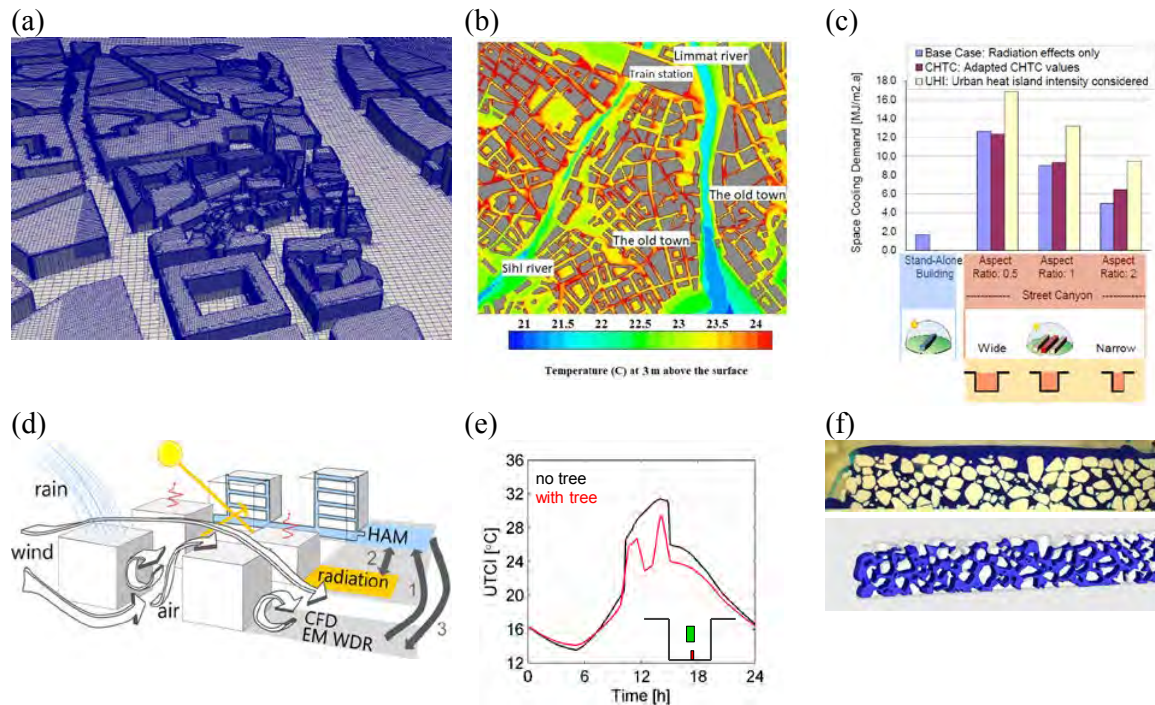

Figure 3. (a) CFD mesh for the old city of Zurich. The area of interest is represented with more geometric details (roofs), while the surrounding neighborhood is represented by simplified building blocks. (b) Air temperature at 3 m height in downtown Zurich during heat wave day June 23 2015 at 2 pm. (c) Annual space cooling demands for different building configurations and using different modelling approaches (Allegrini 2012). (d) All-physics approach of local urban climate model. The momentum, heat and moisture transport in the air domain is solved using computational fluid dynamics (CFD). Wind driven rain is modelled using an Eulerian Multiphase method. Results from the CFD simulation are exchanged with a model for heat and moisture transport (HAM) in urban materials like facades, roofs, pavements and soils. A radiation model solves for the solar radiation, shadowing and thermal radiation between the different surfaces and the environment. (e) Universal Thermal Climate Index (UTCI) for a person (red box) standing below a tree (green box) showing the positive effect of a tree mainly through shadowing on the thermal comfort. (f) top: Liquid distribution in micro-fluid device representing porous asphalt during drainage. bottom: PM-LBM simulation of drainage in porous asphalt (Son et al. 2016).

The urban climate model allows to analyze the influence of urban parameters on thermal comfort by determining the variables at a certain location in the street canyon, such as air temperature, air speed, radiant temperature and relative humidity. These variables are used to determine thermal comfort/heat stress using a common thermal comfort indicator, such as the UTCI (Universal Thermal Climate Index, Bröde et al., 2018). As an example we show the influence of a tree on the UTCI for a person (red box) standing below a tree (green box), showing the positive effect of a tree mainly through shadowing on the thermal comfort.

### COUPLING URBAN CLIMATE AND BUILDING ENERGY

It is clear that space cooling demands of buildings in urban environments exposed to climate change and heat waves will increase in future due to hotter urban climates.

To propose new building designs and/or building energy systems and to adapt existing buildings to future urban climates, the impact of the local urban climate on the space cooling

demands of buildings has to be better understood. At the moment, no full scale studies where models for the different scales of the urban climate are coupled to accurately simulate the local urban climate for building energy simulations taking into account all interactions between the scales, exist. There is a strong need for a better understanding and quantification of the impact of local urban climate, its modification due to climate change as well as possible urban mitigation measures on the cooling demand of buildings in cities. Such knowledge will allow proposing new solutions to improve the energy performance of buildings taking into account their local urban climate.

Most of the building energy simulation models, which are used to predict energy demands of buildings, were originally developed for stand-alone buildings (Hensen 2011). For buildings in urban environments, the space cooling demand is strongly influenced by the local urban climate (Figure 3e) and can be quite different to buildings in rural areas (Allegrini et al. 2012a). The short and longwave radiation exchange between buildings in dense urban areas has a strong impact on the building performance (Allegrini et al. 2012a, Allegrini et al. 2016). The shortwave radiation entering the street canyons is entrapped between the buildings due to multiple reflections between the buildings. Additionally sunlit surfaces exchange hot and radiate longwave radiation with non-sunlit surfaces and heat them up. These increased surface temperatures have a direct impact on the energy performance of the buildings and on the local air temperatures. Another important impact is the increased local air temperatures due to the urban heat island effect. The lowest impact comes from the convective heat transfer coefficients. This study showed clearly the importance of accounting for the local urban climate when quantifying the space cooling demands of buildings in an urban environment.

## **DOWN TO MATERIAL SCALE**

The multiscale urban climate model can be used to understand the impact of different urban parameters on the local heat island effect and to propose adequate mitigation measures. Especially one can study the impact of (1) radiation properties of building surfaces (albedo value), (2) the heat-moisture transport and capacity properties of building materials, (3) the presence of vegetation such as green roofs and facades, (4) the role of impervious versus porous substrates (different pavements and sublayers, different soils, cover ratio), (5) the presence of urban shadowing devices, (6) the role of active evaporative cooling by water spraying during heat waves of collected urban water.

The heat-moisture transport model allows the design of new building materials, which can help in the mitigation of local heat islands. With respect to evaporative cooling materials, we need to optimize their water retention tailoring their pore structure. This requires the use of pore-scale simulation of two-phase flow in porous media and an upscaling using pore-network models for the determination of the macroscopic fluid transport properties

As an example, we recently showed that hydrophobic macro-porous materials, such as porous asphalt with pore sizes ranging from micron to millimeter size, can retain water in their pore structure for long time after wetting by rain or artificial wetting (spraying), as such opening potentials for new evaporative cooling materials (Lal 2016). To study the two-phase flow in such complex materials, we developed a pseudopotential multiphase lattice Boltzmann model (PM-LBM). The use of LBM was motivated by the need for the explicit tracking of the liquid-vapor interface during gravity-driven drainage in macro-porous asphalt as well as the drying process. The PM-LBM was validated with micro-fluidic measurements, where liquid distributions were monitored by high speed camera on quasi-2D transparent micro-fluidic devices, where the porous structure was printed by additive manufacturing (Figure 3e-f) (Son 2016). To predict the unsaturated permeability of building materials, pore-network modeling

was used (Carmeliet et al. 1999, 2004, Vandersteen et al. 2003). The understanding and information obtained from pore-scale investigations enables to understand macro-scale transport processes, and to explore the potential of new evaporative cooling materials.

## The Physics in Natural Ventilation of Cities and Buildings

Yuguo Li

Department of Mechanical Engineering, The University of Hong Kong, Hong Kong SAR, China

*Corresponding email: liyg@hku.hk*

### EXTENDED SUMMARY

Asian cities are mostly taller, denser, deeper and larger than those in the West, and the magnitudes of building drag or urban heat island circulation and their effects on city ventilation are also stronger. The physics of urban climate in these large cities is complex, as a combined result of local circulation and synoptic winds modified by the mountainous topography and land/sea breeze, if any. Natural ventilation of a city refers to the penetration and distribution of rural air into an urban canopy layer. The weakened city ventilation has become one major reason for worsening urban warming and air pollution in cities. Two distinct situations need to be considered, i.e. when the synoptic wind is strong; and when the synoptic wind is weak respectively. For the former, designers are interested to manage city ventilation for removal of the urban heat, moisture and pollutant, or retain of urban heat and moisture. The latter become mostly the conditions for the worst urban extreme heat or haze scenarios to occur. Natural ventilation of a building refers to the introduction of outdoor air into a building by natural forces such as wind and buoyancy. High-rise buildings present an interesting challenge as the top of the building may be in the urban roughness layer or even beyond the atmosphere boundary layer.

Many excellent review papers exist on relevant urban airflows (e.g. Roth, 2000, Britter and Hanna 2003, Arnfield, 2003, Belcher 2005), but not specifically on city ventilation. City ventilation is mainly driven by winds and buoyancy forces such as slope flows, sea-land breezes, etc. The importance of city ventilation may be seen by long recognition that the restricted air flows were the causes of the all major pollution disasters (Brimblecombe and Sturges, 2009). Rigby et al (2006) presented a rose analysis showing the influence of boundary layer ventilation. The wind speed in London is often found to be lower than in a rural area, whilst occasionally accelerated due to urban heat island effects (Lee, 1979).

The purpose here is to review the status of our understanding of the physics in city ventilation under both strong and weak wind conditions. It is known that understanding the urban air flows in calm wind conditions is crucial, as most urban heat wave and severe air pollution episodes occur when wind calmness and inversion coexist, leading to formation of a heat dome or urban heat island circulation. Heat dome comprises a convergent inflow at the lower atmospheric level, divergent outflow at the upper, and a dome-shaped flow field resulting from entrainment and overshoot at the top. Numerous field studies worldwide have confirmed the existence of UHIC during the day and night in many cities. It is interesting that though a strong wind would destroy the heat dome and breakup the inversion, a weak wind may only elongate the dome to become a plume or dome shadow, transport the pollutant downstream to other cities. How such a weak wind impact on the dome formation has not been well studied.

Examples given here including wind weakening phenomenon in a dense high-rise city (Peng et al. 2018), the roles of heat dome formation on urban extreme high temperature events,

spread of SARS CoV virus when there is inversion, and the urban heat domes (Fan et al 2017) and their merging (Fan et al 2018). Different methods are available for investigation, i.e. simple theoretical estimates (Fan et al 2017), water tank models (Fan et al 2016), city scale CFD (Wang and Li, 2016), and meso-scale WRF (Wang et al 2017).

It is concluded that there is a need to establish the need and an approach for designing city climate and environment as for buildings, for example, designing building density and height in a city for better urban climate, and between-city distance needed to avoid regional haze formation.

## **A state-space based method to predict thermal performance of pipe-embedded double skin façade: case study in Guangzhou**

Shuai Yan, Weihua Lv, Chong Shen and Xianting Li\*

Department of Building Science, Tsinghua University, Beijing, China 100084

\*Corresponding email: [xtingli@tsinghua.edu.cn](mailto:xtingli@tsinghua.edu.cn)

### **ABSTRACT**

Pipe-embedded double skin facade, which arranges pipes in shading device, is an alternative to reduce indoor demand and save energy. To simulate annual performance of this system, a simplified approach based on optical and thermal property is proposed at first, in which dynamic performance is acquired through state-space method. Then the model is validated with former investigation and shows good accuracy. Indoor room temperature with the pipe-embedded double skin façade is analyzed under different types of room in Guangzhou at last. Results show that the pipe-embedded double skin façade could guarantee a barely satisfactory indoor environment where indoor heat gain is small in most time. Besides, superiority would be obvious when solar radiation is strong, indicating the applicability in some typical region with abundant sunshine.

### **KEYWORDS**

natural energy, pipe-embedded window, double skin facade, heat gain, free-running temperature

### **NOMENCLATURE**

DSF	double skin façade
PDSF	pipe-embedded double skin façade
CFD	computational fluid dynamics
LMTD	logarithmic mean temperature difference

### **INTRODUCTION**

Glass curtain has been widely applied in recent years. Nevertheless, heat transfer through transparent envelope is significant, which would lead to the increase heating and cooling load in building. To be specific, large amount of solar radiation transmitted directly into the room in summer while the heat dissipated through glass is remarkable in winter owing to its poor thermal insulation. Many researches concentrated on the thermal performance improvement of glass envelope consists: 1) substitution of high thermal performance glazing such as triple glazing (Manz et al., 2006), 2) development of high-efficiency shading devices (Cheng et al., 2013), 3) double skin façade (DSF) with ventilation. Better glazing aims to reduce heat dissipation in winter however better shading aims to decrease solar transmittance in summer, in other words, both the first and second approach is not designed for annual performance. By contrast, double skin façade could be of benefit for both heating and cooling.

Traditional DSF combined with ventilation is made up of the external glass, shading device and internal glass. Researches shows that the outlet air temperature could reach up to 50°C when solar radiation is strong, that is, conventional double skin façade combined with ventilation can't remove heat absorbed by venetian blinds efficiently in some cases. Thus, Shen and Li (2016) proposed the idea to arrange pipes in the shading device and simulated the performance by CFD method. Results shows that inner surface temperature can be reduced dramatically compared with traditional DSF, benefitting not only energy consumption but also thermal comfort.

Hourly indoor temperature prediction plays an important role in thermal comfort and

energy saving. It is difficult to get the hourly indoor temperature in the whole year by CFD method due to its complication and time-consuming character. Therefore, a state-space method based on optical and thermal property is proposed to calculate the hourly indoor temperature at first. Then thermal performance of pipe-embedded double skin façade(PDSF) in Guangzhou under two different types of room is analyzed.

## METHODOLOGY

### Description of PDSF

The detailed structure together with schematic diagram of the PDSF are shown in Figure 1. Compared with traditional DSF, cooling pipes are embedded into the shading device for the case of PDSF. Water flows inside pipes to take away the heat absorbed. On one hand, heat transfer coefficient of water to blinds is much larger than air to blinds, so PDSF would remove the radiation more efficiently. On the other hand, natural cooling source such as direct evaporative cooling, ground source heat exchanger is feasible and of low-cost according to the climate feature.

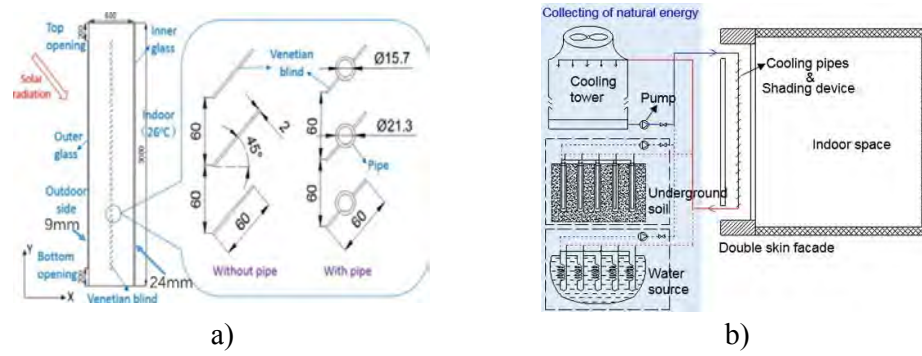

Figure1. description of PDSF system. a)structure, b) schematic diagram.

### Solar radiation distribution

The dynamic optical properties of glazing should be calculated at first, then the overall optical character of DSF could be obtained including reflection, transmission and absorption. Solar radiation consists of two parts, namely direct fraction and diffuse fraction, whose optical character should be calculated separately (Wang et al.,2016)

$$\alpha_{eg}^{dir} + \alpha_{bl}^{dir} + \alpha_{ig}^{dir} + \rho^{dir} + \tau^{dir} = 1 \quad (1)$$

$$\alpha_{eg}^{dif} + \alpha_{bl}^{dif} + \alpha_{ig}^{dif} + \rho^{dif} + \tau^{dif} = 1 \quad (2)$$

where  $\alpha$ ,  $\rho$  and  $\tau$  represents absorptivity, reflectivity and transmittance respectively; subscript  $eg$ ,  $bl$ ,  $ig$  represents external glass, blind and internal glass; superscript  $dir$ ,  $dif$  represents direct radiation and diffuse radiation.

Optical property of diffuse fraction equals to that of direct radiation whose incidence angle is 60 degrees. Thus solar distribution in each layer is acquired, which is the fundamental to thermal performance calculation.

### Energy balance equation

Thermal stratification in the cavity is neglected according to the CFD results (Shen and Li, 2016). Since heat transfer coefficient of water side is much larger than air side, we make the assumption that blind temperature is 0.5°C higher than water temperature, which corresponds to our previous study (Shen and Li, 2016). Thus, surface temperature can be calculated based on thermal network, as shown in Figure.2.

Figure 2. Thermal network of PDSF

where  $R$  represents thermal resistance ( $m^2 \cdot K/W$ ); subscript conv, cond and rad indicates convective, conductive and radiative heat transfer respectively.

LMTD model (Utamura et al., 2008) is utilized to simulate the inlet and outlet water temperature difference.

### Dynamic simulation based on state-space method

State space method, where space is discretized while time is continuous, was widely used (Parker and Bowman, 2012) and adopted in this study. Compared with conventional window, thermal performance of PDSF is related with not only meteorological parameter but also water temperature. That is, temperature of PDSF and other node temperature of room should be solved through two matrices below respectively.

$$M \overrightarrow{T_{glass}} = \vec{b} \quad (3)$$

where  $T_{glass}$  is node temperature of glass,  $M$  is the matrix based on thermal network,  $b$  is a vector related to climate data.

$$C \dot{\vec{T}} = A \vec{T} + B \vec{u} \quad (4)$$

where  $T$  is node temperature,  $C$  represents heat capacity,  $A$  is a matrix related to heat transfer between different node,  $u$  is a vector of thermal disturbance and  $B$  is its' distribution on each node.

By the thermal network in figure 2, there are only four nodes in state-space method, thus it is easier to describe the thermal character than conventional CFD approach.

### Verification with CFD results

Total indoor cooling load simulated by this state-space based method in five typical cities were verified with that by CFD method (Shen and Li, 2016). Standard  $\kappa$ - $\epsilon$  turbulence model and DO radiation model were adopted in the CFD simulation. Results show that the simplified method can achieve the accuracy within 15 percent in all cases. The detailed information can be seen from Figure. 3. Nevertheless, computing time can be reduced from 2 days to 1 hour for each simulation.

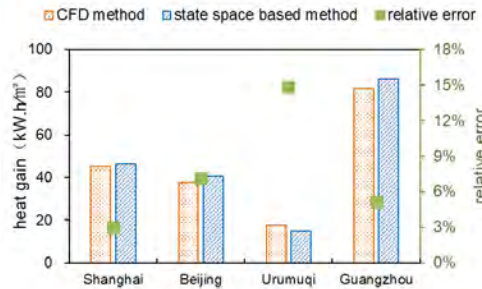

Figure 3. Validation with CFD results

## CASE STUDY IN GUANGZHOU

### Description of case setup

A typical room in Guangzhou which belongs to hot summer and warm winter zone was selected to investigate thermal improvement by PDSF. Hourly outdoor climate parameter including solar radiation, dry bulb temperature etc. can be obtained from China climate database and it is shown in Figure. 4. The dimension of the room is 5.0 m (length)  $\times$  5.0 m (width)  $\times$  3 m (height). All of the building envelope was designed according to the design standard GB 50189-2015. A PDSF, whose size is 5.0 m (length)  $\times$  3.0 m (height), is installed at south orientation. This room locates in middle floor and the east wall is the external wall. Heat transfer through other internal structure is neglected. Thermal and optical properties of the pipe-embedded double skin façade is described as Table 1.

Table 1. Thermal properties of the PDSF

	External glass	Venetian blinds	Internal glass
Material	stalinite	aluminum	Double glazing
Thickness(mm)	9	2	6+12(air)+6
Heat conductivity Coefficient(W/(m·k))	0.28	180	0.09
Density (kg/m <sup>3</sup> )	2200	2700	1000
Specific heat (J/kg·K)	840	100	880
Refractive index	1.4	/	1.4
Absorptivity(1/m)	5	/	20
Transmissivity	/	0.1	/

Two types of room, namely office room and residential room, in which indoor heat gain are different, are adopted in this study for the applicability discussion. Detailed information of these two rooms is listed in Table 2.

Table 2. Indoor heat gain and occupancy of office and residential room

	Office room		Residential room	
	Power(W/m <sup>2</sup> )	Occupancy(hour)	Power(W/m <sup>2</sup> )	Occu-
Occupant	8		3	All-time
Equip-	18	7:00-19:00	5	7:00-22:00
Lighting	8		3	18:00-22:00

Cooling water produced by cooling tower is analysed in this study. The temperature of cooling water is assumed to be considered 3°C higher than wet bulb temperature(Klimanek et al., 2015).

In this study, a triple glazing DSF whose external and internal glass are the same as pipe-embedded DSF was simulated as baseline.

Outdoor climate is described as figure 4. The average outdoor temperature hit the peak at July while solar radiation hit the peak at November.

Figure 4. Monthly average outdoor temperature and solar radiation of Guangzhou

### Performance of decreasing average indoor temperature

Cooling water provided by water pipes can decrease external glass temperature as well as block solar radiation, therefore room temperature can be reduced. Since heating is not required in Guangzhou, the PDSF is operated all-year around.

Figure 5. results of residential room. a) hourly indoor temperature, b) distribution

With built-in pipes in venetian blinds, room temperature can be decreased about 5°C for both office and residential room. Although with pipe-embedded, room temperature would still exceed 30°C in office for some time due to large indoor heat gain.

Superiority of PDSF is significant in spring and autumn when solar radiation is the strong while outdoor air temperature is not so high. What's more, average indoor temperature difference between office and residential rooms is only 3°C, approving that transmitted solar radiation has a tremendous impact on indoor temperature.

### Effect of extending non-air-conditioning period

Accumulated satisfactory hours when indoor room temperature is below 25°C and 28°C, which can guarantee a barely satisfactory environment (Okuma et al., 2007) as to save energy, are utilized for the determination of non-air-conditioning period. From Figure. 6, we can conclude that hours when indoor temperature is within 25°C can be increased from 1000 to 3000 hours by applying PDSF in office room. If a broad range of indoor room temperature is acceptable, the accumulated time can reach more than 4000 hours.

Compared with office room, performance in residential room is more promising. There are 5900 hours when room temperature is under 28°C. It means that the pipe-embedded double skin façade is considerably efficient under this circumstance.

Figure 6 Satisfactory hours in different criteria

## CONCLUSION

PDSF integrated with natural energy is a new approach to reduce heat gain. A state-space based method to evaluate dynamic thermal performance of PDSF is proposed in this paper. Performance of two typical rooms with different indoor heat gain in Guangzhou is analysed as a typical case. The main conclusions are as follows.

- 1) PDSF combined with cooling tower can reduce indoor room temperature significantly in Guangzhou. The average room temperature can be decreased about 5°C.
- 2) Accumulated hour when indoor temperature is within 28°C accounts for 5900 hours for residential room, indicating room temperature can meet the basic requirement in most time with the assistance of PDSF if indoor heat gain is small.
- 3) Performance in October is the most efficient when solar radiation is strong because shading blind embedded with water-pipes can block solar radiation and take it away directly, which indicates that PDSF could be promising in regions with strong solar radiation such as western china.

### **ABSTRACT**

In the last few decades a new type of persistent efflorescence has started appearing on ceramic brick facades in the UK, the Netherlands and in Belgium. Since the problem undermines the aesthetic appearance of masonry buildings, it results in a growing number of complaints from building owners.

In the laboratory, gypsum efflorescence is typically studied via wicking tests. However, these often yield gypsum subflorescence instead, leading to significant pore clogging just below the evaporation surface. To gain further insight in that subflorescence and pore clogging, a correct quantification of the amount and the distribution of the gypsum crystallised in the pore space is necessary. Micro-CT achieves this by allowing visual inspection as well as quantitative data gathering. Because of the non-destructiveness of micro-CT, samples can be scanned before and after subflorescence/pore clogging has occurred. The suggested methodology includes visualization and characterization of the pore space. Observing the changes in pore structure, with the assumption that these are induced only by the presence of the salt crystals, it is possible to accurately quantify the volume of gypsum present, as well as the location of the affected pores in 3D. Due to the partial volume effect, the CT dataset can be used to detect objects smaller than the voxel size because the density difference between gypsum and air is large enough.

The obtained results confirm the presence of a thin gypsum layer just below the evaporation surface of the sample. Other techniques such as the wicking test and MIP also confirm the observations regarding pore size change and gypsum content.

### **KEYWORDS**

Salt crystallization, Pore clogging, Brick sample, Micro-CT, Pore network properties

### **INTRODUCTION**

The development of gypsum efflorescence on newly erected ceramic brick facades is a rising problem in the UK, the Netherlands and Belgium (Chwast et al, 2015). Unlike the common efflorescence, composed of soluble salts which are easily washed away by natural weathering, the new efflorescence consists of slightly soluble gypsum, which makes it persistent and hard to remove. Once formed on the masonry surface, they stay and permanently spoil the facade's appearance.

Even though salt crystallization in porous materials has already been the subject of study for many decades, there is still a lack of knowledge and understanding in relation to the involved pore clogging and its impact on the moisture transfer properties of porous materials. In order to study this phenomenon in laboratory conditions, wicking experiments are often performed.

Such experiments usually reveal gypsum's tendency to crystallize under the surface, inducing significant pore clogging and resultantly a strong drop in the wicking rate.

In this paper, the resultant changes in the brick's pore structure, with the assumption that these are induced only by the presence of the salt crystals, will be quantified based on CT datasets. It will be shown that such CT analysis makes it possible to accurately quantify the volume of salts present as well as the location of the affected pores in 3D.

## METHODS

### Wicking test

The effect of gypsum pore clogging is generated with a wicking test. It is composed of a brick sample fed with a gypsum solution from the bottom side, while evaporation is permitted only from the top side. The gypsum solution for the wicking test is prepared by dissolving 2.2 g of calcium sulphate dihydrate (Fisher Chemicals, 99% pure) in 1l of distilled water (conductivity of pure water  $1.2\mu\text{S}/\text{cm}$ ). The prepared solution is 85% saturated, and its concentration can be calculated as  $2200\text{ g}/\text{m}^3$ . The experimental set-up is composed of a glass container with at the bottom a layer of gypsum solution. The container is closed with a plastic lid, to which a brick sample is mounted. In this way, a constant contact between the solution and the brick sample is maintained throughout the experiment. The experiment is conducted in a climate chamber, under constant environmental conditions, at  $21^\circ\text{C}$  temperature and 40% relative humidity, for a duration of 14 days.

### CT characterization

Computed tomography (CT) is a non-destructive visualization technique, generating images of slices of a sample based on the attenuation of X-rays. Hence, it enables the 3D visualization of the internal structures of the object. As CT is a fast and non-destructive technique, it has become a reliable method to analyze the heterogeneity of interior components as well as the porosity network of the studied sample. A more detailed explanation of the principles of CT can be found in Claes et al. (2018). Also Aikens (1991), Kak and Slaney (1988) and Herman (2009) provide more general information about the technique.

In order to determine the effect of the salt precipitation, the same sample is scanned by micro-CT before and after the above described wicking experiment. Both scans are performed using the same scan parameters (80 kV and  $160\mu\text{A}$ ) and both have a resolution of  $3.5\mu\text{m}$ . The quantitative data are generated through the attenuation of X-rays, which are sensitive to sample density and atomic number, and are stored in voxels as relative gray scale values. Since in theory the only difference between both scans is the presence of salt, which will cause a higher attenuation of the x-rays compared to the air present in the pores of the original sample, resulting in higher greyscale values of the voxels. Thus, a subtraction of both datasets should result in the quantification of the precipitated salt. Hence, it becomes very important to subtract the correct corresponding voxels of both datasets, in order not to introduce artificial artefacts in the results. This is achieved by a registration process involving the determination of a geometrical transformation that aligns points in one view of an object with corresponding points in another view of that same object. The inputs of the registration algorithm are the two views to be aligned; the output is a geometrical transformation, which is a mere mathematical mapping from points in one view to points in the second. In order to retain cubic voxels, the values of the voxels of the transformed view will be linearly interpolated.

## RESULTS & DISCUSSION

### Effect on the pore network

A visual inspection of the micro-CT slices taken at the same depths from the top evaporation surface show that, in the top of the sample, gypsum is present at the edges of large pores and clogs smaller pore throats (Figure 1 A-B). Comparison of slices taken towards the bottom of the sample indicate that no visual gypsum is present (Figure 1 C-D).

Figure 1. Micro-CT slices of the brick sample parallel to the evaporation surface. a) Original state at 130  $\mu\text{m}$  below the evaporation surface, b) State with salt present at 130  $\mu\text{m}$  below the evaporation surface; orange markers illustrate the differences, c) Original state at 1.5 mm from the evaporation surface, d) State with salt at 1.5 mm from the surface, no differences are visible between c and d.

These images are used to deduct the pore network in these volumes by applying a hysteresis segmentation (Claes et al., 2018). Subsequently these pore networks are split into pore bodies and pore throats using the workflow of Blunt et al. (2013).

Based on a visual inspection of the slices, the salt precipitation occurs in the top layer of the studied sample. Hence, two corresponding volumes of  $500 \times 500 \times 120$  voxels ( $1.75 \times 1.75 \times 0.42 \text{ mm}^3$ ) are selected in this layer.

In general the CT-detectable open porosity is decreased by 1.2 %, from 15.6 % porosity in the original sample to 14.4 % in the affected sample. Moreover, the salt subflorescence has a clear effect on the pore size as well as on the overall distribution of pore bodies and throats in the studied volumes. As expected from the visual observations in Figure 1, the number of pore bodies and throats increases in the volume affected by salt precipitation. The average pore radii become 5 % smaller when affected by the salt. This can be explained by the rims of salt formed at the edges of the pores. Figure 2 represents the calculated pore size distributions of the reference and affected volume. The number of pores in the bin with the smallest pore radii also increases from 2460 pores to 3283. Additionally a clear shift towards smaller coordination numbers can be noticed in the sample where salt is present, even though it has a larger number of throats in the same sample volume (8324 compared to 6777). This results in a halving of the simulated permeability but these simulations only take into account the visible porosity in the CT scan.

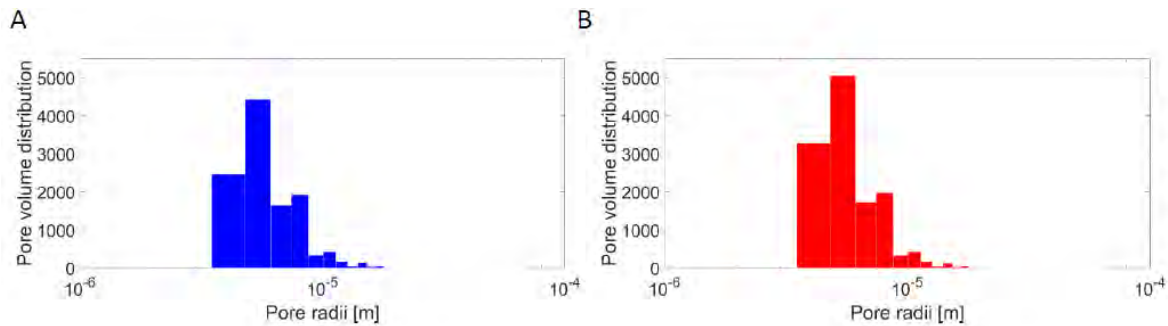

Figure 2. Pore volume distribution. a) Reference sample, b) Affected sample.

### Validation

The results of the visual comparison of the slices agree with observations made in lab results and confirm the creation of a salt subflorescence layer just below the top evaporation surface. Admittedly, the influence of the scan resolution remains apparent, as only half of the open porosity can be CT-detected (15.6 % vs 31.8 % which is the actual open porosity of the brick samples). The obtained pore size distributions are further matched to distributions acquired by mercury intrusion porosimetry (MIP). Todorovic and Janssen (2018) noted that the curves of samples containing gypsum shifted in two general directions: firstly a downward shift corresponding to a decrease in open porosity, and secondly a shift to the left, towards smaller pore radii. The same observations can be partially made based on Figure 2. It is important to notice that due to the scanning resolution of 3.5  $\mu\text{m}$  the spectrum of CT-detectable pore radii is limited. Hence, most of the clogged open porosity was not visible in the reference scan, since these pores fall below the resolution. The beginning of the shift to the left is visible but the main shift occurs for pores with radii of  $10^{-6} \text{ m}$  which are not captured in the micro-CT scan.

### Quantification and spatial distribution of the salt

The validation of the results obtained in the prior section indicate that they are greatly affected by the limited scan resolution, as only half of the expected open pores are visible in the scan. Another approach is therefore necessary to accurately quantify the distribution of precipitated gypsum. Micro-CT datasets have the added advantage that objects smaller than the voxel size can still be detected if the density difference between the competing components is large

enough. For the studied problem this is the case because  $\rho_{\text{gypsum}} (2300 \text{ kg/m}^3) > \rho_{\text{air}} (1.25 \text{ kg/m}^3)$ . This is due to what is generally called the partial volume effect (Figure 3 A). Because the borders of the scanned sample or a component in the sample may not coincide with the borders of the pixels of the detector, the partial volume effect occurs: features smaller than the resolution will also contribute to the attenuation coefficient of the voxel in a linear way.

Hence, in order to quantify all gypsum present in one slice, slices corresponding to the same depth are subtracted from each other. In Figure 3 B-C the histograms of these subtractions are depicted. The histogram of a slice where no salt is visible corresponds to a symmetrical bell curve centered approximately around zero. Hence this curve is interpreted as a representation of the noise present in the subtracted images. For the slices nearer to the top of the sample, the histograms become asymmetrical, and show an increase in positive difference values around 1200. These curves will therefore be modeled as a sum of two normal distributions. Parameter  $p$  represents the contribution of the noise component to the overall model, while a factor  $(1-p)$  is assumed to define the gypsum. The distributions are fitted using a maximum likelihood method. Table 1 summarizes the modeled parameters.

Table 1. Overview of typical values of the fitted parameters.

slice depth	$p$	$\mu_1$	$\sigma_1$	$\mu_2$	$\sigma_2$
0,2 mm	0.85	-112	568	903	1137
1,2 mm	0.98	5.6	620	25.5	1087

Based on these models the parameter  $(1-p)$  represents the relative amount of voxels for which the composition has changed between the two scans. Hence, they can be used to characterize the volume percentage of salt in each slice. The profile is shown in Figure 3 D and clearly indicates the presence of a gypsum crust at the top of the sample. The top 49  $\mu\text{m}$  are not processed as these are too much affected by the surface roughness of the brick sample. The sudden drops in the profile can be explained by spurious additional noise in some slices.

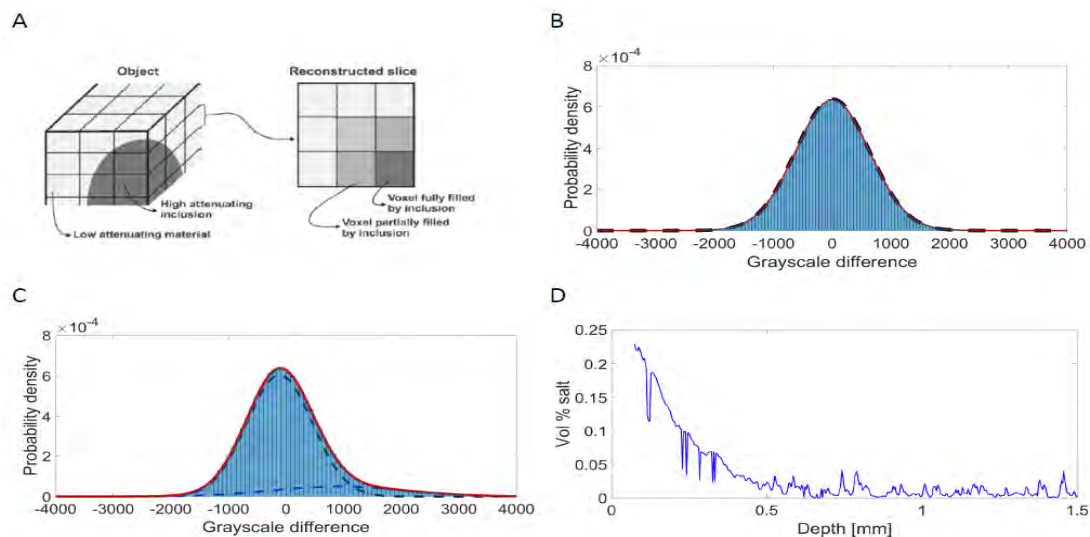

Figure 3. Localisation and quantification of the salt layer. a) Schematic overview of the linear partial volume effect (modified from Pullan et al., 1981), b) Histogram of the difference between two slices near the bottom of the sample (black dotted line represents the noise component, red line represents the overall model), c) Histogram of the difference between two slices near the top of the sample (black dotted line represents the noise component, blue

dotted line represents the salt component, red line represents the overall model), d) Volume percentage salt in function of sample depth.

### Validation

In order to validate the results of the calculated presence of gypsum in the section above, these results are compared to the lab measurements. On average 0.046 g of gypsum precipitated in the 28.7 mm diameter ceramic brick plugs. This corresponds to a total amount of gypsum of 71 g/m<sup>2</sup>. By calculating the surface below the curve in Figure 3 D up to 450 µm below the top surface, a total amount of 91 g/m<sup>2</sup> is obtained from our CT measurements. Both measurement methods are thus in agreement with each other.

### CONCLUSIONS

In this paper the location and concentration of the gypsum subflorescence layer in bricks is successfully determined based on 3.5 µm resolution micro-CT scans. The evaporated gypsum is concentrated in the top 450 µm layer of the sample. Based on the pore network analysis general observations about the change in pore geometry can be made. However, comparison with MIP measurements indicate the strong importance of the contribution of pores below the scanning resolution. The partial volume effect can overcome some of these limitations, but additional visualization techniques with smaller resolutions will need to be used in the future in order to perform accurate fluid flow simulations.

### ACKNOWLEDGEMENT

This project has received partial funding from the FWO Odysseus grant ‘Moisture transfer in building materials: analysis at the pore-scale level’. Their support is kindly acknowledged.

## **Determination of the input data for computational simulation of active glazing with changeable optical properties**

Dariusz Heim<sup>1\*</sup>, Dominika Knera<sup>1</sup> and Anna Wieprzkowicz<sup>1</sup>

<sup>1</sup>Department of Environmental Engineering, Lodz University of Technology, Poland

### **ABSTRACT**

Nowadays, many construction components applied in the energy efficient buildings are characterized by dynamically changeable physical properties. Some of them are actuated by the user or building management system, while the others are self-regulated. The second group of mentioned elements is often named intelligent or smart components. Change of their properties is triggered by physical processes e.g. thermal or chemical.

Energy performance of the building can be precisely determined based on the results of computational simulation obtained using one of the widely well-known computational tools e.g. Energy Plus or ESP-r. In the numerical analysis the effect of changeable properties can be also included towards better modelling of physical processes in the buildings. However, the exact material data and its characteristics are necessary for a proper definition of such component properties - thermal or optical characteristics. The main goal of this study is to refine the ESP-r material database, in order to include in the calculation the effect of changeable optical properties of glazing unit filled with material characterized by variable solar transmittance.

The basic general equation of transmittance, reflectance and absorptance as a function of incidence radiation were provided. The material optical database developed in this study consists of experimentally determined reflectance, absorption and transmittance of solar radiation for five angles of incident (as required for ESP-r optical databases). All these data were provided for double glazed unit where the inner cavity was filled with material characterized by changeable optical properties. All optical data were obtained based on the spectral characteristic of the material layer (in different thicknesses) in a wave length range of solar radiation (300-1200 nm). It was concluded, that overall transmittance is determined by the material filling the cavity, but the reflectivity mainly depends on the external surface of glazing and interrelations between glazing and subsequent layer.

### **KEYWORDS**

Solar energy, heat transfer, transmittance, reflectance, phase change materials.

### **INTRODUCTION**

The application of paraffin as a filling of transparent building components is well known since the end of the nineties. (Ismail and Henríquez 2002) proved that additional layer of PCM can improve the thermal efficiency of the whole window, while (Weinläder, Beck, and Fricke 2005) dedicated their research to comfort analysis. PCM was not only used as a layer of a glazing pane but also as a filing of the shading elements (Bianco et al. 2018) and in other technologies as well (Silva, Vicente, and Rodrigues 2016). Additionally, PCM was used in hybrid TPV systems where PV cells were thermally stabilized by PCM layer located at the back side of the panel (Machniewicz, Knera, and Heim 2015). Additionally, the application of PCM glazing components can also lead to achieve future energy standard according to the requirements of new energy performance directive (Firlag 2015). Determination of optical and

thermal properties of PCM-glazing component is very important for proper estimation of its efficiency using modelling techniques. Moreover, it is necessary to determine the optical data, especially of any complex glazing structure for the purpose of building energy performance simulation (Clarke 2001), (Hensen and Lamberts 2011). Many authors provided those data obtained experimentally using spectrophotometric techniques or direct measurements (Goia et al. 2012). Nevertheless, both techniques ignore the effect of local optical phenomena (Duffie and Beckman 2013) on interfaces between glass, air and PCM layer.

The main idea of using PCM in glazing was raised by the necessity of the improvement of their thermal inertia (Grynning, Goia, and Time 2015). Although PCM application in glazing is relatively brand new idea, some previous research study was devoted to analyse other liquids e.g. water as a glazing extender. (Chow, Li, and Lin 2011) revealed that water-flow window can work as a hot-water preheating device. (Sierra and Hernández 2017) showed the active behaviour of water flow glazing by a variable  $g$  factor. Additionally they concluded that the best glazing to manage the incoming solar energy is the one that allows to enter only visible spectra when the system is flowing and the absorption occurs only in the water chamber. The PCM glazing will play the similar role but the heat will not be extracted from the system to external storage tank but isothermally stored in the PCM layer.

The main purpose of this study was to develop the methodology for determining total solar transmittance, reflectance and absorptance in a glass pane with phase change material, in solid a liquid state. The basic equations were provided for double glazed window with PCM and optical data for standard angle of incidents was determined. Results were presented in the standard of ESP-r (Environmental System Performance) database format.

## METHODOLOGY

The proposed methodology is based on the physical fundamentals of solar radiation's transmission through transparent media like glazing (Chwieduk 2014). Physical fundamentals of the phenomena occurring within glazing are mostly related to the optics. The phenomena of radiation's passage through two transparent covers should be analysed taking into account the multi inter reflections on all interfaces. These multi-reflections in double glazed window with air, argon or any other gases between glass panes are schematically presented in figure 1.

Figure 1. Transmittance, reflectance and absorptance components including inter reflections on glass surface and absorption in a glass pane.

Taking into account inter reflections on glass surface and absorption in a glass pane, the total reflectance ( $\rho$ ), absorptance ( $\alpha$ ) and transmittance ( $\tau$ ) of the component can be calculated from the following formulas (eq. 1-3):

$$\rho = \rho_e + \frac{\tau_e^2 \rho_i}{1 - \rho_e \rho_i} \quad (1)$$

$$\alpha = \alpha_e + \frac{\tau_e (\alpha_i + \alpha_e \rho_i)}{1 - \rho_e \rho_i} \quad (2)$$

$$\tau = \frac{\tau_e \tau_i}{1 - \rho_e \rho_i} \quad (3)$$

where indexes  $i$  and  $e$  refer to the internal and external glass covers respectively.

When glazing cavity is filled with PCM the repeated reflection on all interfaces become more complex due to additional effect of reflection on PCM layer. This process is schematically presented in figure 2, where  $m$  means material between two glasses.

Figure 2. Transmittance, reflectance and absorptance components including inter reflections on glass surface and absorption in a glass pane filled with PCM (material).

The general formula for total solar reflectance ( $\rho$ ), absorptance ( $\alpha$ ) and transmittance ( $\tau$ ) becomes as follows:

$$\rho = \rho_e + \tau_e^2 \rho_e + \frac{\tau_e^2 \tau_m^2 \rho_{mi}}{1 - \tau_m^2 \rho_{me} \rho_{mi}} \quad (4)$$

$$\alpha = \alpha_e \left( 1 + \tau_e \rho_{em} + \frac{\tau_e \tau_m^2 \rho_{mi}}{1 - \tau_m^2 \rho_{me} \rho_{mi}} \right) + \alpha_m \left( \tau_z \frac{1 + \tau_m \rho_{mi}}{1 - \tau_m \rho_{me} \rho_{mi}} \right) + \alpha_i \left( \frac{\tau_e \tau_m}{1 - \tau_m^2} \right) \quad (5)$$

$$\tau = \frac{\tau_e \tau_m \tau_i}{1 - \tau_m \rho_{me} \rho_{mi}} \quad (6)$$

The indexes concerns the surface where optical processes appears, where  $i$  and  $e$  refer to the internal and external glass covers respective and  $m$  corresponds to PCM layer.

The equations presented above require very precise sets of data which are usually unavailable or impossible to be obtained during tests. Therefore, the following assumptions and simplifications were done:

- 1) The absorptivity of the single PCM layer in both phases is the same for all angles of incident. It means that reflectivity of the whole component is determined primarily by reflectivity of external glass surface.
- 2) The reflectivity of single PCM layer in liquid state changes versus angle of incident cognately as the glass – only direct reflectance is considered.
- 3) The transmissivity of single PCM layer in both phases is a function of the incident angle according to the optical length of the beam during transmission through the material.

### OPTICAL PROPERTIES OF PCM DOUBLE GLAZED WINDOW

The results of presented analysis were obtained for glass pane that consists of two glasses 4 mm each with 16 mm air cavity or PCM layer between them. The cross section through the unit is presented in figure 3a - standard double glass pane and 3b - glass pane with PCM.

The main difference between both cases is the heightened potential to absorb solar radiation in a material layer located between glasses. Especially, when PCM is in solid state the absorption appears on the surface exposed to solar radiation. The total transmittance of single PCM (16 mm thick) layer in solid state is less than 10%, while in liquid state it is above 80%. It means that for the case considered here the solid PCM is similar to opaque material. The colour of solid paraffin or fatty acids is white or light grey. It means that reflectivity can be assumed as 0.5 - 0.7 and decreases when material melts. The liquid PCM is fully translucent and has neutral colour.

Figure 3. Cross section through glass pane a) standard, b) with PCM.

For the purpose of computational simulation the datasets including angular optical properties are necessary to analyse any physical processes in a glazing unit. The main goal of the work presented in the paper was to develop the characteristic data based on the physics of radiation transmission through glazing. Taking into account the formulas 1-6, the optical characteristics of double glazed unit without, with liquid and with solid PCM were determined. The results are presented in figure 4 a-c as a function of incident angle. It can be noted that when material is solid, PCM glazing characteristic is similar to standard glazing but transmittance is slightly lower as an effect of higher reflectance. In solid state the reflectance is much higher and strongly depends on reflectance of PCM.

Figure 4. Transmittance, reflectance and absorptance versus angle of incident for a) clear glass double pane window unit, b) glass unit with liquid PCM, c) glass unit with solid PCM.

## DISCUSSIONS

In a case of liquid PCM the obtained results show that total transmittance is more than 20% lower than for standard glazing unit and its function versus angle of incident has similar character. The absorptance of liquid PCM is similar to external glazing for the angles up to 50 deg. For higher angles the absorptance of external glazing increases due to the additional reflections between glass and PCM layer.

In solid state the glazing unit is almost blind and most of solar energy is absorbed on the PCM external surface due to the highest absorptivity, almost 0.3. This absorptivity decreases as a function of angle of incident while absorptivity of external glazing increases. This is caused by the longer optical path of the radiation beam, and as it was stated for the liquid state, the interreflections between glass and PCM occur.

In both cases the absorptance on the internal glass surface is very low and has no effect on thermal performance of the whole system. It means that PCM layer should protect building interior against overheating caused by solar radiation. The excessive solar heat gains will be stored as an latent heat in PCM layer and any heat transfer to external environment will be possible only by conduction (inside the component) and convection between glass surface and internal air. Heat exchange by radiation, when melting temperature will be close to indoor air temperature, seems to be negligible.

## CONCLUSIONS

The paper presents the methodology of optical properties determination for complex glazing structure. The formulas were developed based on the physical fundamentals of solar radiation's transmission through transparent media. The problem was graphically illustrated and related formulas were also derived.

The final results of transmittance, reflectance and absorptance versus angle of incident were presented in a form of ESP-r optical database and compared with case of standard, double glazed clear glass window. In both phases, solid and liquid, PCM-glazing is characterized by the lower transmittance than standard glass unit. In solid phase the component is almost blind, but the absorptance of PCM layer is relatively high. This feature will determine the ability to absorb solar energy and convert it to heat.

## **Predicting the thermal conductivity of porous building materials with nanopores or reduced gas pressures**

Wouter Van De Walle<sup>1,\*</sup>, Hans Janssen<sup>1</sup>

<sup>1</sup>KU Leuven, Department of Civil Engineering, Building Physics Section, Kasteelpark Arenberg 40, 3001 Heverlee, Belgium

### **ABSTRACT**

Porous materials with nanopores or reduced gas pressures like aerogels, nanocellular foams or vacuum insulation panels show a great potential as insulation materials, due to their extremely low thermal conductivity. Understanding the relation between their pore structure parameters and effective thermal conductivity is crucial for further optimization. This paper discusses the extension of a numerical framework simulating the heat transfer directly at the material's pore scale. A novel methodology to model the reduced gaseous conductivity in nanopores or at low pressures is presented, accounting for the three-dimensional pore geometry while remaining computationally efficient. Validation with experimental and numerical results from literature indicates the accuracy of the methodology over the full range of pore sizes and gas pressures. A simple case study is analysed, which shows the expected improvements of the thermal conductivity when reducing the pore size for materials with different porosities. The numerical framework thus offers the possibility for a more thorough understanding and optimization of the thermal conductivity of superinsulators.

### **KEYWORDS**

Thermal conductivity; porous materials; superinsulators; nanopores; low-pressure

### **INTRODUCTION**

Heat losses through opaque building components like walls and roofs account for a large part of the total heating demand in buildings. Hence, porous insulation materials are often applied, offering a relatively low thermal conductivity due to their porous nature (Smith et al., 2013). To comply with progressively stringent energy requirements though, increasingly large insulation thicknesses are needed, hindering the design and the refurbishment of new and existing buildings. In the search for better performing insulators, a promising solution is offered by materials having pores with diameters in the nanoscale range and/or with reduced gas pressures inside. Examples are aerogels or aerogel-based materials (Baetens et al., 2011), nanocellular foams (Liu et al., 2015) and vacuum insulation panels (Jelle et al., 2010). Research has shown that in these materials the gaseous conduction shifts from the Fourier to the Knudsen regime, resulting in a reduced gaseous and hence overall effective thermal conductivity (ETC) (Jelle et al., 2010). Furthermore, the effect becomes even more crucial at increasing material porosities where conduction through the gaseous phase becomes progressively more dominant in the total heat transfer (Solórzano et al., 2009). Modelling efforts so far though have mainly focussed on obtaining analytical expressions, predicting the ETC as a function of several pore scale parameters like porosity and pore size (He & Xie, 2015; Wang et al. 2017). A more detailed understanding of the pore structure influence on the total ETC is hence needed to improve their performance significantly. To this aim, a numerical framework was recently implemented predicting the ETC of porous building materials based on their pore structure. A 3D voxel image representation of the microstructure, obtained via either micro-CT scanning

**Figure 1: The numerical framework simulates the pore scale heat transfer to deduce the ETC. (a) micro-CT image of cellular concrete; (b) virtual material; (c) finite element mesh; (d) temperature profile.**

or virtual generation, is used as input for the pore scale heat transfer simulation (Figure 1); more details can be found in the paper by Van De Walle & Janssen (2016). Currently, the model framework is limited though to porous materials with pore dimensions above several micrometres and containing gas at atmospheric pressure. Extension to a physical description of the Knudsen effect on the gaseous conductivity could enlarge its scope and facilitate the characterization of possible optimization strategies for superinsulating materials.

This paper discusses the implementation of the dimension- and pressure-dependent gaseous conduction in the aforementioned numerical framework. A novel simulation methodology based on the kinetic theory is introduced to obtain the local gaseous conductivities, offering an efficient calculation procedure while taking into account the pores' specific geometry. The proposed methodology is validated with experimental and numerical results from literature. Finally, the model is applied in an exploratory case study to investigate the effect of the pore size at different material porosities. Currently, only materials in dry conditions are targeted.

## GASEOUS CONDUCTIVITY

The kinetic theory framework is used to model the microscopic gaseous heat transfer in pores. Firstly, the general theory is revisited for clarity, then the extension to reduced dimensions and/or gas pressures is explained. Finally, the implementation of the methodology in the numerical framework is discussed.

### General kinetic theory

The kinetic theory framework allows to describe the heat conduction through gas as a function of the gas properties. Apart from the density  $\rho_{gas}$  [kg/m<sup>3</sup>], the specific heat capacity at constant volume  $c_{V,gas}$  [J/kgK] and the mean molecule speed  $v_{mean}$  [m/s], the gaseous thermal conductivity depends on the mean free path  $L_{MFP}$  [m], which is the average distance a gas molecule travels before colliding with another gas molecule (eq. 1), (Zhang, 2007; Jiji, 2009).

$$q_{cond} = -\frac{1}{3} \cdot \rho_{gas} \cdot c_{V,gas} \cdot v_{mean} \cdot L_{MFP} \cdot \frac{dT}{dx} = -\lambda_{gas,bulk} \cdot \frac{dT}{dx} \quad (1)$$

Here,  $q_{cond}$  [W/m<sup>2</sup>] is the total heat flow caused by the temperature gradient  $dT/dx$  [K/m], and  $\lambda_{gas,bulk}$  [W/mK] is the bulk gaseous thermal conductivity. The mean free path between successive collisions depends on the temperature and pressure of the gas, as well as on the gas molecule properties. However, as argued by Jiji (2009), the mean free path between collisions is not completely suited to describe the energy transport, since it doesn't consider the efficiency of energy exchange between two colliding particles. Therefore the 'energy' mean free path was introduced, which should be used in eq. 1 to obtain correct results. This energy mean free path can easily be deduced for bulk gases by reverse calculating equation 1, leading for example to an energy mean free path of 180 nm for air at 20 °C and atmospheric pressure.

Apart from gaseous heat conduction, the kinetic framework can equally be applied to describe heat conduction in solids by electrons, phonons (acoustic waves), and radiative heat transfer by photons (electromagnetic waves), considering the waves as particles (Chen, 2005). Although less accurate than more detailed simulation strategies like molecular dynamics or lattice Boltzmann simulations, the kinetic theory is capable of predicting reasonably well the thermal transport and thermal conductivity. This paper focusses solely on the implementation for gaseous conduction.

### Extension to pore cavities with reduced dimensions and gas pressures

When the pore dimensions or gas pressure start to reduce, gas particles start colliding relatively more often with the pore boundaries instead of with each other, which is called the Knudsen effect. This translates to a reduction in the effective mean free path of the molecules and - according to eq. 1 - to a reduction of the gaseous conduction. The effective mean free path can be calculated according to Matthiessen's rule, combining the bulk mean free path and the mean free path induced by the boundaries, as shown in eq. 2 (Jiji, 2009).

$$\frac{1}{L_{MFP,eff}} = \frac{1}{L_{MFP,bulk}} + \frac{1}{L_{MFP,bdy}} \quad (2)$$

Again, the effectiveness of energy exchange between molecules and boundaries will influence the thermal transport. This is usually described with the thermal accommodation coefficient  $a$ , varying between 0 and 1, and very similar to the better-known absorptivity coefficient  $\alpha$  used in thermal radiation simulations (Zhang, 2007; Jiji, 2009). Hence, an 'energy' boundary mean free path should be defined including this factor, thus directly incorporating the boundary resistance effect. Apart for simple structures like parallel plates, accurate calculation of this energy boundary mean free path is far from trivial. A novel method is therefore implemented in the model framework to account for the real 3D geometry of pores.

### Including nanoscale gaseous conduction in the model framework

To calculate the gaseous conductivity in each pore, the energy boundary mean free path needs to be determined. A calculation methodology based on the analogy with radiative heat transfer is proposed, simplifying the simulation procedure. Introduced by Loeb (1954) and later extended by Van De Walle & Janssen (2016), the radiative heat transfer in a pore cavity can be described as a conductive process with a radiative conductivity depending – amongst others – on the pore dimensions and the wall's absorptivity. The formulas proposed by Van De Walle & Janssen (2016) to calculate this conductivity are shown in eq. 3 and 4. Eq. 3 is equalized to the more general form of the radiative conductivity originating from the kinetic theory.

$$\lambda_{rad,pore} = 4 \cdot \sigma \cdot T^3 \cdot d_{mean} \cdot C(\alpha, S_f) = \frac{1}{3} \cdot 16 \cdot \sigma \cdot T^3 \cdot L_{MFP,rad,eff} \quad (3)$$

$$S_{f,2D} = h_{mean} / d_{mean} ; S_{f,3D} = h_{mean} \cdot w_{mean} / d_{mean}^2 \quad (4)$$

Here,  $T$  [K] is the average temperature inside the pore,  $\sigma$  [W/m<sup>2</sup>K<sup>4</sup>] the Stefan-Boltzmann constant and  $d_{mean}$ ,  $h_{mean}$  and  $w_{mean}$  [m] the mean distance between opposing pore walls parallel ( $d_{mean}$ ) or perpendicular ( $h_{mean}$ ,  $w_{mean}$ ) to the heat transfer direction.  $C(\alpha, S_f)$  [-] is a factor taking into account the effect of the absorptivity and the geometry of the pore walls using the directional slenderness factor  $S_f$  [-], and was defined based on a series of radiative simulations in several pores with varying geometries (Van De Walle & Janssen, 2016).

Since the bulk mean free path of photons  $L_{MFP,rad,bulk}$  travelling in a non-absorbing medium like air is considered very large ( $\sim$ kilometres), the effective mean free path reduces to the boundary mean free path. Indeed, radiation is often modelled as only depending on the system boundaries. Using the analogy between gas particles and photons as well as between the thermal accommodation coefficient and the absorptivity, we can rewrite the last two parts from eq. 3 to finally formulate an expression calculating the energy boundary mean free path for gas particles in a certain pore (eq. 5).

$$L_{MFP,bdy,en} = \frac{3}{4} \cdot d_{mean} \cdot C(a, Sf) \quad (5)$$

Here,  $a$  is now the thermal accommodation coefficient instead of the radiative absorptivity. Hence, combining eq. 5, 4, 2 and 1, the reduced gaseous conduction can be calculated for every pore, knowing the gas state (pressure and temperature), the bulk gas properties ( $R_s$  [J/kgK],  $c_{V,gas}$  and  $\lambda_{bulk,gas}$ ) and the material properties (pore dimensions and thermal accommodation coefficient).

### VALIDATION OF GASEOUS CONDUCTION CALCULATION

The implemented gaseous conductivity calculation procedure is validated against experimental and numerical results found in literature for different geometries, gasses and thermal accommodation coefficients.

#### Gas confined between parallel plates

The accuracy of the implemented calculation procedure to predict the gaseous conductivity variation is examined firstly for the simple case of parallel plates. Results are compared with experimental measurements of Braun & Frohn (1976) on Ar gas at pressures from 8.5 Pa to 66735 Pa, and with numerical DSMC simulations by Denpoh (1998) on N<sub>2</sub> gas at plate separation distances from 1.6 nm till 22  $\mu$ m. Details of both studies are summarized in Table 1, results are brought in Figure 2a. For both cases, the calculation procedure proves to accurately predict the gaseous thermal conductivity over the whole range of pressures and plate separation distances, even at varying thermal accommodation coefficients. Furthermore, they agree also very well with the often applied analytical prediction formula of Zhang (2007), derived for heat transfer between parallel plates.

#### Cuboid nanopore

The gaseous conductivity in real, more complex shaped pores depends (apart from the pore size and gas pressure) also on the pore's specific geometry. The performance of the novel calculation procedure – able to take the three-dimensional shape of the pore into account – is validated on a cuboid nanopore. Predicted results are compared with numerical DSMC simulations performed by Zhu et al. (2017) on Ar gas in a cuboid pore, varying the side length from 24 nm till 1.4  $\mu$ m; details are mentioned in Table 1. The gaseous conductivity predicted by our model agrees very well with the simulation results of Zhu et al. over the whole range of pore sizes, see Figure 2b. Furthermore, the model clearly outperforms the parallel plates formula of Zhang, underlining the importance of taking the true pore geometry into account.

**Table 1. Properties used in the model to predict the gaseous thermal conductivity (NIST).**

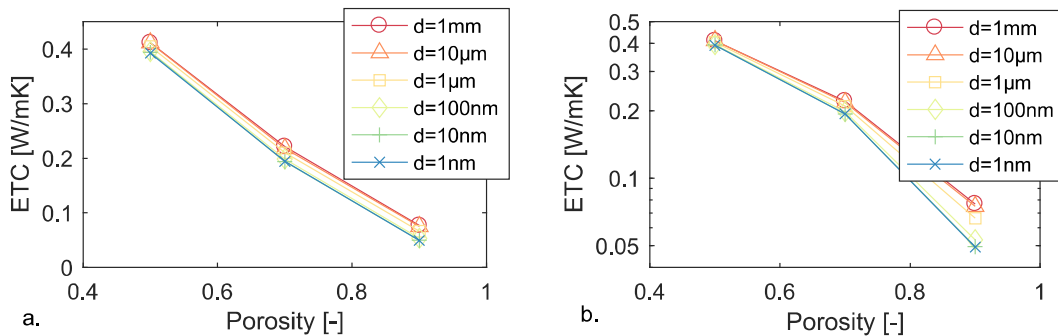

Study	Geometry	Gas	$\lambda_{gas,bulk}$ [W/mK]	$a$ [-]
Braun & Frohn, 1976	// plates	Ar @ 323 K	0.0188	0.7385
Denpoh, 1998	// plates	N <sub>2</sub> @ 343 K	0.0286	0.1 – 0.5 – 1
Zhu et al., 2017	Cuboid	Ar @ 300 K	0.0177	1

**Figure 2: Gaseous conductivity results predicted by our model agree very well with experimental and numerical literature for gas confined between parallel plates (a) and gas in a cuboid nanopore (b).**

### CASE STUDY

Lastly, a case study is performed to investigate the potential impact of reducing the pore size and thus the gaseous conductivity on the total ETC of a porous sample. A body-centred cubic (BCC) unit cell is used as sample pore structure, considering the spheres as air-filled cavities inside a solid matrix. Three different material porosities are considered (50 %, 70 % & 90 %). The thermal conductivity of the matrix is set to 1 W/mK, simulations are performed at 20 °C mean temperature and 101325 Pa air pressure inside the pores. The specific heat capacity at constant volume is assumed to be 717 J/kgK (NIST), while a common value of 0.9 is taken for the thermal accommodation coefficient (Zhang, 2007). First, the ETC of each sample is calculated setting the pores' diameter to 1 mm, hence having the bulk air thermal conductivity inside them. Subsequently, the dimensions of each sample are rescaled five times, obtaining five different pore diameters between 1 nm and 10  $\mu\text{m}$ . The total ETC of each sample is calculated using the numerical framework described in the introduction, taking into account the reduced gaseous thermal conductivity in every pore. The effect of the pore dimensions on the effective matrix conduction and radiative heat transfer is not taken into account here. A resolution of  $400^3$  for the voxel grid image is applied together with a mesh size of 3 times the respective voxel size, showing no further improvement with increasing grid and mesh refinement. As expected, the ETC generally decreases with increasing porosity and decreasing pore diameter (Figure 3). Furthermore, the effect of the pore size becomes more pronounced at increasing porosities, since gaseous conduction becomes progressively more dominant in the total heat transfer. The steepest drops are observed when decreasing the pore size from 10  $\mu\text{m}$  to 100 nm, resulting in an ETC decrease of over 30 % for the sample with 90 % porosity. However, at the relatively high matrix conductivity involved here, the sample's porosity seems to remain the most important parameter. Future research will focus on studying

**Figure 3: The ETC decreases with increasing porosity and decreasing pore size (a); at higher porosities the effect of a smaller pore size becomes more pronounced (b).**

more complex materials and including the nanoscale effect on the matrix conduction and the radiative heat transfer in nanoporous materials.

## CONCLUSIONS & FUTURE WORK

The paper presents the extension of a numerical framework to study the heat transfer in porous insulation materials showing low thermal conductivities due to the Knudsen effect. A novel computationally efficient method for calculating the gaseous conductivity in nanopores and at reduced gas pressures is discussed and validated against experimental and numerical results found in literature. An exploratory case study showed the effect of reduced pore dimensions on the ETC of a porous material, at three different porosities. Future work will focus on validating the model with experimental measurements on real materials having nanopores or reduced gas pressures.

## Rational selection of experimental readouts for hygric material characterisation

Evy Vereecken<sup>1,\*</sup>, Hans Janssen<sup>1</sup> and Staf Roels<sup>1</sup>

<sup>1</sup>KU Leuven, Department of Civil Engineering, Building Physics Section, Belgium

### ABSTRACT

To reduce the experimental effort and time required for the hygric characterisation of building materials, dynamic measurements in combination with parameter estimation are promising. However, noisy input data as well as limited and noisy output data complicate a reliable estimation of the material properties. A well-considered design of the dynamic experiments is advisable to reduce parameter uncertainty and to resolve non-identifiability issues.

Based on a virtual hygric test case, this paper shows the profile likelihood analysis to be an interesting starting point for the optimal design of hygric experiments. Trajectories of internal observables, such as relative humidity, plotted for the parameter sets along the profile likelihood curve are used to map highly uncertain ranges in the prediction space. This way, a first indication of information-rich (but originally non-measured) readouts that can reduce the parameter uncertainty is achieved. A *profile likelihood sensitivity (PLS) index* is used to quantify the individual uncertainty impact of the model parameters on a dynamic model prediction. Additionally, the *PLS entropy* quantifies the parameters' individual contribution to the *overall* prediction uncertainty. Both quantitative measures are applied to select the optimal readouts for reducing parameter uncertainty. The major advantage of the methodology is that it is a sample-based approach, and hence no gradient or curvature information of the objective function is required. This renders the methodology preferable over classical approaches based on Fisher information especially when dealing with non-linear problems.

Hygric properties, dynamic experiments, optimal experimental design, profile likelihood analysis, PLS index and entropy

### INTRODUCTION

The reliable evaluation of moisture transfer in building materials is of great importance for the assessment of hygric damage patterns, building energy consumption, etc. In this respect, an accurate description of the moisture storage and transport properties of building materials is essential. Traditionally, these hygric properties are mainly determined based on steady-state measurements, which are tedious and time-consuming though. To reduce the experimental efforts required for such hygric material characterisations, dynamic measurements in combination with inverse parameter estimation show a lot of promise (Vereecken et al., 2018). However, noisy input data together with a limited and noisy output can complicate a reliable estimation of the properties. A well-considered design of the dynamic experiment helps reducing parameter uncertainty and could even resolve non-identifiability issues (i.e. parameters that cannot be uniquely derived from the available experimental output). Optimal Experimental Design (OED) methods can be applied to define such a purposeful information-rich design. Often, these OED methods aim at maximizing an optimality criterion that makes use of the Fisher information matrix (a.o. Dantas et al., 2002; Balsa-Canto et al., 2007), which is a matrix that quantifies the amount of information about an unknown model parameter

comprised in an observable. Unfortunately, the calculation of the Fisher information matrix requires information on the curvature or gradient of the log-likelihood objective function, which can be hard or even impossible to obtain for non-linear problems.

To resolve these issues, this paper explores, for a virtual hygric test case, the applicability of a sample-based OED approach evolved in systems biology research (Raue et al., 2009; Flassig et al., 2015). The method uses the information obtained in a profile likelihood analysis to map highly uncertain ranges in the prediction space. In this way, information-rich (but originally perhaps non-measured) readouts that reduce the parameter uncertainty can be selected. Quantitative measures for the uncertainty impact of the model parameters and their individual contribution to the overall prediction uncertainty are applied to make a rational selection between different potential readouts.

## METHODS

The next paragraphs describe the virtual benchmark case, the parameter estimation method, the profile likelihood analysis and how to use this information to make a rational selection of suitable additional readouts in further experimental planning.

### Initial benchmark description

In the benchmark case, the vapour resistance factor and the sorption isotherm of a calcium silicate sample are to be determined based on a dynamic experiment. The material's actual hygric properties (= target values) are shown in Figure 1a-b. A cylindrical sample with a diameter of 8 cm, a height of 4 cm and at an initial relative humidity of 12% is exposed to a dynamic step function in relative humidity (see Figure 1c). The sample's side and bottom are covered with a vapour-tight foil, which yields one-dimensional moisture transport. The mass transfer coefficient at the top of the sample is  $3 \cdot 10^{-8} \text{ s/m} + N(\mu, \sigma^2)$  with  $\mu = 0$  and  $\sigma = 2 \cdot 10^{-9}$ . The moisture transfer in the sample is simulated by use of a control volume model in order to create the virtual experimental output. Initially, the sample's mass change measured with a 1-hour time interval is assumed to be the experimental output. This output is subjected to white measurements noise  $\varepsilon \sim N(\mu, \sigma^2)$  with  $\mu = 0$  and  $\sigma = 0.011$ .

Figure 1. a) Actual sorption isotherm and b) actual vapour diffusion resistance of the calcium silicate sample; c) relative humidity in the environment above the top of the sample.

### Parameter estimation

The parameters searched for are given in Table 1, together with the target values (= actual values in the benchmark case) and the lower and upper values of the search space. To estimate the unknown parameters, Bayesian inference is applied. Thereto, the Differential Evolution Adaptive Metropolis algorithm developed by Vrugt (2016) is used. In the estimation process, the moisture transfer in the calcium silicate sample is simulated with the same control volume model as used to simulate the benchmark experiment. A maximum log-likelihood (LL) is pursued, with the log-likelihood expressed as:

$$LL = \frac{-n_m}{2} \log(2\pi) - \sum_{t=1}^{n_m} \log(\hat{\sigma}_t) - \frac{1}{2} \sum_{t=1}^{n_m} \left( \frac{\tilde{y}_t - y_t}{\hat{\sigma}_t} \right)^2 \quad (1)$$

where  $n_m$  the number of measurement points for the sample's mass increase,  $\hat{\sigma}_t$  the standard deviation of the observations' measurement noise and  $\tilde{y}_t$  and  $y_t$  the mass increase in the virtual experimental data set and simulated in the estimation process, respectively. For the priors in the Bayesian inference, a uniform distribution is assumed.

Table 1. Unknown parameters together with the target values and the upper and lower boundaries in the search space. The parameter  $w_{sat}$  in the sorption balance is assumed to be known (811.14 kg/m<sup>3</sup>). Additionally,  $w(0.54)$  is assumed to be measured beforehand (= 2.9 kg/m<sup>3</sup>) and is used to infer the parameter  $k$  in the sorption balance.

	Vapour resistance $\mu(RH) =$ $1/(a+b \cdot \exp(c \cdot RH))$			Sorption isotherm $w(RH) =$ $w_{sat} \cdot [1 + (k \cdot \ln(RH))^{1/(1-m)}]^{-m}$	Noise balance	Mass transfer coefficient
Parameters	a	b	c	m	$\sigma_M$	$\beta$
Target value	0.174	$2.806 \cdot 10^{-4}$	7.229	0.4321	0.011	$3 \cdot 10^{-8}$
Lower boundary	0.05	$10^{-10}$	4	0.1	$10^{-5}$	$10^{-9}$
Upper boundary	0.8	$10^{-1}$	30	0.8	1	$10^{-6}$

### Profile likelihood analysis

To assess the identifiability and the confidence of the estimated model parameters, the profile likelihood analysis developed by Raue et al. (2009) is applied. In this approach, the profile likelihood  $PL$  curve for a model parameters  $\theta_i$  is calculated by:

$$PL(\theta_i) = \max_{\theta_j \neq i} L(\theta_j) \quad (2)$$

with  $L$  the likelihood and  $\theta_j$  the other parameters searched for in the estimation process. Hence, the PL curve for a parameter  $\theta_i$  can be constructed by a re-optimisation of the parameters  $\theta_{j \neq i}$  for fixed values of  $\theta_i$  within an interval in the search space. In the current study, the knowledge on the likelihood of the candidate solutions analysed in the Bayesian inference procedure is used to draw the PL curves. A frequentist optimisation method as applied in (Vereecken et al., 2018) is furthermore used to create additional points to check and to complete the PL curves. The profile likelihood-based confidence region (CR) is defined by:

$$\left\{ \theta_i \mid -2 \log(PL(\theta_i)) \leq -2 \log(\hat{L}) + \chi_{\alpha}^2 \right\} \quad (3)$$

with  $\chi_{\alpha}^2$  the  $\alpha^{th}$  quantile of the  $\chi_{df}^2$ -distribution, with  $df = 1$  degree of freedom and  $\hat{L}$  the maximum likelihood estimate. The borders of this confidence region define the confidence interval (CI). A finite CI indicates a practically identifiable parameter, which means that - based on the available data - for  $\theta_i$  a limited range of values with a likelihood not significantly different from  $\hat{L}$  can be determined. A (semi-)infinite CI with a variable likelihood level is associated with practical non-identifiability, whereas an infinite CI with a constant likelihood

level below the desired threshold indicates that the parameter is both practically and structurally non-identifiable and, thus, that a unique parameterisation is theoretically not possible for the model.

### Optimal experimental design

To define an OED, insight on the impact of the parameter's uncertainty on model predictions is required. To analyse this impact, in the current approach, the set of parameters along the PL curves in the confidence region are used (in case of a semi- or infinite confidence region the set of parameters along the PL curve in a region of a few orders of magnitude around the maximum likelihood estimate (MLE) can be used). The spread of the model prediction trajectories drawn for this set of parameters contains information on the parameter's uncertainty impact; a large spread indicates a large impact of the uncertainty of the specific parameter on the specific model prediction. To quantify the individual uncertainty impact of a model parameter  $\theta_i$  on a model prediction  $p_i(t_k)$ , the profile likelihood sensitivity (PLS) as defined by Flassig et al. (2015) can be used:

$$s_i(t_k) = \left( \frac{\max(\{p_i(t_k)\}) - \min(\{p_i(t_k)\})}{\left\langle \hat{p}(t) \right\rangle_t} \right)^2 \quad (4)$$

where  $\max(\{p_i(t_k)\})$  define the maximum/minimum for a model prediction  $p_i$  at time  $t_k$  and where the denominator corresponds to the time average of the model prediction for the MLE of the parameters. The overall uncertainty of the set of model parameters ( $n_\theta$ ) for a specific model prediction over a period defined by  $n_t$  time-points can be obtained as:

$$s_{tot} = \sum_{i=1}^{n_\theta} \sum_{k=1}^{n_t} s_i(t_k) \quad (5)$$

To reduce the uncertainty on a model prediction, and thus to reduce the uncertainty of the parameters that produce this prediction uncertainty, an additional readout that maximizes the PLS index ( $s_i$  or  $s_{tot}$  depending on the interest in a single parameter  $\theta_i$  or in the total set of parameters, respectively) should be selected. When a reduction of the uncertainty of a set of model parameters it pursued, it is furthermore of importance to look for a design with a more or less equal contribution of these parameter uncertainties to the PLS index. Shannon's entropy gives information on this contribution and can be calculated as (Flassig et al., 2015):

$$J_{tot} = \sum_{k=1}^{n_t} J_k = \sum_{k=1}^{n_t} \sum_{i=1}^{n_\theta} - \frac{s_i(t_k)}{\sum_{i=1}^{n_\theta} s_i(t_k)} \log \left( \frac{s_i(t_k)}{\sum_{i=1}^{n_\theta} s_i(t_k)} \right) \quad (6)$$

The larger Shannon's entropy the more homogenous the PLS index of the individual parameters ( $s_i$ ) contributes to the total PLS index ( $s_{tot}$ ).

## RESULTS

The OED methodology is applied to define the best position to measure the relative humidity in the sample. Four possible designs are compared: a RH-sensor at 1, 2, 3 or 4 cm from the top of the sample. Figure 2 shows the PL curves for the model parameters that define the

hygric properties, and this for the case when the experimental output is limited to the sample's mass increase (and thus without a RH-sensor). The four parameters are practically identifiable, as is the case with the other model parameters (not shown) as well. Based on the parameter sets along the PL curves below the 95% threshold, the trajectories of different model predictions are drawn. As an example, Figure 3a shows the trajectories for RH<sub>4</sub> (= RH at the bottom of the sample), and this for the model parameter  $m$ . The individual PLS indices as a function of time are given in Figure 3b, and this for the model prediction RH<sub>4</sub>. Finally, Figure 3c shows for the four designs the criterion space with the total PLS index and entropy. The maximum PLS index and entropy is obtained for RH<sub>4</sub>. Hence, of the four designs this is the best option to choose as an additional readout. Overall, the largest reductions of the confidence intervals are obtained when including data on RH<sub>4</sub>, as indicated in Table 2. Note also that some CI's become slightly wider after including a RH-sensor, which might be the result of the extra noise term  $\sigma_{RH}$  included in the parameter estimation process.

Figure 2. Profile likelihood curves for the model parameters  $a$ ,  $\log(b)$ ,  $c$  and  $m$ .

Figure 3. a) Trajectories of RH<sub>4</sub> along the PLS curve for the parameter  $m$ , b) PLS indices of the different model parameters for prediction RH<sub>4</sub> and c) criterion space.

Table 2. Upper and lower bounds of the CI's for the initial experiment and the experimental designs. The narrowest CI's are indicated in bold.

	Mass only	Mass + RH <sub>1</sub>	Mass + RH <sub>2</sub>	Mass + RH <sub>3</sub>	Mass + RH <sub>4</sub>

## DISCUSSION

A sample-based approach that starts from the information in a profile likelihood analysis is used to make a decision on the optimal position of a RH-sensor in a hygric experiment. A RH-

sensor at the bottom of the sample is found to be most efficient in reducing the confidence region. However, it should be kept in mind that such a reduction is not necessarily always accompanied by a closer agreement with the target values.

One of the advantages of the presented sample-based approach is that it is based on information that is already at hand when analysing the practical identifiability based on the PL curves. Additionally, the method yields information on the uncertainty induced by the individual parameters and their contribution to the overall prediction uncertainty. This way, one can also focus on specific model parameters. A disadvantage of the sample-based approach might be its limitation to the readouts in experimental planning. In its current form no direct information on the best input conditions is achieved. Ultimately, as with all OED methods, the OED process is an iterative process that requires a priori knowledge. In the presented approach, a first experiment should be performed before a rational selection of further readouts can be made, whereas in the classical OED approaches initial parameter assumptions have to be made.

## CONCLUSIONS

The profile likelihood analysis is shown to be a highly valuable starting point for the optimal design of hygric experiments. Based on the trajectories of internal observables plotted for the parameter sets along the profile likelihood curve uncertain ranges in the prediction space are mapped. A quantitative measure of the parameters' uncertainty (PLS index) and their contribution to the overall uncertainty (PLS entropy) enable a rational selection of highly informative readouts. The major advantage of the methodology is that it is a sample-based approach, which makes that no gradient or curvature information of the objective function is required. This way, especially when dealing with non-linear problems, the methodology is preferable over classical approaches based on Fisher information.

### **ABSTRACT**

This work represents the determination of the discharge coefficient  $c_d$  of a window in the Research Centre on Zero Emission Buildings' (ZEB) Test Cell Laboratory (TCL), located at the campus of the Norwegian University of Science and Technology (NTNU) in Trondheim, Norway, for the later use in building energy performance simulation (BEPS) software. For example, the BEPS program IDA Indoor Climate and Energy (IDA ICE) considers window openings to always be of rectangular shape and the user can only enter the percentage of window area to be opened together with a discharge coefficient  $c_d$ . By adjusting the  $c_d$  which depends on the actual shape of the window and whether the opening is used for single-sided natural ventilation or cross ventilation among others, it is possible to approximate other window opening forms such as tilted, pivoted etc.

While several studies found the discharge coefficient for large, sharp-edged openings such as windows or doors to be between 0.60 and 0.65 (Cruz & Viegas, 2016; Flourentzou, van der Maas, & Roulet, 1998; Heiselberg, Svidt, & Nielsen, 2001), it is still questionable which value to use for tilted windows.

For a subsequent calibration process of a simulation model of the TCL it was necessary to perform measurements for the discharge coefficient which describes flow losses in natural ventilation, based on the research of Heiselberg et al. (2001) in order to quantify airflows through the opened window. Measurements were carried out using Blowerdoor test equipment to determine  $c_d$  for the TCL's window. This was done for a tilted window with different opening angles and different pressure differences across the window. By experiment, the mean  $c_d$  was found to be 0.75. It can be seen that Heiselberg et al. results are slightly higher than the ones obtained in the present work. This is most likely a result of different window shapes (vertical vs. horizontal shape, but both bottom hung) and measurement inaccuracies. The results of these measurements can be used as input to BEPS programs.

Building energy performance simulation model, calibration, discharge coefficient, measurements

### **INTRODUCTION**

Natural ventilation is often used to supply indoor environments with fresh air from the outside and it is considered to be able to reduce cooling energy demands of office buildings significantly, since people are found to be satisfied with a wider temperature range and their office indoor environment in general when given control over it (Brager, Paliaga, & de Dear, 2004; de Dear & Brager, 1998; Leaman & Bordass, 1999). The use of natural ventilation instead of mechanical cooling systems therefore can enhance working conditions while saving energy costs.

The quantification of air flowing through a window thus plays a critical role in determining the cooling potential and the indoor thermal comfort. While several studies confirmed the discharge coefficient  $c_d$ , which is often used in BEPS programs to account for turbulence and friction losses, for sharp-edged openings to be between 0.60 and 0.65 (e.g. Cruz & Viegas, 2016; Flourentzou et al., 1998; Heiselberg et al., 2001), it is still questionable which  $c_d$  to use in case of tilted windows since it is very much dependent on the specific case of application, as the following literature review will show.

Wang et al. (2017) investigated a row of windows typically used in buildings, both analytical and with Computational Fluid Dynamics (CFD) simulations. The model used for the analytical approach originally goes back to Awbi (1996) and describes the volume flow rate through a single opening due to temperature difference. Wang et al. found good coherence between their detailed CFD calculations and the analytical approach for the tilted window with a maximum deviation under 20 %. But they also suggested dismissing a constant  $c_d$  of 0.6 for all kinds of window openings when using the analytical model. The coefficient increases with increasing buoyancy and decreases with an increasing flow area.

The module for air flow networks in the simulation program TRNSYS (Transient System Simulation Tool) integrates a COMIS (Conjunction of Multizone Infiltration Specialists) type network into the program suite, that offers the possibility to calculate bidirectional air flows through opened (including tilted) windows and their  $c_d$  factor (TRNSYS, 2009). At standard opening angles from  $\alpha = 3^\circ$  to  $7^\circ$  the equation gives discharge coefficients lower than 0.65 (mostly between 0.3 and 0.5).

Maas (1995) conducted CFD calculations and measurements for different opening angles ( $\alpha = 1.02^\circ$  to  $7.17^\circ$ ) of a tilted window (width  $w \times$  height  $h = 0.82 \text{ m} \times 1.12 \text{ m}$ ) with and without a window reveal of 20 cm under realistic boundary conditions (measurements in an actual building). Similar to Hall (2004) Maas found that a radiator right below a window leads to a lower air exchange through the window. Furthermore, he quantified the impact of a window reveal with a decrease of air flows through the window with 50 % (Maas, 1995).

Grabe (2013) found that the assumption of equal in and outflow cross sections might not be right. Smoke visualizations showed the outflow area (in case of warmer indoor temperatures located at the window top) being constantly larger than the inflow area by the factor 2.5 (Grabe, 2013). In a precedent study Grabe, Svoboda, and Bäumler (2014) found that the incoming mass flow through a tilted window can be expressed through a logarithmic relation (Grabe et al., 2014).

Heiselberg et al. (2001) investigated the characteristics of air flow in rooms for a bottom hung ( $w \times h = 1.6 \text{ m} \times 0.4 \text{ m}$ ) and a side hung window ( $w \times h = 0.81 \text{ m} \times 1.38 \text{ m}$ ) in a series of laboratory measurements. The windows were mounted in a wall separating two rooms, one of which simulating outdoor conditions. A ventilation system was used to generate pressure differences and to measure the air flow rates through the openings. For the case of the bottom hung window with single sided ventilation three opening areas have been investigated:  $0.019 \text{ m}^2$ ,  $0.026 \text{ m}^2$  and  $0.045 \text{ m}^2$ . For this window, the measured discharge coefficients showed a significant dependency on the opening area, the window type and the pressure difference between the two rooms used for the experiment, but only a small dependency on the temperature difference. For the largest opening area the  $c_d$  was roughly between 0.78 and 0.85, for the intermediate between 0.87 and 0.92 and for the smallest between 0.96 and 1.02 (Heiselberg et al., 2001).

A comparison of the named studies is not trivial, as all the named authors pointed out that their findings would be valid for similar boundary conditions and window shapes only. The big difference from Heiselberg's findings to those from TRNFLOW for example, is mainly a result of different area calculations and different governing equations.

### ZEB Test Cell Laboratory

The measurements for this study were conducted at the ZEB Test Cell Laboratory (Goia et al. 2017), a facility used for testing building envelope systems in calorimetric and comparative tests. It is located on the campus of the NTNU in Trondheim, Norway. The building consists of two 10.9 m<sup>2</sup> test cells, each surrounded by a guard volume. Both cells have one façade to the outside, facing exactly South, which can be replaced according to the research needs. This way it is possible to investigate different window types, window opening strategies, façade types, insulations, heating, ventilation and lighting strategies etc. with real weather conditions and, if required, with real occupants. Each cell and each guard volume can be conditioned independently from each other. This part also has an own, independent HVAC system. Fig. 1 shows a 3D perspective from inside the Test Cell Laboratory with highlighted investigated window (red).

Fig. 1. 3D perspective from inside the Test Cell Laboratory. Highlighted, the investigated window.

The cell envelopes to the guard volume are made of prefabricated sandwich panels with two 0.6 mm stainless steel sheets and 10 cm injected polyurethane foam in between, resulting in a U-value of 0.23 W/m<sup>2</sup>K. Between the slab of the building and the test cell floor is a gap of ca. 0.5 m, which is also conditioned by the guard volume HVAC system. Its air exhausts are located along the test cell's surfaces to guarantee an even distributed air flow and temperature around it. A weather station on the roof is continuously collecting wind speed and direction, temperature, relative humidity, solar radiation and other weather data. These, along with the measurement values from the cells are stored on a server in the control room.

The facility is used for testing different building parts and conditioning strategies under real weather conditions, primarily for the purpose of indoor comfort analysis. A calibrated virtual model in a thermal simulation program therefore can help to reduce duration and costs of measurements by preselecting only the most promising set-ups for real life tests.

### Research question

Many of the common BEPS tools, such as IDA ICE, require the input of a suitable discharge coefficient to consider special window opening forms (e.g. tilted window) for the

determination of natural ventilation air flows. As the literature review has shown, the discharge coefficient is not constant and it very much depends on the case of application.

Due to simplifications IDA ICE cannot determine the air flow through a tilted window correctly, as only rectangular windows are supported (Bring et al., 1999). A possible solution for the problem can be to change the window geometry in the simulation model. The program's distributor EQUA therefore gives modelling guidelines which can be seen in Fig. 2. With this approach, the window is split into several smaller ones, which correspond to the same area as the original one, so that solar gains and losses through heat transmission etc. stay the same. Only the grey parts are (fully) openable (Moosberger, 2017). However, it is still questionable which discharge coefficient should be inserted when this method is used. Therefore it was decided to perform measurements for the discharge coefficient based on the research of Heiselberg et al. (2001).

Fig. 2. EQUA's modelling guidelines for tilted windows (Brozovsky, 2018)

## METHODS

Since the investigated window form significantly differs from the ones used in the previously listed studies, own measurements were taken. They were conducted at different pressure differences and opening degrees with Blowerdoor test equipment (Brozovsky, 2018). The pressure difference is measured by the Blowerdoor test equipment and the window's opening area was determined by measurements. Thereby the narrowest passage of the flow had to be found for the complex frame geometries. Following equations 1 - 3 were used for the calculations.

$$c_d = \frac{\dot{V}_{BD}}{\dot{V}_{theo}} \quad \text{eq. 1}$$

$$\dot{V}_{theo} = A_{op} \cdot u_{theo} = A_{op} \cdot \sqrt{2 \frac{\Delta p}{\rho_0}} \quad \text{eq. 2}$$

$$A_{op} = s \cdot (h + w) - A_c \quad \text{eq. 3}$$

with

$\dot{V}_{BD}$	Air volume flow measured by blower door [m <sup>3</sup> /h]
$\dot{V}_{theo}$	Theoretically achievable volume flow without friction [m <sup>3</sup> /h]
$A_{op}$	Opening area of window [m <sup>2</sup> ]
$u_{theo}$	Theoretically achievable mean air speed through opening without friction [m/s]
$\Delta p$	Pressure difference across opening [Pa]
$\rho$	Density of incoming air [kg/m <sup>3</sup> ]

The measures of the investigated window are  $w \times h = 0.70 \text{ m} \times 1.21 \text{ m}$ . The theoretically possible volume flow without friction then was obtained from the pressure difference and the density. The Blowerdoor equipment estimates the actually occurring air flow through the

rotational speed of the fan. Under realistic conditions, the actual air flow must always be lower than the theoretically possible flow. A high potential for error must be considered especially for small openings, when the clearance between the window frames is minimum. All measurements were taken under isothermal conditions.  $A_{op}$  was determined with equation 3 with tilt width  $s$  and window height  $h$  (according to Figure 2), window width  $w$  and constriction area  $A_c$  due to the window fitting etc.

## RESULTS

Fig. 3 and Table 1 show the results of the analysed measurement data. As a comparison, also Heiselberg et al.'s findings (2001) with the largest window opening area are plotted on the figure. By experiment, the mean discharge coefficient was found to be  $c_d = 0.75$  for the tilted window being used in the laboratory which is good accordance with the research by Heiselberg et al. (2001).

Fig. 3. Measured discharge coefficients for different opening areas and pressure differences (blue) and measurement results by Heiselberg et al. (2001) (red)

Table 1. Measured  $c_d$  values for different opening areas

Opening area $A_{op}$ [m <sup>2</sup> ]	Tilt width $s$ [m]	Tilt angle $\alpha$ [°]	Mean $c_d$ [-]
0.042	0.024	4.1	0.74
0.065	0.037	5.4	0.79
0.105	0.060	7.1	0.74
0.154	0.088	8.5	0.73

## DISCUSSIONS

It can be seen that Heiselberg et al. results are slightly higher than the ones obtained in the present work. This is caused by different window shapes (vertical vs. horizontal shape, but both bottom hung) and measurement inaccuracies. Still, the findings are in accordance with Heiselberg et al. as they assume that “[...] for large opening areas the discharge coefficient approaches the commonly used value of 0.6, while it will have a larger value for small opening areas” (Heiselberg et al., 2001) which was also found by Wang et al. (2017). The overall mean discharge coefficient for all opening sizes and pressure differences of the investigated and tilted window is  $c_d = 0.75$ .

## CONCLUSIONS

The results of these measurements can be used as input to BEPS programs. It gives confidence in the use of discharge coefficients determined by Heiselberg et al. (2001). The obtained discharge coefficients were consequently used in a calibration process of an IDA ICE simulation model of the TCL (Brozovsky, 2018).

### **ABSTRACT**

The phenomenon of droplets impacting porous media is ubiquitous in rain events. Rain is a major source of moisture in buildings. When a water droplet impacts a permeable surface, it spreads on the surface and is absorbed into the porous material due to capillary action. This paper presents an experimental investigation of the absorption and film forming during train of liquid droplets impacting porous stones, towards establishing the fate of rain droplets during rain events.

### **KEYWORDS**

Rain water droplet, porous materials, impact, absorption, film forming.

### **INTRODUCTION**

The phenomenon of drop impacting porous media is ubiquitous in nature and is associated with mechanisms found in various industrial applications. Rain is a major source of moisture in buildings and a main agent of degradation.

When a liquid droplet impacts a permeable surface, it spreads on the surface and is absorbed into the porous material due to capillary action. The spreading behavior of the impinging droplet on the surface is known to depend on the properties of the liquid, i.e. density, viscosity and surface tension, impact conditions such as drop size and impact velocity, and the surface wettability and roughness (Lee et al. 2016a). In porous media, absorption is governed by both the properties of the liquid and of the porous medium, i.e. porosity, pore size, wettability (Lee et al. 2016b). Once the deposited droplet is completely depleted from the surface, the liquid further redistributes within the porous medium due to capillary forces, while evaporation occurs at the surface (Reis et al. 2003). In case of saturation of the porous medium, the remaining water lies at the surface in a pool, and, in the event of further impacts, a water film can build up.

For a better understanding of the absorption process inside porous media, observing directly the liquid content redistribution in the porous medium is required. Absorption in porous media has been studied with several non-destructive techniques, namely X-ray, neutron and gamma-ray radiography, magnetic resonance imaging (MRI) and nuclear magnetic resonance, and destructive techniques.

In this study, we aim to capture the full deposited droplet contact area, absorption and film forming process of trains of impinging droplets on natural porous stones by using neutrons as the means of investigation. Neutron radiography allows visualizing the moisture content

distribution in porous stones. During the experiments, we measure the mass of deposited water to validate the neutron measurements. The deposition and absorption process of trains of impinging droplets is continuously characterized during deposition, absorption, evaporation and redistribution. We provide the total mass in/above the stone and moisture distribution, in a time-resolved manner.

## METHODS

### Samples

Three stones with varying porosity and uptake characteristics are selected: two sandstones (Meule and Bentheimer) and one limestone (Savonnières), Figure 1. The porous stones are cut in cubes of 20 x 20 x 10 mm<sup>3</sup> for characterization and drop impact tests.

Figure 1. Photos of Bentheimer (left), Meule (center) and Savonnières samples.

### Water droplet generation

Water droplets are generated at the flat tip of a needle by pushing a syringe pump. The droplets have an initial diameter of 2 mm. When the droplet is released, it accelerates by gravity reaching an impact velocity of 0.5 m/s, 1.0 m/s and 3.0 m/s, and the rates are varied to 4, 8 or 16 drops per minute.

### Neutron radiography

The absorption process into the porous stone is captured by neutron radiography. In a nutshell, neutrons are attenuated by the hydrogen of water, but penetrate the porous stone, and then activate a scintillator which is photographed by a camera.

The experiment for the absorption of drop impact is performed at the NEUTron Transmission RAdiography (NEUTRA) beamline of the Paul Scherrer Institut, Villigen, Switzerland. The NEUTRA beamline is operated with neutrons within a thermal spectrum (Lehmann 2008). The necessary exposure time for each image is 3 seconds and the nominal spatial resolution of the neutron radiography is 47.2  $\mu\text{m}/\text{pixel}$ . Figure 2 shows a schematic overview of the neutron beamline and the experimental setup for drop impact.

Figure 2. Schematic of experimental setup at NEUTRA beamline configuration.

Using Beer-Lambert law, the variation of attenuation of the neutron beam yields the moisture content, further details on image analysis and post-processing can be found in (Sedighi Gilani et al. 2012). Figure 3 shows the comparison between mass obtained from neutron images and deposition.

Figure 3. Validation by comparing total mass (mg) versus time comparing the total mass from neutron imaging (thick red) with actual water mass deposited (thin black). Total mass of water resting on the stone in blue, in the stone in dark blue.

## RESULTS

We present here only the results for Savonnières but results of all 3 stones are presented at the conference. In general, the uptake is faster for Savonnières with more water in the stone and less on the surface. The other two stones undergo less moisture uptake in the same time and hence the surface water pool appears earlier and develops more.

Figure 4. Moisture content (in thickness (mm) per pixel) for train of water droplets on Savonnières at the rate of 4 drops per minute for three impact velocities from top to bottom after 3, 33, 93 and 180 seconds.

In Figure 4, moisture content distribution is given after deposition of 1, 3, 7 and 13 droplets for three impact velocities. Absorption occurs from the deposited droplet into the stones via

the contact area, With time, water is transported in the stone further and further from the point of impact. In time water distribution has an elliptical shape that is quite independent from the impact velocities, as, by that time, the contact area is similar in all these cases.

Figures 5 and 6 provide moisture content profiles versus time above and below the stone surface, taken at the center of the droplet and right below/above the surface respectively. Faster droplet rate leads to the development of water accumulation and thus water pool and film on the surface.

Figure 5. Vertical moisture content profiles for train of water droplets on Savonnières at the rate of 4, 8 and 16 drops per minute for three impact velocities from top to bottom of 0.5, 1 and 3 m/s. Pink line represents the stone surface.

Droplets spreading on the surface depends on impact velocities. Then, water is transported in the stone further and further from the point of impact. In time water distribution has an elliptical shape that is quite independent from the impact velocities. Faster droplet rate leads to the development of water accumulation and thus water pool and film on the surface. Film forming is found to be dependent on both transport properties and saturation degree of the stones. Moisture distribution within the porous stones, which are here all rather isotropic, is found to be dependent on impact velocity and thus of maximum spreading, for the first droplets of the train. Afterwards, the pooling of water yields similar moisture distribution.

## CONCLUSIONS

This paper presents an experimental investigation of absorption and film forming during trains of liquid droplets impacting porous stones. Neutron radiography is used to quantify moisture absorption in three natural stones of varying porosity and moisture uptake characteristics. Film forming is found to be dependent on both transport properties and saturation degree of the stones. Moisture distribution within the porous stones, which are here all rather isotropic,

is found to be dependent on impact velocity, and thus maximum spreading, for the first droplets of the train. Afterwards, the pooling of water yields similar moisture distribution. This experiment provides very detailed information of rain droplet absorption and redistribution in porous materials and can be used in conjunction with rain deposition modeling to understand the fate of water with the built environment.

Figure 6. Horizontal moisture content profiles above and below the contact line for train of water droplets on Savonnières at the rate of 4, 8 and 16 drops per minute for three impact velocities from top to bottom of 0.5, 1 and 3 m/s.

## ACKNOWLEDGEMENT

We acknowledge the important contribution of the PhD work of Dr. Jaebong Lee to this paper and for running the experiment. His PhD was made possible through Swiss National Science Foundation project no. 200021-135510. Guylaine Desmarais is acknowledged for the support in the preparation and running of the PSI Neutra experiment.

## **Application of Rain Intensity Dependent Rain Admittance Factor (RAF) in Hygrothermal Performance Assessment of Wall Systems**

Emishaw Iffa\*, Fitsum Tariku

BCIT Building Science Centre of Excellence, BC, Canada

### **ABSTRACT**

Wind-driven rain (WDR) is one of the main moisture loading sources on the exterior enclosures. The direct impact of wind-driven rain on the hygrothermal performance of building envelope has been well documented. Rain admittance factor (RAF) and rain penetration values characterize the amount of water reaching the exterior surface and the exterior surface of the water-resistive barrier respectively based on measured horizontal rain intensity. In common RAF factor calculation from horizontal rainfall data procedures, such as ASHRAE 160, RAF values are not affected by the intensity of the rainfall. However, a previous study shows RAF coefficients are sensitive to the rainfall intensity. Thus it is important to investigate how the sensitivity of using horizontal rainfall intensity dependent RAF factors and the subsequent rain penetration relates to hygrothermal performance assessment of building envelope components. This study is based on five years of WDR and horizontal rainfall data collected at different orientations of façades at a two-story test building in a mild coastal climate. The data is categorized into two sets based on rain intensity. The correlation between the measured moisture content on the sheathing board of a building envelope at different points utilizing RAF values based on the proposed approach and the overall measured RAF values is studied using WUFI simulation. Results show that an average percentage difference between the moisture content values of a sheathing board using RAF values of the rain intensity dependent approach and the overall RAF measured value can be as large as 9 %.

### **KEYWORDS**

hygrothermal performance, rain admittance factor, rain intensity, water penetration, wind-driven rain.

### **INTRODUCTION**

Moisture ingress on building envelopes due to rain load along with vapour diffusion and built-in moisture is the main cause for moisture related problems such as corrosion, mould, rotteness and their consequential effects such as compromised structural integrity and health-related problems. Accumulated moisture in components of wall systems due to wind-driven rain (WDR) can be prominent in wet climates such as the coastal climate of British Columbia. Designers are expected to take the rain load effect into account on the overall hygrothermal performance of a building enclosure. Incorporating the wind-driven rain effect requires measuring or accurately estimating the number of raindrops that are impinging on the vertical building surfaces due to wind forces blowing towards the building.

Many factors affect the amount of wind-driven rain, including rain intensity, wind speed and direction, topography, building geometry, the orientation of the building assembly, and the location of the area of interest on the building elevation. However, the primary components to

wind-driven rain intensity are rain intensity, wind speed and wind direction. Most wind-driven rain computational models are based on semi-empirical and numerical analysis methods. The most commonly used numerical analysis method is mainly developed by Choi in the 1990s (Choi, 1994a, 1994b, 1999). According to Hens (2015), the semi-empirical analysis method was developed in the 1950s by Lacy (Lacy, 1965) using experimental-based relations of raindrop size, raindrop speed, and horizontal rain intensity. The calculation of raindrop size and terminal velocity was based on Best's work (Best, 1950a, Best, 1950b). Recently, based on Lacy's findings, a semi-empirical estimation formula is developed by Straube and Burnett (2000).

To estimate the amount of wind-driven rain without direct field measurement at the location of interest, historical weather data can be used. To account for other factors, such as the building geometry, orientation of the building assembly, and the area of interest on the wall façade, semi-empirical studies have provided coefficients to be used in calculations. The two commonly used factors are *the wall factor*,  $W$  (BSI EN 13013-3, 1997), and *Rain Admittance Factor*,  $RAF$  (Straube and Burnett, 2000), which considers the building aspect ratio, the presence of a roof overhang and the area of interest within the wall facade. The wind-driven intensity on a vertical surface according to Straube and Burnett's method (Straube and Burnett, 2000) can be calculated as:

$$R_{wdr} = RAF \times DRF(V_t) \times \cos(\theta) \times U(h) \times R_h \quad (1)$$

Where  $R_{wdr}$  is wind-driven rain intensity (mm),  $RAF$  is Rain Admittance Factor,  $DRF(V_t)$  is Driving Rain Factor ( $1/V_t$ ),  $\theta$  is the angle of the wind to the wall's normal,  $U(h)$  is the wind speed at the height of interest (m/s),  $R_h$  is horizontal rainfall intensity (mm/hr.m<sup>2</sup>).

The driving rain factor (DRF) is a multiplicative inverse of terminal velocity. A droplet size, the main parameter in terminal velocity calculation (Dingle and Lee, 1972), can be estimated based on horizontal rain intensity (by Best 1950a). The last 3-terms on the right side of equation 1,  $\cos(\theta) \times U(h) \times R_h$ , represent free-field wind-driven rain under the rain intensity through a 1 m<sup>2</sup> area of the unobstructed vertical field.

Commonly, a median droplet size is used while employing the Straube and Burnett model. A work by Cornick and Lacasse (2009) used the predominant raindrop diameter instead of the median drop size. Using the predominant raindrop diameter provides a lower terminal velocity and a higher WDR load (Van Den Bossche et al, 2013). A work by Van Den Bossche et al. (2013) stresses the drawbacks of using single rain droplet diameter and their simulation work shows using a median droplet in WDR calculation can introduce an error up to 20% as the horizontal rain intensity increases.

In this study, the dependency of the Rain admittance factor (RAF) on rainfall intensity for different orientations and elevations is examined. Based on the newly obtained RAF coefficients, the effect of RAF values variation between the existing RAF calculation and the proposed approach on hygrothermal performance of building enclosure is investigated.

## WEATHER DATA ANALYSIS

In this study, fifty-seven months of weather data between January 2009 to September 2013 was collected at the BCIT's Building Envelope Test Facility in Burnaby (BETF), British Columbia, Canada. The horizontal rain intensity, vertical rain intensity, wind speed and

directions are measured using a horizontal rain gauge, 15 wall rain gauges, and an anemometer. The data is used to calculate the free-field wind-driven rain, the Driving Rain Factor (DRF) and the Rain Admittance Factor (RAF) at different elevations and orientations.

An hourly data of horizontal rain, wind speed and direction is used to calculate the free-field wind-driven rain using Equation 1. The weather data is categorized into classifications based on rain intensity as class I (high horizontal rain intensity) and Class II (low horizontal rainfall). The effect of small wind speed is found to be less significant in the computation of RAF values, thus classifying the data based on wind speed is excluded in this paper. The horizontal rain intensity of above 2mm/hr is classified as high rain intensity class. Correspondingly, horizontal rain intensity below and equal to 2mm/hr is considered as low rain intensity scenario. In order to accommodate the sensitivity of data sensors, rain intensity and wind speed values below 0.1mm/hr and 0.5 m/s are unused. The vertical rain intensity measured at different locations and orientations, as shown in Figure 1b, is used to find a semi-empirical RAF value. Once the free-field wind-driven rain is calculated, the RAF values are obtained as gradients of vertical rain intensity (the wind-driven rain) and the free-field wind-driven rain.

Figure 1 a) a rain-screen wall system b) rain gauge locations and c) vertical rain gauge

## SIMULATION DESIGN

In order to study how the rain intensity dependant RAF values affect the hygrothermal performance of a building envelope, a WUFI simulation for rain screen wall system is conducted. The indoor conditions of relative humidity and temperature are set using ASHRAE 160P intermediate model.

As shown in Figure 1a, the components of the wall system are regular Portland Stucco which is used as an exterior cladding, 10mm rain- screen air-gap, spun bonded olefin as a sheathing membrane (as a second plane of protection from precipitation and water intrusion), plywood sheathing board, 6 mil polyethylene sheet as a vapour and air barrier material, and gypsum board as an interior finishing layer. The initial conditions of 20°C and 80% RH are used for all wall component members and the simulation is run for two consecutive years.

## RESULTS AND DISCUSSIONS

The rain dependant RAF values were computed using the collected data of horizontal rain intensity, wind speed and direction and the wind-driven rain which is collected by vertical rain gauges at different elevations and directions of the BCIT Building Envelope Test Facility (BETF) walls. The horizontal and the vertical rain intensity values data used in this study are measured from January 1<sup>st</sup>, 2009 to September 30<sup>th</sup>, 2013. Figure 2 (a) shows the measured horizontal rain and wind speed of the year 2009. The wind-driven rain collected by vertical rain gauges on the South-East facing wall is shown in Figure2 (b). The selected elevations and the directions for the rain gauges are top-center, mid- centre, top-corner and mid-corner points

of the four walls of the BETF. This data is used to simulate the hygrothermal performance of a rain screen wall located in Metro Vancouver.

(a)

(b)

Figure 2. One year measured data. a) Horizontal rain and wind speed, b) WDR at different wall locations.

The horizontal rain intensity, the wind speed and direction data were used to calculate the free-field wind-driven rain and the DRF. The RAF values at each wall rain gauge location were determined by the slope of the plot of wind-driven rain intensity against the calculated free-field wind-driven rain (Tariku et al. 2016). The RAF values at the different locations on the walls are compared to the RAF values in literature and shown in Table 1.

Table 1. Calculated rain-dependent RAF and literature-based RAF values

Vertical Rain-gauge locations	Low rain Intensity	High rain intensity	BSI EN 13013-3, 1997
Top Centre	0.23	0.32	0.5
Middle Centre	0.23	0.31	0.4
Top Corner	0.26	0.38	0.5
Mid Corner	0.33	0.37	0.4

In order to study how this variation in RAF values affects the hygrothermal performance of building envelope, two types of simulations are conducted. The first simulation is using the measured variable RAF values based on the horizontal rainfall at the specific hour of interest. Thus in this simulation when the horizontal rain intensity class changes so does the RAF value used. In the second simulation category, the calculated constant RAF values are used.

Figure 3 shows the moisture content of the plywood sheathing board for a rain-screen wall system on three locations. As can be seen in the figure, the moisture content values for the Metro Vancouver weather data, the simulation based on constant RAF provides a lower moisture content value throughout the simulation periods of all three locations. The percentage difference of the water content of the plywood values between the two simulations for the gauges locations of top-centre, mid centre and top-corner has reached up to 5.8%, 9.0% and 6.2% respectively. The schematic diagram shown in Figure 3d shows the rain gauge locations used in the study.

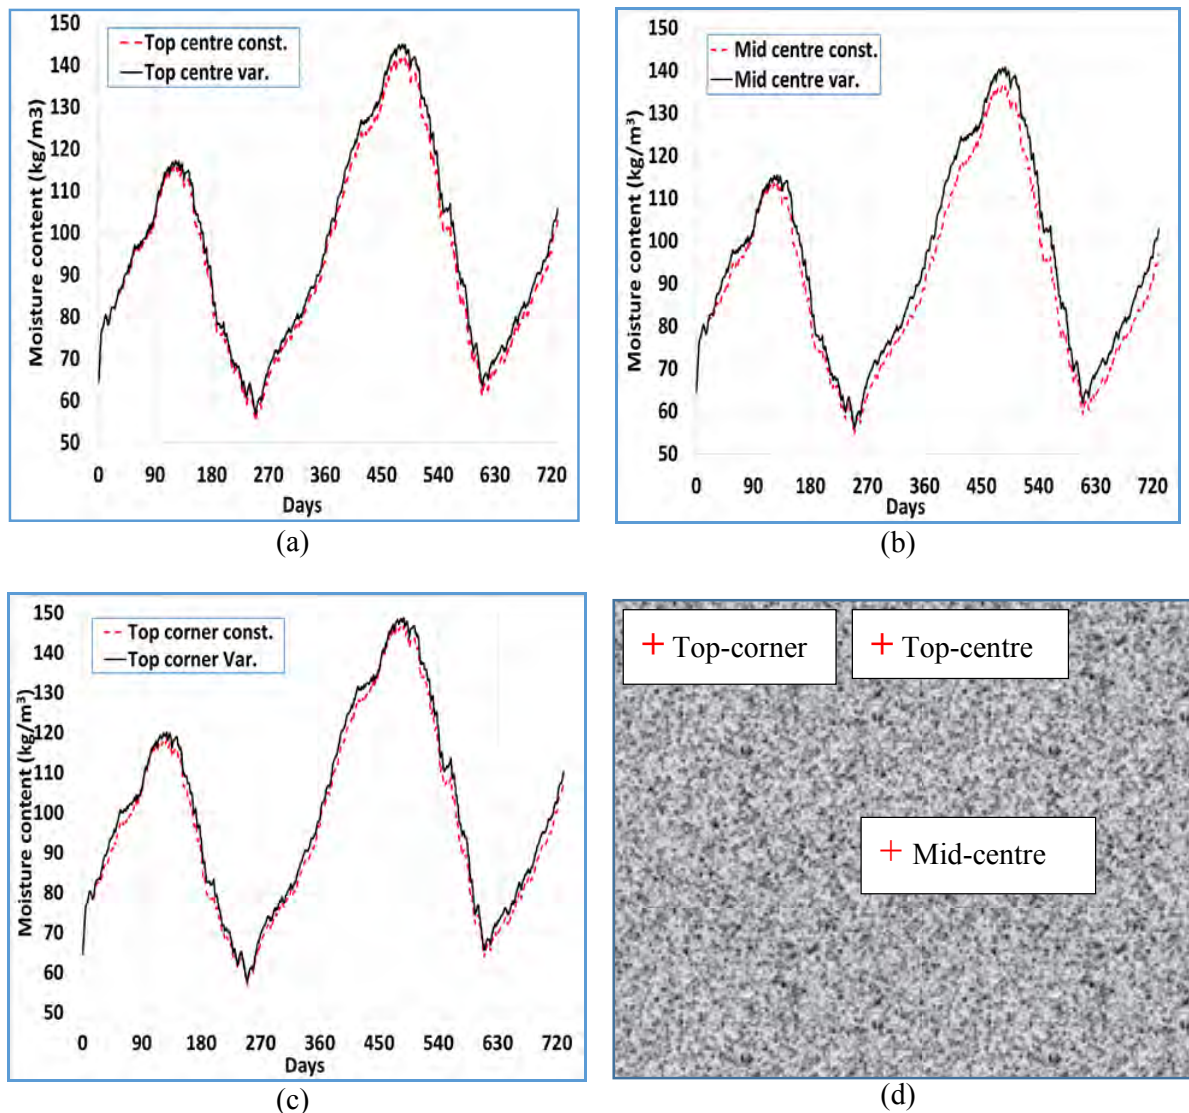

Figure 3. Water content of the plywood for constant and rain intensity dependant RAF values at (a) top-centre (b) mid-centre and (c) top-corner

Considering the above figure is moisture content values of a sheathing in a rain-screen wall design with a moisture barrier, it can be deduced that the variation between the two models can be pronounced in the absence of rain gap and prolonged time period.

## CONCLUSIONS

In this study, the variation of the proposed approach's RAF values from the existing literature calculation method is studied and the variation's effect on the hygrothermal performance of rain screen wall system is examined. Results show that there is a direct relationship between rain intensity and calculated RAF values. The total water content of the plywood sheathing for wall systems with rain screen is simulated for both constant and rain intensity dependent RAF values developed under this study. A percentage variation up to 9% is observed between the new approach and constant RAF model for studied wall systems at different elevations. These findings support the initial hypothesis of this study that applying a constant RAF value for any rain load can affect the overall hygrothermal performance study of building enclosures.

### ABSTRACT

For hygrothermal simulations it is often advised to homogenize masonry wall constructions into a 1D solid brick construction. This saves computational time, but it may lead to an underestimation of moisture related risks. Some literature states that the impact of mortar is negligible, but no specific attention was paid to historic masonries, which often have high absorptive mortars (e.g. lime) and/or bricks. Hence, this study investigates the impact of the interface resistance between brick and mortar, in relation to the properties of the adjacent materials during absorption as well as under real climate conditions. As expected the impact of interface resistances is more pronounced during an absorption test compared to under real climate conditions. Nevertheless, due to the interface resistance, increased frost risks do arise in a number of cases subjected to real climate conditions. The results are found to be highly dependent of the climate, the sequence of rain and frost events, and the properties of the adjacent materials. In conclusion, one can state that there can be an increased risk of frost damage due to the effect of interface resistances in historic masonries. However, deriving generic guidelines on the impact of these effects remains a challenge due to a high dependency on climate and material parameters.

Interface resistance, HAM simulations, Masonries, Frost damage

### INTRODUCTION

The hygrothermal response of porous materials has been studied and documented intensively. (Pel, 1995; Künzeli, 1995; Grunewald, 1997) These studies have led to an increased reliability of risk assessment on building facades due to Heat, Air and Moisture (HAM) modelling software. In these models it is often advised to homogenize masonry constructions from a combination of mortar and bricks to solid brickwork to simplify the model and thereby save computational time (Dephin User Manual, 2006; Vereecken et al, 2013). This approach raises several questions. For instance, what happens in the mortar, which represents in reality +/- 20% of the masonry?

Figure 1. X-ray visualization of absorption in a brick/mortar sample. Left: Hydraulic lime mortar, Right: cement mortar. Red/blue= Low/high moisture content. In collaboration with UGCT.

To answer this question, Vereecken investigated the impact of the simplification in the article ‘Hygic performance of a massive masonry: How mortar joints influence the moisture flux?’ (Vereecken et al., 2013). This publication reported that for the investigated material properties massive masonry constructions can be homogenised to a solid brick construction in

perspective of HAM modelling. The statement is based on several simulations and measurements on ceramic brick and cement mortar. However, it can be assumed that the impact of mortars in historic constructions may be bigger, as mortars generally have higher absorption coefficients in comparison to cement mortars. This is visualized by means of tests with X-ray attenuation (Figure 1). It can be seen that the hydraulic lime mortar (often used in historic constructions) serves as a capillary highway and humidifies the brick sideways, which is not the case for the cement mortar. Due to these capillary highway, the moisture penetrates deeper into the structure, which may perhaps increase the frost risk. In (Figure 1, left) it is clear that the brick and the mortar influence each other's moisture content over the interface between them. Here the so called interface resistance (IR) will be decisive for the moisture flux. From this visualisation it can be concluded that the potential impact of mortars and their adjacent IR may be bigger for high absorptive mortars.

What is an IR between porous materials? Qui et al, 2003; Derluyn et al, 2011 and Guimarães et al, 2018 have listed several causes: a mismatch between the physical-chemical properties, the pore network and the surface energy of both systems, the modification of the hygric properties of the mortar and the transport of fine particles to the interface due to curing, the creation of compaction pores near the interface, and cracking of the interface due to hygric tensions.

The amount of research that addresses the impact of interface resistance (IR) between porous media is limited (Qui et al, 2003; Derluyn et al., 2011). The order of magnitude of an IR found by Derluyn et al, 2011 is between 0 and  $5E10$  m/s. It must be noted that the highest IR was found for the combination of a ceramic brick and cement mortar, for a sample where the mortar was cured in contact with oven dried bricks. It can be discussed whether these values derived by Qui and Derluyn are representative for the combination of ceramic brick and hydraulic lime mortar. Next to that, to date the dependency of the IR on the moisture content and flow direction is unknown. On the other hand, it can be argued that these results provide at least an order of magnitude of the potential impact, which should suffice to indicate the impact on the hygrothermal performance of masonry constructions. This study will therefore proceed with adopting an IR of  $5E10$  m/s. In preliminary simulations the IR was modified to see the impact, and it showed that the presence of the IR is more important than its magnitude in perspective of the amount of absorbed moisture.

Where does this interface resistance occur?

Figure 2. X-ray tomography, voxel size  $90\text{ }\mu\text{m}$  A) perpendicular section to the building facade with the facade at the top side. B) parallel section to the building facade through the bed mortar. In collaboration with UGCT and the Belgian Royal Institute for Cultural Heritage.

With X-ray tomography a historic masonry core of a Flemish church was investigated to visualise the interfaces between the pointing mortar, the bed mortar and the bricks. From the images, shown in Figure 2, the following aspects can be deduced:

- pointing mortar – brick(A/B): very clear separation of materials, interface appears fractured ( $\pm 0.3\text{mm}$ ).
- bed mortar – brick(A): very diverse interface; some places seem in perfect contact whereas in other places cracks are visible. Around the interface the attenuation changes. This may be the effect of a changed density/porosity at the interface (0-0.5mm).
- pointing mortar – bed mortar: poor compaction of the pointing mortar results in a poor contact.

To summarize, traditionally masonry constructions are homogenised in HAM simulations. This seems to be a valid approach based on the state-of-the-art literature, but no specific attention has been given yet to high absorptive mortars and interface resistances, which are as shown in figure 2 on different ways present in historic constructions. This study aspires to contribute to this understanding, in order to develop in depth guidelines for HAM simulations for historic masonry constructions.

## METHODOLOGY

First, six types of historic bricks commonly found in historic buildings in Belgium are characterized by their density, capillary moisture content, absorption coefficient and vapor diffusion resistance. The same is done for three historic mortars, based on replicas made from contemporary raw materials.

Subsequently, some combinations of bricks and mortars were simulated in Delphin 5.9, mimicking a simple absorption test. The section of the materials was based on the absorption coefficients, extreme values are preferred to indicate clear but at the same time realistic differences. The material functions (moisture retention curve, liquid water conductivity and vapor permeability curve) were scaled based on the materials available in the software database. As a reference, the materials used by Vereecken (ceramic brick/cement mortar) were approximated as good as possible based on the available data and added to the simulations.

In a third phase, simulations under realistic climate conditions (Essen, Bremerhaven and Munich) were executed for four brick/mortar combinations and three types of interface resistances. To investigate the impact of the interface resistances in the construction, a combination of moisture saturation degree, freeze thaw cycles (FTC) and ice mass density outputs were analyzed.

Based on the literature reported above and the X-ray tomography (Figure 2), three variations on the interface resistances in the setups are simulated: 1) perfect hydraulic contact is assumed (IR0), 2) an interface resistance of  $5\text{E}10 \text{ m/s}$  is added at all interfaces between brick – mortar (IR5), 3) on top of the IR's in IR5 an additional IR of  $5\text{E}10 \text{ m/s}$  is added in the mortar at a depth of 20mm from the surface, to represent poor contact between the pointing mortar and the bed mortar (IR5PM).

## RESULTS

Table 1 (the abbreviations represent brick type B\_V: Veldovensteen (Dutch, literal translation: Field oven stone), M\_H: Hydraulic lime mortar, B\_REF/M\_REF: Reference material from Vereecken Roels et al, 2013) shows the results of the material characterization

for the materials which are used in the simulations. Generally, the absorption coefficients of the historic bricks and mortars are higher than for the reference materials.

Table 1. Material properties bricks and mortars: Mean (Standard deviation)

	Density [kg/m <sup>3</sup> ]	A <sub>w</sub> [kg/m <sup>2</sup> .s <sup>0.5</sup> ]	Θ <sub>cap</sub> * [m <sup>3</sup> /m <sup>3</sup> ]	μ <sub>dry</sub> ** [-]	Mat. func.*** /

### Absorption

From the normalized (based on capillary moisture content) absorption curves it is clear that the absorption occurs in several linear phases (Figure 3). The number and transitions of these phases depends on the obstructions the moisture front has to overcome. These obstruction can be a low absorptive mortar (M\_REF), an IR (IR5, IR5PM) or the top of the specimen. For example Figure 3A shows the moisture content of B\_REF-M\_H after 3.5 hours. At that point in time the moisture front reaches location 1, where the IR and the mortar result in a decline of the water absorption (point A). A similar observation can be made when the water front reaches location 2 after 16h for the same configuration (3B). The large difference in the absorption curves for high absorptive mortars (M\_H) without (IR5) and with (IR5PM) pointing mortar IR are due to reduced moisture buffering in the mortar. In cases with the low absorptive reference mortar (M\_REF) these difference are negligible.

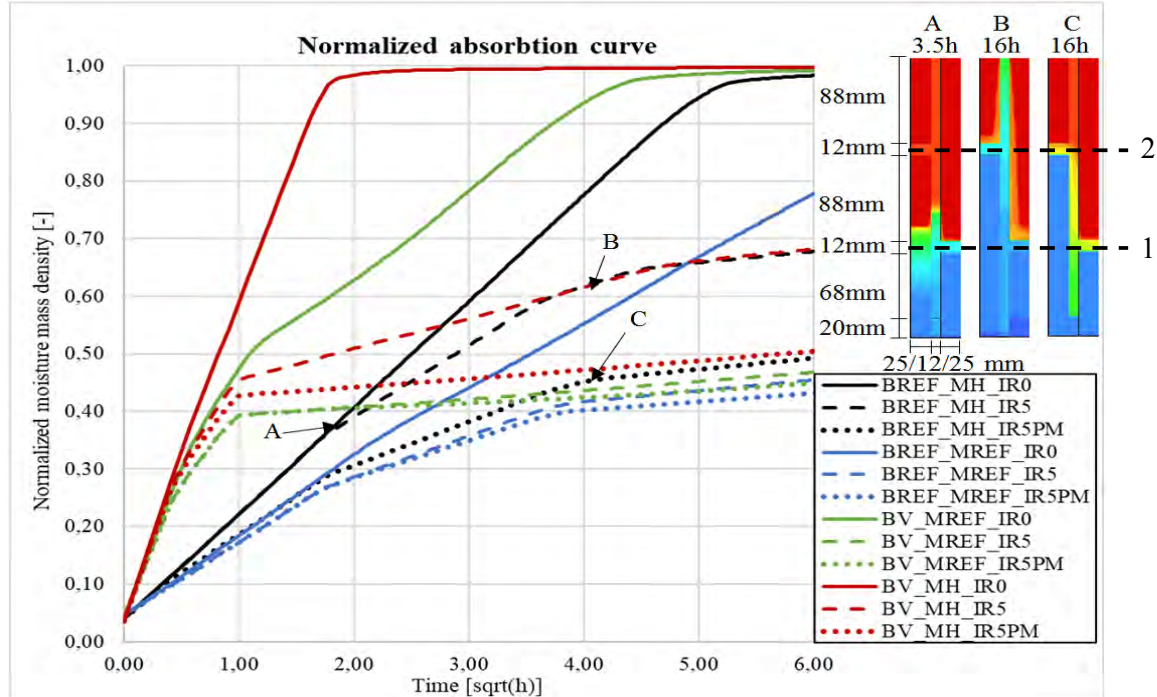

Figure 3. Normalized absorption curves, ABC moisture saturation degree after 3.5h/16h/16h of respectively BREF\_MH\_IR0/ BREF\_MH\_IR5/ BREF\_MH\_IR5PM

It is clear that in all cases the absorption is slowed down by the interface resistances, especially in combination with high absorptive mortars, which could insinuate a decreased frost damage risk. But is this also the case under real climate conditions?

### Real climate conditions

For these simulations with realistic exterior climate conditions (Essen, Munich, Bremerhaven) the same configuration as shown in Figure 3 (A) was used, except for the lime plaster of 10 mm, which was added to the interior side. The normalized average moisture mass density reveals that the interface resistances affect the moisture distribution in the brickwork, especially during rain events, as well as during the convective drying phase (Figure 4). The interface resistances decreases the amount of absorbed water during a rain event due to a reduced redistribution of the moisture in the masonry, and the drying potential shortly after the rain event is increased as well. But in the second drying phase, indicated in figure 4 as zone a, the drying potential is decreased due to the hampering of moisture redistribution which makes the brickwork more vulnerable to critical frost cycles for a longer period of time after a rain event. To conclude the sequence of wetting and drying, and the trade-off between reducing absorption and hampering drying yields a complex balance that is very sensitive to material properties and boundary conditions.

In the analysis several effects of the interface resistances were found that induce increased frost risks:

- moist trapped in the bed mortar behind the IR between a pointing mortar and a bed mortar (Figure 4 A/B and zone a)
- generally a slight increase in of freeze thaw cycles due to a decreased redistribution and drying, biggest impact for case B\_V, M\_H due to higher moisture contents deeper in the construction
- reduced drying of the brick to the mortar due to the IR, especially in case of high absorptive mortars (Figure 4 DEF, case B\_REF,M\_H).
- reduced drying of the mortar to the brick, especially in case of high absorptive bricks combined with a low absorptive mortar (Figure 4 G/H/I, case B\_V, M\_REF).

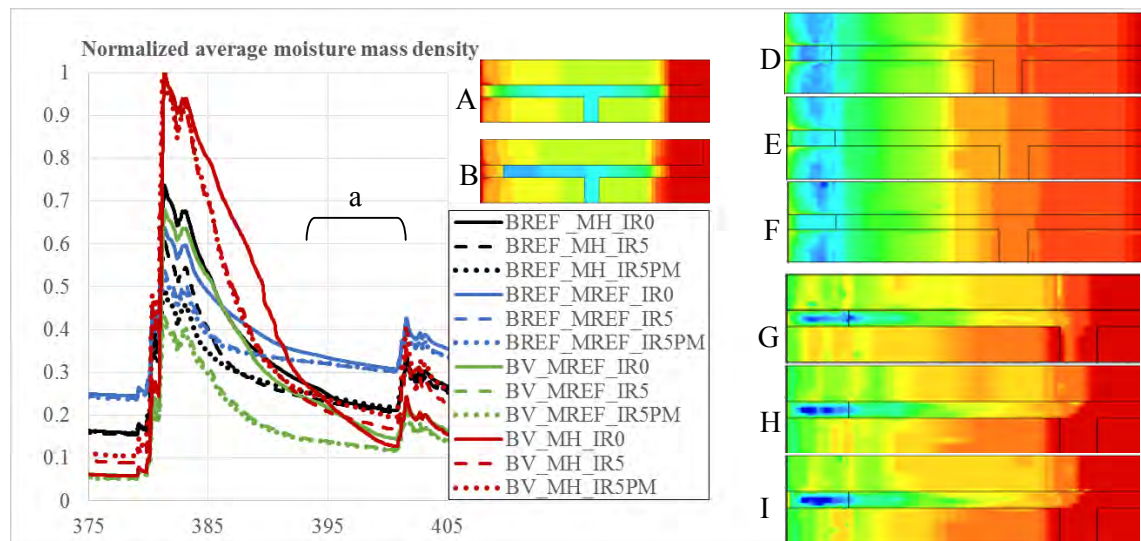

Figure 4 Normalized average moisture mass density during and after a rain event (Munich) based on the capillary moisture content, A/B: Ice mass density for respectively BREF\_MH IR0/IR5PM at day 393.5 (Munich), D/E/F: cumulative critical FTC for respectively BREF\_MH IR0/IR5/IR5PM (Munich) and G/H/I cumulative FTC for respectively BV\_MREF IR0/IR5/IR5PM (Bremerhaven)

Despite the effects described above, it must be noted that the overall differences between IR0, IR5 and IR5PM are limited for the combinations that were studied here.

The risk for mould growth at the interior surface was investigated as well, the IR seems to have reduced the risk on mould growth in all cases. As expected, masonries with hydraulic lime mortar are far more vulnerable to mold growth at the interior surface due to the capillary highway effect described in (Figure 1).

## CONCLUSIONS

Homogenisation of historic masonries with lime mortars in HAM simulations can lead to an underestimation of several risks. Therefore it is advised to avoid homogenisation if possible in perspective of historic constructions.

Next to that, the described effects are found to be strongly dependent on several parameters such as the sequencing of wetting/freezing and the properties of the adjacent materials which hampers straight forward conclusions.

The impact on the moisture content of interface resistances in brickwork in real climate conditions seems rather limited compared to absorption tests. Therefore it is plausible that IR can be neglected but further validation of the reliability of this approach should be made. Follow up research is planned to validate the IR between historic materials more in depth based on CT(computerized tomography).

Due to the large number of uncertainties and highly sensitive trade-off between wetting and drying effects, additional research should also further investigate what the impact is of the variation in the material properties (pointing mortars, bed mortars and bricks), the interface resistances, and the climate conditions.

## ACKNOWLEDGEMENTS

This research is funded by the Research Foundation - Flanders (FWO). The center for X-ray tomography (UGCT) at Ghent University is acknowledged for its help with the visualizations. The Royal Institute of Cultural Heritage (KIK) is acknowledged for providing the drilling core of historic masonry.

### **ABSTRACT**

Water that enters the drainage cavity of a rain screen wall assembly through deficiencies in the cladding will either be drained or retained by absorption or adhesion on the drainage surfaces. The objective of this study is to gain insight into the different factors that affect the quantity of water drained or retained in a drainage cavity. Drainage tests have been conducted for water flowing between two vertical polycarbonate plates with different gap widths to determine the effect on the drainage rate. Tests showed that even small cavities with a width of 1 mm can already drain more water than the amount that would enter the cavity during a rain event. Experiments were performed to determine the contact angle of water on a range of different sheathing materials such as asphalt saturated building paper, spun-bonded polyethylene wrap and cross-woven polyolefin wrap by the use of an optical goniometer. Drainage tests have been conducted for different combinations of these materials to quantify the effect of surface energy on the drainage rate. A larger contact angle results in a smaller quantity of water retained during the drainage test. These tests result in a retained portion of water and a drainage rate for different combinations of materials. The retained portion of water may be considered as a moisture load applied to the outer-most layer of the wall assembly's back-up wall in hygrothermal simulations.

### **KEYWORDS**

Water drainage, small drainage cavities, contact angle, retention

### **INTRODUCTION**

Rain screen wall systems or drained wall assemblies are commonly used to reduce the risk for moisture damage due to rain penetration behind the cladding. If openings or deficiencies are present in the cladding, raindrops may penetrate and enter the drainage cavity during a rain event. Most of the water that enters the drainage cavity will flow down along one of the drainage surfaces or between both as singular droplets, rivulets or multiple streams resulting in a film flow. Also some droplets may be retained in the cavity depending on the surface energy of the materials that define the drainage cavity, the gap width and the initial velocity and volume of the droplets entering the drainage cavity. Accurate knowledge of the retained portion of water is important given that in undertaking hygrothermal and durability analyses, it is considered to be the moisture load applied to the outer-most layer of the wall assembly's back-up wall. According to the Swedish SP Certification Rules no. 021, the quantity of retained water in drained facades should be determined by tests and be applied as input for hygrothermal simulations according to EN 15026 (SP Certification, 2009; Künzle et al., 2008).

Several detailed studies have been completed on film flow dynamics both in the laboratory or by numerical and analytical modelling (Ambrosini et al., 2002). Experimental studies have

been undertaken to investigate the transition from falling film flow to rivulet flow (Martin et al., 2015), rivulet geometry (McCreery et al., 2007) and the transition from laminar to meandering flow on both a single surface (Le Grand-Piteira, 2006) and between two planes (Drenckhan, 2004). As well, the retention of droplets has been studied (ElSherbini and Jacobi, 2006). Research on film flow dynamics has been conducted within the field of chemistry to improve applications such as heat exchangers, the field of geophysics to gain insight into the transport of contaminants in the Earth's substructure (McCreery et al. 2007) or within the field of building engineering mainly focusing on water runoff on a building facade due to wind driven rain (Blocken and Carmeliet, 2012; Van Den Bossche et al., 2015). Research concerning water flow and retention of water in wall drainage cavities however is very limited. Straube and Smegal (2007) performed drainage tests to obtain a better understanding of the drainage capacity in wall cavities given that, as it was stated by Onysko et al. (2007), even when hydrophobic materials are applied not all injected water drains out from the cavity. Drainage tests of smooth non-absorptive materials showed that a drainage gap of 1 mm between two stiff acrylic sheets ( $23\text{--}25\text{ g/m}^2$ ) stored less water than a single acrylic sheet ( $65\text{ g/m}^2$ ). Additionally, spray tests on a polyethylene sheet ( $35\text{ g/m}^2$ ) showed a smaller quantity of retained water compared to an acrylic sheet ( $65\text{ g/m}^2$ ) which is likely due to the increased hydrophobicity of the polyethylene as compared to the acrylic sheet. It was concluded that several wall assemblies even those having small gaps ( $< 1\text{ mm}$ ) could drain more water than would ever enter the drainage cavity during a rain event as drainage rates exceeded  $1\text{ l/min.m}$ . Given that wind driven rain loads on buildings seldom exceed  $2\text{ l/m}^2\text{.h}$ , and infiltration rates are typically between 1% up to 10%, it can easily be assumed that the accumulated drainage rate, even for tall buildings, will never exceed  $1\text{ l/min.m}$ . Blocken and Carmeliet (2006) performed an experimental study on different vertical surfaces (PVC, PMMA, PTFE, glass, glass with hydrophilic coating and glass with hydrophobic coating) to evaluate the impact of contact angle on the quantity of adhered water. Although it is often assumed that hydrophobic vertical surfaces promote drop run-off and therefore show less adhered water, no clear relation between the contact angle measurements and the quantity of adhesion water could be found.

To gain a better understanding of the parameters that affect drainage and retention in wall assemblies, an experimental research program was carried out. The objective of this research program was to evaluate the impact of the drainage cavity width and the surface characteristics of the drainage surfaces on the amount of water that is retained within the cavity. This program and the results derived from the work are described in detail in this paper.

## METHODS

Drainage tests were conducted for water flowing down between two parallel vertical polycarbonate (PC) plates ( $609.6 \times 609.6\text{ mm}$ ). Gap widths of 0.99 mm, 1.96 mm, 3.12 mm and 4.84 mm ( $\pm 0.01\text{ mm}$ ) were defined by use of spacers inserted between the PC plates at both vertical edges. A copper tube was installed on top of the test setup and aligned with the position of the rear PC plate. The tube contained 16 evenly spaced openings of 0.5 mm diameter located every 12.7 mm along its length; this arrangement provided an evenly distributed water deposition rate across the drainage cavity. A gutter located beneath the PC plates collected the drained water. To introduce a water flow, a peristaltic pump (Stenner Pumps 85 pump series) was connected to the copper water deposition tube by means of a flexible plastic tube. An average flow rate of  $0.769 \pm 0.002\text{ l/min.m}$  was applied during 3 cycles of 10 minutes and water deposition was evenly distributed over 16 openings in the copper tube. Both the mass of water that flowed through the pump and the mass of drained water were weighed with an accuracy of 0.1 g. By subtracting the mass drained from that

deposited, the mass of retained water in the cavity could be calculated for each setup. Before each experiment, the pump was turned on for a few minutes in order to reach a steady state for the water content of all tubes both before and after the experiment.

Figure 1: Test setup

Additionally, the drainage capacity of different commonly used sheathing membranes was evaluated. The sheathing membranes were taped onto the PC plate at the back of the test setup with a cavity width of 1.96 mm by means of two vertical strips of double-sided tape (350 mm o.c.). The same procedure as described above was applied to obtain the drainage characteristics of the sheathing membranes. To evaluate the impact of the surface characteristics of the plates or the sheathing membrane on the retention of water in the cavity, the contact angle of a distilled water drop on the different sheathing membranes was measured by means of a goniometer (Ramé Hart model 100-00-115). The optical sessile-drop method was applied to determine the static, advancing and receding contact angle. The reported values are the average of 8 contact angle measurements of different locations on the sample; these are in Table 1.

## RESULTS

As water drops flow down, they leave behind smaller droplets, i.e. trace droplets. The impact of gap width on the volume of these trace droplets is evaluated by introducing water flow in between two PC sheets with different gap widths. During the test, the amount of water added to the drainage gap and the drained amount was measured and the retained portion is calculated. Results for the different gap widths and a single sheet are shown in Figure 2a).

Figure 2: Drainage tests on PC a) Retention during test, b) Retention during test and after drainage has finished per m<sup>2</sup>

These measurements show that a steady-state is achieved after less than 100 seconds for all gap widths. Small peaks are visible which represent the droplets injected to the cavity from discharge of the copper tube. For gaps of 3 and 5 mm a larger variation is visible due to a smaller relative impact of forces due to surface tension compared to gaps of 1 and 2 mm

which causes larger deviation of the flow of drops after collision with other drops along their downward path. As a results, a larger wetted area is achieved for larger gap widths, i.e. the wetted area of the test setup with a 5 mm gap is 11.51% larger compared to the 1 mm gap. Figure 2b) shows the average amount of water retained per  $\text{m}^2$  during the test including droplets adhered to the plate and drops flowing downwards. The error bars represent the minimum and maximum values. Additionally shown in Figure 2b) is the amount of water retained per  $\text{m}^2$  after drainage has finished, i.e. the number of water droplets adhered to the PC plates. The latter was based on pictures captured after the test, assuming that the volume of the trace droplet is half a sphere (Blocken and Carmeliet, 2006). The amount of trace droplets and the average base area was measured at different locations of the test setup as it was observed that values at the top of the setup differed from values at the bottom. The error bars show the standard deviation of the retained amount of water based on three different experiments for each gap width. The graph illustrates that for an increasing gap width, an increasing amount of water was retained in the gap both during flow and after drainage. The retained volume during the test for a gap width of 2 mm was similar to the retained volume in a gap of 1 mm. However, it should be noted that this value also includes the capillary retained portion at the bottom of the test setup which was significantly larger for the 1 mm gap (3.3 g) compared to the 2 mm gap (< 1 g). The increasing amount of retained water for an increasing gap width was mainly due to an increasing amount of drops per  $\text{m}^2$ . The average drop base area ranged from  $1.155 \pm 0.045 \text{ mm}^2$  for a 2 mm gap to  $1.300 \pm 0.108 \text{ mm}^2$  for a 5 mm gap. Only the average base area of the trace droplets of the 1 mm gap was significantly smaller, i.e.  $0.563 \pm 0.044 \text{ mm}^2$ . The vertical spacing between the drops ranged from 3 – 5 mm. It was visually observed that most of the drops adhered only to one of the plates. Only some drops were retained between both plates for the 1 mm gap.

The same measurements were conducted for test setups with a 2 mm gap and a sheathing membrane adhered to the back plate of the setup thus permitting evaluating the importance of membrane contact angle and surface roughness on retained water.

Table 1. Contact angles distilled water on sheathing membranes

No. Sample	Description	$\theta_{C, \text{static}}$	$\theta_{C, \text{advancing}}$	$\theta_{C, \text{receding}}$
0	Polycarbonate	$79.1 \pm 1.5$	$83.3 \pm 1.5$	$48.7 \pm 1.5$
1	Cross-woven polyolefin wrap	$77.7 \pm 5.8$	$85.1 \pm 4.0$	$50.8 \pm 4.7$
2	Spun-bonded polyethylene, grooved	$84.2 \pm 4.0$	$88.4 \pm 1.8$	$57.3 \pm 3.6$
3	Spun-bonded polyethylene, continuous	$90.4 \pm 2.1$	$96.5 \pm 3.3$	$73.1 \pm 2.7$
4	Asphalt saturated Kraft building paper	$105.4 \pm 6.4$	$111.3 \pm 2.1$	$74.9 \pm 2.1$

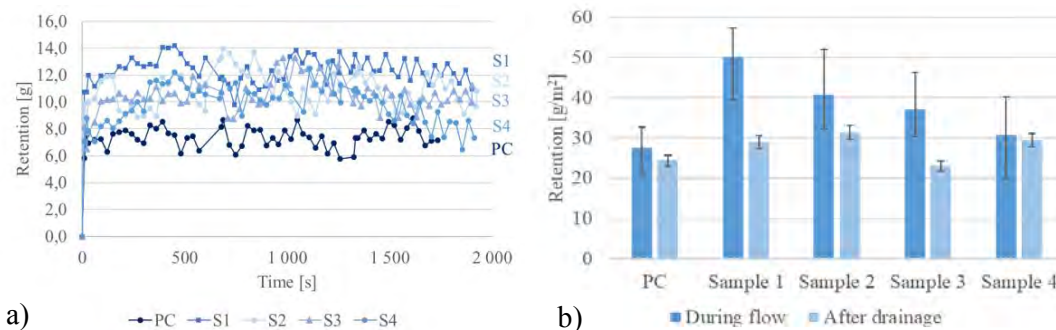

Figure 3: Drainage tests on sheathing membranes a) Water retained during test, b) Water retained during test and after drainage had finished per  $\text{m}^2$

Figure 3a) shows the retained amount of water in the cavity as a function of time for the different sheathing membranes tested. For all sheathing membranes a steady-state is reached as for the PC plates with small peaks. However, a larger variation about the average value is apparent due to the surface roughness which causes deviation of the flow of drops and a difference in wetted area (woven pattern of sample 1, grooves of sample 2, ink on sample 3, bulging of sample 4). Sample 4 shows the largest wetted area ( $0.323 \text{ m}^2$ ) with an increase of 12.5% compared to the setup with two PC plates. The building paper, due to water absorption, bulges that in turn causes locally reduced thickness of the gap width. As a result, drops will not flow in a straight downward path but will follow the path of smallest resistance in between the bulged areas. Sample 1 on the other hand shows the smallest wetted area ( $0.248 \text{ m}^2$ ) which is 7.8% smaller than the wetted area of the PC. Due to the vertical threads of the sheathing membrane, the deviation of drops from their downward path is significantly less compared to drops flowing down, e.g. over sample 4 that were affected by the bulged areas on their way down. By comparing the average retention during the test for the different sheathing membranes (Figure 3b), it can be stated that the quantity of retained water decreased for increasing contact angle. The error bars of the measurements during flow represent the minimum and maximum values. After drainage had finished this trend was less apparent. The largest amount of retained water was measured for sample 2 and 4. The surface of sample 2 contained grooves resulting in locally reduced thickness of the gap width ( $< 1 \text{ mm}$ ) which caused capillary retention at the top portion of the grooves. Locally reduced gap width is also observed for sample 4 due to bulging of the building paper resulting in a larger amount of retention. The larger contact angle of sample 3 ( $\theta_{C, \text{static}} 90.4 \pm 2.1$ ) compared to polycarbonate ( $\theta_{C, \text{static}} 79.1 \pm 1.5$ ), results in a smaller drop base area as well as fewer drops per  $\text{mm}^2$ . In contrast, sample 1 had a contact angle similar to polycarbonate but the number of drops per  $\text{mm}^2$  was larger. This is also apparent when the vertical spacing between the drops is compared (PC:  $4.27 \pm 0.29 \text{ mm}$ ; S1:  $3.41 \pm 0.32 \text{ mm}$ ). This is caused by the woven pattern of the sheathing membrane resulting in trace droplets every other thread.

## DISCUSSIONS AND CONCLUSIONS

Drainage tests performed on two polycarbonate plates with different gap widths, showed that smaller quantities of water are retained in the cavity for gap widths of 2 mm and 1 mm compared to the retained quantity on a single sheet or in a gap of 3 and 5 mm. This confirms the results found by Straube and Smegal (2007) who stated that a drainage gap of 1 mm between two acrylic sheets stored less water than a single acrylic sheet. Further analysis should reveal whether this can also be stated for gaps smaller than 1 mm as more water drops will presumably be retained between both plates as a result of larger quantities of capillary retained water. The average base area and consequently the trace drop diameter differed over the area of the setup. This is in contrast with the observations of Blocken and Carmeliet (2006) who stated that the base diameter was fixed. This is probably due to a different method of adding water to the test setup, i.e. spraying of water onto the vertical sheet or water drops flowing downwards only from the top of the setup. De Vogelaere and Pacco (2012) developed a numerical model at Ghent University to simulate runoff patterns on building facades. By use of a micro model, a simulation was conducted of the cumulated runoff volume on a PMMA surface over time. The shape of the resulting graph is very similar to the graphs obtained from the experiments in this paper including a steady-state with small peaks achieved after less than 100 seconds. Further analysis should be carried out to confirm the results of the simulation model.

Drainage test were also performed for different sheathing membranes. These tests showed that the quantity of water in the gap between the polycarbonate plate and the sheathing membrane

during water flow depends on the contact angle of the sheathing membrane. After drainage has finished, this is however less apparent. As stated by Blocken and Carmeliet (2006) not all retained water is present in the gap as single drops, but also some portion is retained in between the PC plate and the membrane due to locally reduced thickness of the gap. Future research should include a broader range of contact angles and smooth surfaces as it was observed that the presence of grooves and threads affects the quantity of retained water and the size of the wetted area.

Overall, measurements showed that less than 0.5 % of water added over the course of the test (+/- 4.8 l) was retained in between the plates or on a single sheet both during water flow and after drainage has finished. Future research will focus on the development of a drainage model to predict the drainage capacity required for a drainage gap in function of the applied materials and gap width necessary to prevent the build-up of hydrostatic pressure which may cause water to penetrate further into the wall assembly.

### ABSTRACT

The harsh Norwegian climate requires buildings designed according to high standards. The airtightness of the building envelope is crucial to attain an energy efficient building and to avoid moisture problems. A considerable part of building defects registered in the SINTEF Building defects archive are related to leakages through door sills especially in combination with balconies.

The aim of the study has been to examine the rain tightness of the joint below door sills. A laboratory investigation using a driving rain cabined according to EN 1027 has been conducted to provide answers to the matter. In total 14 different test were conducted. Two different sills were included, both a traditional "high" sill and a "lower" handicap-sill. Two different underlays for the sill were included in the investigation. In addition, 3 different heights of the joint-sealing below the sill were chosen (0, 5 and 10 mm). All the tests except two were performed with silicon as joint sealant material.

It was found that the workmanship of the joint-sealing was challenging due to the geometry of the detail. Even if the silicon sealant was carefully applied, voids between the sealant and door sill were found when inspecting closely. When improving the faults, the test showed that the joints was tight. 11 of the 14 tests showed no water leakages at 600 Pa pressure difference. However, leakages were observed at lower pressure differences for the sills with no silicon sealing and for the configurations where there were faults in the silicon sealing.

The laboratory study revealed that the joint below the door sill is vulnerable to small mistakes in the workmanship. Given a carefully application and control of the silicon sealing it is possible to achieve a high water tightness performance. However, improvements to the sealing detail is needed to further increase the robustness of the detail.

Laboratory investigation, Driving rain, Door sill

### INTRODUCTION

Norway is characterized by an extremely varied climate, the rugged topography and long coastline being one of the main reasons for large local differences over short distances and extreme seasonal variations (O'Brien et al., 2004). The climate puts a great demand on the building envelope of Norwegian buildings. The building envelope may be exposed to severe winds, snow loads, precipitation, freeze/thaw cycles, and rather large temperature fluctuations. The Norwegian report "Climate in Norway 2100" is an updated scientific base for climate adaptation in Norway (Bauer et al., 2015). By assuming a further increase in the greenhouse gas emissions, the climate scenarios show an increase in the yearly precipitation by 10-20 %

depending on the climatic model used. Heavy showers will occur more frequently and rainfall flood become more powerful and occur more often.

Increased precipitation is also affecting the strain from wind-driven rain. Wind-driven rain is one of the most important moisture sources affecting the hygrothermal performance and the durability of building facades (Blocken and Carmeliet, 2012; 2004). Measures to adapt the built environment to the anticipated climate changes were studied by Lisø (2006). Lisø stresses the immediate need for information and research with respect to vulnerability in the built environment and technical solutions. This to prevent or minimize negative climatic impacts on buildings.

The SINTEF Building Research design guidelines recommends a rain tightness performance of the wind barrier of minimum 300 Pa (SINTEF, 2007). Skogstad et al. (2011) performed laboratory testing of the rain tightness of wind barriers and sealing around windows. The tests were performed with a pressure difference ranging from 0-600 Pa. Sealing compound of acrylic was found to be rain tight at 100 Pa pressure difference.

Both the Norwegian planning and building legislation (TEK) and the Equality and Anti-Discrimination Act (Lovdata, 2018) dictates that housings should be available for all people. This entails the need for level door sills which can easily be crossed by wheelchairs. As a result, the height of door sills must not exceed 25 mm. This applies to the height difference between the interior floor and the top of the door sills, as well as the difference in height between outdoor surfaces and the top of the door threshold. Hence, these solutions require level interior and exterior surfaces. This increases the risk for static pressure of water as well as presence of snow and freeze/thaw cycles in front of the sill. A robust solution is proposed in the SINTEF Building Research Design Guidelines which includes a gutter in front of the door to direct the water away from the detail (as seen in Figure 1). However, this solution is costly due to material and time use.

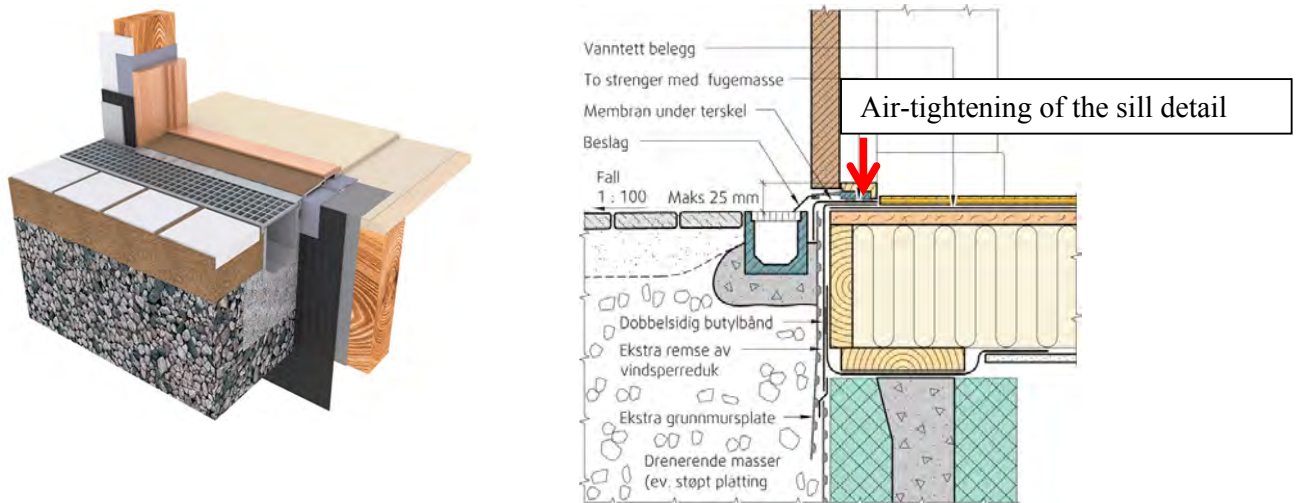

Figure 1. Level door details from the SINTEF Building Research design guidelines 523.731 (SINTEF, 2010).

The purpose of the study has been to examine the rain tightness of the joint below the door sill. A laboratory investigation using a driving rain cabinet has been conducted to provide answers to the matter. Tests have been carried out according to EN 1027 (Standard Norge 2016). In total 14 different test sections were tested. Two different sills were included; a traditional "high" sill and a "lower" handicap-sill. Two different underlays (wood and radon-

membrane) for the sill were included in the investigation. In addition, 3 different heights of the joint below the sill were tested (0, 5 and 10 mm). All the tests except two were performed with silicon as the joint sealant material. The remaining were sealed with no use of sealant.

## METHOD

### Test method

The water tightness was tested in accordance with EN 1027 *Windows and doors Water tightness Test method, method 1A – static pressure* (Standard Norge, 2016). The method is designed to determine the water tightness of completely assembled windows and doors. It is also suitable to determine the water tightness of wall sections. Inside the test chamber a controlled static pressure can be applied across the specimen and a nozzle system can apply a continuous regularly dispersed film of water all over the surface of the test section. The water is sprayed by nozzles at an angle of  $84^\circ$  onto the test section at a rate of approximately 2 l/min per nozzle. The test begins with 15 minutes of water application before a static pressure is established over the test section. The water tightness are tested with 5 minute intervals at pressure differences of 50, 100, 150, 200, 250, 300, 450 and 600 Pa. The penetration of water is observed visually during the testing. Location, point in time and pressure is continuously registered during the tests.

Figure 3. Test equipment for testing according to EN 1027. (left) nozzle system. (right) an example of a door mounted in the apparatus.

### Design of the specimens

Testing of a worst-case scenario with no exterior flashings and gutters gives conservative results. Hence, test specimens were designed by fixing the door sill to a wood sill or a radon membrane with three different joint heights, see Figure 4, 5 and 6. Six of the specimens were designed with a radon membrane between the door sill and the wood sill. A foam gasket was positioned into the joint as a backing material for the compound sealant. The joint was then sealed with silicon compound exterior to the gasket. The sealing of the test samples were carried out as close to a real-life situation for application as possible. The test specimens were positioned on the floor when applying the silicon compound.

Figure 4. Design of the test specimen.

Figure 5. Standard door sill.

Figure 6. Handicap door sill.

## RESULTS

Challenges related to the workmanship of the application of the silicon compound was encountered even in a controlled laboratory environment and when carried out by qualified craftsmen. When applying the sealing compound as carefully as possible (see Figure 7), small faults were found by close inspection, as seen in Figure 8.

Figure 7. Application of silicon compound.

Figure 8. Small defects in the silicon compound was found by closer inspection.

Visual inspections of the specimens were carried out during the tests. The location of leakages occurring at given air pressure differences were registered during tests. It was not practically feasible to register the amounts of the water leakages. Test results are shown in Table 1.

Table 1. Results from the driving rain measurements.

	Without sealing	0 mm	5 mm	10 mm
HC without radon	Leakages at 50 Pa	No leakages	No leakages	No leakages
HC with radon		No leakages	No leakages	No leakages
Regular without radon	Leakages at 250 Pa	No leakages	No leakages	Leakages at 0 Pa
Regular with radon		No leakages	No leakages	No leakages

## DISCUSSIONS

Based on the performed tests it is possible to evaluate the resistance of water penetration through the door sill structure. Laboratory testing is carried out under controlled conditions and does not represent the variation in building materials and workmanship as it would be on a building site.

The workmanship of the sealing of the joint was challenging due to the geometry of the detail. Even if the silicon sealant was carefully applied, voids between the silicon sealant and the door sill were found when inspecting closely. When improving the faults, the test showed that the joints were surprisingly tight. Most of the tests showed no water leakages at 600 Pa pressure difference. According to the SINTEF Building Research design guidelines this is *high performance*. However, leakages were observed at lower pressure difference for the sills with no silicon sealing and at faults in the silicon sealing. This indicates that the detail is vulnerable and that great care should be taken when applying the silicon sealant. The performance of the sealed joint is depending on the workmanship of the craftsmen. In order to further improve the robustness of the detail there is a need to introduce sealing methods which ensure high performance more independently of workmanship.

The handicap sill with sealing compound was found to be watertight at 600 Pa. Without sealing compound water leakages were registered at 50 Pa pressure difference. High performance was also found for the regular door sill except for the 10 mm joint height without radon membrane where water leakages was observed at 0 Pa pressure difference. By closer inspection it was observed that the water leakage was caused by small imperfections in the sealing compound. Based on the measurement campaign we were not able to reveal any difference between underlay of wood and underlay of radon membrane indicating that the silicon sealant had sufficient adhesion between the door sill and radon membrane.

## CONCLUSIONS

A laboratory study was conducted in order to examine the rain tightness of the joint below a door sill. Most of the tests showed no water leakages at 600 Pa pressure difference. Given a careful application and control of the silicon sealing it is possible to achieve high water tightness performance. However, the laboratory study revealed that the joint below the door sill is vulnerable to small mistakes in the workmanship. To further improve the robustness of the detail an improved sealing method is needed.

## ACKNOWLEDGEMENT

The experiments were carried out as part of the *Tall Timber Facades* project (part of the WoodWisdom 2014-2017 program). The authors also acknowledge the Centre for Research-based Innovation "Klima 2050" for providing necessary funding.

### ABSTRACT

Water transport in masonry walls composed of bricks and mortar joints can be strongly affected by the interface between brick and mortar. In this study, water uptake experiments and numerical simulations are performed to study the effect of interface resistance on moisture transport in masonry samples with horizontal and vertical interfaces. Neutron radiography is used to measure moisture content distribution in different masonry samples. An interface resistance is introduced to consider the imperfect contact between brick and mortar in the numerical model. A good agreement between measured and simulated moisture contents is found for different masonry samples. The orientation, horizontal or vertical, of the interface between brick and mortar has no influence on the value of the interface resistance. However we found that the interface resistance is affected by capillary pressure at the interface. A lower capillary pressure at the interface leads to a larger interface resistance.

### KEYWORDS

Masonry, interface resistance, neutron imaging, capillary moisture transport

### INTRODUCTION

Liquid water transport in single materials such as masonry, brick or mortar, is well understood and explained with capillary transport theory. However, moisture transport in masonry walls composed of bricks and mortar joints deviates from what is expected from the capillary transport theory. Many researchers attribute the deviation to the imperfect contact and hence the interface resistance at the brick/mortar interface (Qiu et al. 2003, Derluyn et al. 2011, Janssen et al. 2012, Delgado et al. 2016), while some attribute the deviation to a change of the moisture properties of the mortar joint, compared to bulk mortar (Brocken 1998). Nevertheless, most numerical hygrothermal models still use the assumption of perfect hydraulic contact at the brick and mortar interface (Zhou et al. 2016). It is unclear how the interface resistance affects the hygrothermal performance of masonry walls. Moisture flow across the brick/mortar interface needs to be accurately quantified in order to better understand moisture transport in masonry.

The masonry samples used in previous studies on interface effects are quite simplified (Qiu et al. 2003, Derluyn et al. 2011, Delgado et al. 2016). The samples normally consist of a layer of brick, a layer of mortar, and a second layer of brick, where only horizontal interface exists between brick and mortar joint. By comparison, masonry is much more complex than this in reality. There are both horizontal and vertical interfaces between brick and mortar in masonry. The effect of interface resistance on moisture transport in such complex geometry is not yet studied.

The objective of this study is to understand capillary water transport in masonry with horizontal and vertical joints. Neutron radiography is used to measure moisture content distribution. Numerical model is used to study capillary moisture transport and to obtain the interface resistance at different brick/mortar interfaces. The effect of horizontal and vertical interfaces on moisture transport is described.

## METHODS

Four masonry samples with horizontal and vertical interfaces between brick and mortar are used for capillary water uptake experiment. Two of them are shown in Figure 1. The type of brick is kiln-fired clay brick. Portland cement mortar is used for making mortar joints. The sand grain size in the mortar ranges between 0.1 and 3 mm. The water-cement ratio is 0.16. The masonry samples are made by joining wet bricks with fresh mortar. Then the masonry samples are covered with vapor tight sheeting for 72 h for initial curing. Afterwards, the plastic sheeting is removed and the masonry samples are let to be cured for 28 days at room condition. Given the power of the neutron beam, the thickness of all the masonry samples is 1 cm. Neutron radiography, a non-destructive imaging technique that uses thermal neutrons to probe the sample, is used to measure the time- and space-resolved moisture content distribution in different masonry samples. The experiments were performed at the NEUTRA (Neutron Transmission Radiography) beamline at PSI (Paul Scherrer Institute) in Villigen, Switzerland. The neutron beam passing through the experimental sample is recorded by a detector system. The detector system consists of a scintillator screen with a CCD camera. The CCD camera has a field of view of 254 x 214 mm<sup>2</sup>. The pixel size is 0.196 x 0.196 mm<sup>2</sup>. The exposure time in the experiments was 20 s per radiography.

Figure 1. Two masonry samples for water uptake experiments showing the four types of interface (A, B, C and D) considered in this study.

The masonry samples are initially dried in an oven at 60 °C before capillary water uptake experiments. The experimental setup consists of a balance, a support for the samples that rests on the balance and a water reservoir. The sample is first installed on the support. Next, the water surface in the reservoir is brought up to the bottom of the masonry sample and then capillary water uptake starts. The mass of the experimental sample is measured at the start and end of each on a separated balance, as well as during the experiment with the balance in the experimental setup at an interval of 12 s.

The governing equation for 2-dimensional isothermal moisture transport in masonry is described by Richards equation:

$$\frac{\partial w}{\partial p_c} \frac{\partial p_c}{\partial t} + \frac{\partial}{\partial x} \left( K(p_c) \frac{\partial p_c}{\partial x} \right) + \frac{\partial}{\partial y} \left( K(p_c) \frac{\partial p_c}{\partial y} \right) = 0 \quad (1)$$

where  $w$  is the moisture content (kg/m<sup>3</sup>),  $p_c$  is the capillary pressure (Pa),  $K(p_c)$  is the liquid permeability (s), which is a function of capillary pressure. At the interface between mortar and

brick, an interface resistance  $R$  (s/m) is introduced. Moisture flow across the interface is described by:  $g_f = \frac{\Delta p_c}{R}$ , where  $\Delta p_c$  is the capillary pressure difference between the interface

(Pa). At the bottom side of the masonry samples, a constant capillary pressure of -10 Pa is applied to represent capillary saturated condition. The capillary pressure curves of brick and mortar are described using a bimodal function of the van Genuchten model. The liquid permeability of the brick is determined based on the method proposed by Carmeliet et al. (2004). The moisture transport equation is solved using the finite element simulation program COMSOL. Rectangular meshes are used to discretize the geometric domain. More meshes are mapped around brick/mortar interface and the lower part of the domain. The COMSOL solver used is the direct solver MUMPS with its default solver options. Numerical time steps are automatically selected by the COMSOL solver.

The interface resistance is obtained by comparing simulated moisture profile results with measured moisture profile results. Only interfaces below the wetting front are considered for numerical simulation in this study. There are four types of interface between brick and mortar that affects moisture distribution in this study (Figure 1). Interface A is the horizontal interface between the first layer of brick and the second layer which is mortar. Interface B is the horizontal interface between this second layer, i.e. of mortar, and the third layer, i.e. of brick. Interface C is the vertical interface between two first layers, of brick and of mortar. Interface D is the horizontal interface between a first layer of mortar and a second layer of brick. Moisture transport in the two samples shows symmetric behavior. For sample (a), two profiles in the right part (profile I and II in Figure 1a) are selected for comparison. For sample (b), two profiles in the right part of this sample (profile III and IV in Figure 1b) are selected.

## RESULTS

The moisture content distribution in the uptake experiment in sample (a) is given in Figure 2. The advance of wetting front is symmetric with respect to the middle of the sample. At the time of 409 s, the wetting front in the first layer of brick reaches the top of the brick element. By comparison, the wetting front in the two vertical mortar joints in the first layer shows an inverted bell curve. The wetting front reaches a higher height at the two edges of the mortar joints, while the middle part of the mortar joint shows the lowest height of wetting front. The higher wetting front at the two edges of the mortar is due to moisture transport from the surrounding bricks. At the time of 1525 s, the wetting front is already in the horizontal mortar joint above the first layer of brick, whereas the wetting front shows a shape of inverted triangle in the two vertical mortar joints. At the time of 10027 s, the wetting front is highest in the vertical mortar joint, in the third layer of the sample.

Figure 2. Moisture content distributions in sample (a) at different times.

The moisture content distribution in the uptake experiment in sample (b) is given in Figure 3. As the first layer of the sample is made of mortar, the advance of wetting front is very slow in this sample. For example, at the time of 5012 s, the wetting front only reaches the height of 1 cm. The wetting front shows an almost uniform distribution in the first layer of mortar joint. By comparison, at the time of 10026 s, the wetting front is higher at the location of the two vertical mortar joints than in the brick.

Figure 3. Moisture content distributions in sample (b) at different times

Figures 4 and 5 shows the comparison between simulated and measured moisture profiles in samples (a) and (b). In general, the simulated moisture content profiles agree mostly well with the simulated moisture content profiles. Not only the simulated locations of wetting front agree well with measurements, but also the simulated moisture contents at different locations agree well with the measured moisture contents. However, there are some disagreements between measurement and simulation at some profiles. This might be due to material heterogeneity. In the numerical model, the same brick and mortar material properties are used for each sample. In reality, the material properties of brick and mortar might be slightly different.

The obtained interface resistances for the four types of interface A, B, C and D are:  $8.0 \times 10^9$ ,  $5.0 \times 10^{12}$ ,  $4.0 \times 10^9$  and  $20.0 \times 10^9$  m/s. A larger value of interface resistance means a larger capillary pressure drop across the interface and a smaller moisture flux across the interface.

Figure 4 Measured and simulated moisture contents at profiles I and II for sample (a).

Figure 5 Measured and simulated moisture contents at profiles III and IV for sample (b).

## DISCUSSIONS

Based on the results presented above, we propose that the interface resistance may be dependent on capillary pressure at the interface between two materials. A lower capillary pressure at the interface will lead to a larger interface resistance. Interface B has the largest interface resistance. The capillary pressure at Interface B is much lower than at the other types of interface. On the one hand, Interface B is at a higher location above two layers, i.e. of brick and mortar. There is already a large capillary drop when moisture reaches Interface B by capillary transport. On the other hand, the interface resistance at Interface A leads to an additional capillary pressure drop.

The interface resistance at Interface C ( $4.0 \times 10^9$  s/m) is slightly smaller than that at Interface A ( $8.0 \times 10^9$  s/m). Interface A is a horizontal interface between the first layer of brick and the second layer of mortar, whereas Interface C is a vertical interface between brick and mortar in the first layer. When wetting front reaches Interface A, there is already some capillary pressure drop. By comparison, Interface C is along the direction of moisture transport. Capillary pressure at lower location is larger than at higher location. The top location of Interface C is the same as that of Interface A. Therefore, the capillary pressure at Interface A is definitely larger than that at Interface C. The obtained interface resistance at Interface C is the averaged value along this interface. Due to higher capillary pressure at the interface, the interface resistance Interface C is smaller than that at Interface A. There are both horizontal and vertical interfaces between brick and mortar in masonry. Compared to the flow, the magnitude of interface resistance does not seem to be affected by the direction of interface. Instead, the interface resistance is apparently related to capillary pressure during wetting at the interface. The larger the capillary pressure, the smaller the interface resistance at the interface. The datasets offer more result, which will be studied in the next phase.

## CONCLUSIONS

Different masonry samples with horizontal and vertical interfaces are used to study the resistance to moisture transport across the brick/mortar interface. Neutron radiography is used to measure the time- and space-resolved moisture content distribution in different masonry samples. A 2-dimensional moisture transport model is built to study moisture transport in

masonry samples. An interface resistance is introduced to consider the imperfect contact between brick and mortar. There is very good agreement between measured and simulated moisture contents for different masonry samples. Compared to the flow, the magnitude of interface resistance is not affected by the direction of interface. Horizontal interface or vertical interface between brick and mortar has no influence on the value of interface resistance. It is found that interface resistance seems to be affected by the capillary pressure at the interface, and not by the orientation of the interface. A lower capillary pressure at the interface will lead to a larger interface resistance.

### **ABSTRACT**

Aerogel-enhanced products are often indicated as promising materials for increasing the thermal resistance of the building envelope. In particular, aerogel-enhanced blankets have already showed their effectiveness in several retrofitting projects. This paper aims to review the current state of the art regarding aerogel-enhanced blankets. In these materials, a fiber matrix bonds together the aerogel structure, compensating the low mechanical properties of the aerogels without reducing their exceptionally low thermal conductivity. This paper describes current aerogel-enhanced blankets existing worldwide and produced by different companies. Then, a new aerogel-enhanced blanket developed by the authors is presented. Thermal characterization tests confirm the superior performance of aerogel-enhanced blankets, which show a thermal conductivity as low as 0.013 W/(mK). Finally, future research challenges for aerogel-enhanced blankets are presented.

### **KEYWORDS**

High-performance envelope, aerogel, aerogel-enhanced blanket, super-insulating materials.

### **INTRODUCTION**

The development of innovative materials aiming to achieve energy savings is a main focus in the building technology sector. In this context, silica aerogel-enhanced products are often indicated as promising materials for increasing the thermal resistance of the building envelope. While aerogels seem to be promising but still uncommon materials, the global market for silica-based aerogels continues to grow annually at over 10%, passing from US\$ 427 Million in 2016 to a forecast of US\$ 1.92 billion in 2022 (GVR, 2016). Nowadays, the primary market sector for aerogel-enhanced products is represented by the oil and gas fields which mainly use aerogel-enhanced blankets. However, the building and construction aerogel-market sector is supposed to increase more than the other sectors (Berardi and Nosrati, 2018).

Silica aerogels have extraordinary small pores, which result in remarkable thermal properties, and mechanical strength. Table 1 reports the main physical properties of silica aerogels. In Table 1, it emerges that while the compression strength of the aerogel has a value around 300 kPa, their tensile strength is only 16 kPa, making aerogel extremely fragile. In order to strengthen the tensile properties of the silica aerogels to be used as an insulating material, it has been recently proposed to reinforce the aerogels with mechanically stronger materials and non-woven fiber matrixes such as glass, mineral or carbon fibers. When the fibers or fibrous matrix are added to the pre-gel mixture which contains the gel precursors, the resulting dried composite is an aerogel-enhanced blanket (Aegerter et al., 2011, Baetens et al., 2011).

Nowadays, the main reasoning for the use of aerogel-enhanced insulation is related to the possible space saved resulting from the exceptional thermal properties and fire resistance. In

particular, aerogel-enhanced products during building retrofits guarantee the advantage of significant space saving and provide a high thermal resistance in thin layers (Ibrahim et al., 2014, Ghazi Wakili et al. 2014, Galliano et al., 2016). In fact, already a few years ago, the retrofit of a wall with 1 cm thick aerogel blankets on the interior side demonstrated to be economically feasible by Shukla et al. (2014), although the high material cost at that time.

Table 1. Main physical properties of silica ( $\text{SiO}_2$ ) aerogels.

Property	Value
Density	3 to 350 kg/m <sup>3</sup> (typical 70 to 150 kg/m <sup>3</sup> )
Pore diameter span	1 to 100 nm (~20 nm on average)
Pore particle diameter	2 to 5 nm
Average pore diameter	20 to 40 nm
Porosity	85 to 99.9 % (typical ~95%)
Thermal conductivity	0.01 to 0.02 W/mK
Primary particle diameter	2 to 4 nm
Surface area	600 to 1000 m <sup>2</sup> /g
Tensile strength	16 kPa
Compression strength	300 kPa
Coefficient of linear expansion	2 to 4×10 <sup>-6</sup>

Aerogel-enhanced blankets composed of synthetic amorphous silica are a valid possibility whenever space and weight constraints exist. Several studies have investigated the use of aerogel blankets in buildings and reported about the in-situ behaviour of such products. For example, at the University of Nottingham, the energy efficient retrofit project of a 1930's house was investigated. The research aimed to understand the impact of thermal bridging on the heat loss using aerogel blankets of 20 mm thickness implemented internally with 12 mm of gypsum plaster-board. Results showed that after retrofit, the heat loss through the retrofitted wall was highly reduced, while for the separating wall, there was an increase of the heat losses due to the growing thermal bridges (Cuce et al., 2014, Cuce and Cuce, 2016). Although these preliminary experiences seem promising, a systematic evaluation of the available aerogel-enhanced blankets is still missing. This paper aims to review thermal properties of products currently on the market, to present an innovative aerogel-enhanced blanket, and to review current challenges for these highly promising insulating products.

## LITERATURE REVIEW

Aerogel-enhanced blankets are flexible, highly porous, and have a remarkably high thermal resistance. In fact, they have started to be produced and commercialized by several manufactures worldwide, such as Aspen Aerogel Inc., Cabot Corporation, Svenska Aerogel AB, Acoustiblok UK Ltd., Active Space Technologies, Joda, and Airglass AB. For example, Spaceloft developed by Aspen Aerogels Inc. (MA, US) is a flexible fiber-reinforced blanket with a declared thermal conductivity of 0.013 W/(mK) at 0°C. Other common aerogel blankets are Cryogel<sup>®</sup>Z by Aspen, available in 5 mm and 10 mm thickness and suitable for industrial application, and Thermal-Wrap<sup>™</sup>, available in 5 mm and 8 mm thickness by Cabot Corporation. The thermal conductivity of these last two products is 0.014 W/(mK) and 0.023 W/(mK) respectively. Similarly, among the aerogel-based commercial blankets, Proloft by Advanced Technologies has attracted some attention as a thermal barrier strip to provide thermal bridging protection around window frames.

The advantages of aerogel-enhanced blankets are that the final panel does not show any granularity of the aerogel, since the aerogel particles are chemically attached to the fiberglass matrix. Commercially available aerogel-enhanced blankets are made with amorphous silica,

and they usually suffer for dust production. However, several health organizations, including the International Occupational Safety and Health Organization, have declared aerogel blankets not hazardous for the human health. The non-toxicity combined with the excellent fire protection are promising characteristics of these blankets, which are recyclable, have minimal to no Ozone Depleting Potential and a Global Warming Potential below than 5. Table 2 reports the main properties of different aerogel-enhanced blankets available on the market.

Table 2. Main properties of the most common aerogel-enhanced blankets available on the market.

Commercial name	Manufacture	Fiber composition	Density (kg/m <sup>3</sup> )	$\lambda$ (W/mK)
Thermal Wrap	Cabot	Polyestere and PET	~70	0.023
Cryogel x201	Aspen aerogel	Polyester/fiber glass	~130	0.014
Cryogel Z	Aspen aerogel	PET / fiber glass	~160	0.014
Dow Corning HPI 1000	Dow Corning	Fiber glass	-	0.015
Pyrogel HPS	Aspen aerogel	Fiber glass	~200	0.014
Pyrogel XTE	Aspen aerogel	Fiber glass	~200	0.014
Pyrogel XTF	Aspen aerogel	Fiber glass	~200	0.014
Spaceloft	Aspen aerogel	Polyester/fiber glass	~151	0.015
Silica aerogel fiberglass blanket	Joda	Fiber glass	<300	0.016
Silica aerogel ceramic fiber blanket	Joda	Ceramic fiber	<301	0.016

Figure 1. Aerogel blankets Cryogelx201 (left) and Dow Corning HPI 1000 (right).

Lakatos (2017) and Nosrati and Berardi (2018) assessed how the thermal conductivity of aerogel-blankets increases as a function of the moisture content. In particular, Lakatos (2017) studied the application of the aerogel-blanket to a brick-based wall. Firstly, sorption isotherms were investigated to understand the temperature sensitivity of moisture uptake. Each aerogel slab was tested after wetting the dried samples for 0, 4, 8, 12, 16, 20 hours at 293 K and 93% relative humidity, showing significant higher thermal conductivity in the wetting stage.

A comprehensive investigation of the thermal conductivity of the aerogel-enhanced Cryogel by Aspen Aerogel and Thermal Wrap by Cabot blankets in humid conditions at transient and steady-state regimes was made by Hoseini et al. (2017). The moisture build-up in the two aerogel blanket samples was measured as a function of the relative humidity and temperature. Transient plane source tests revealed that the thermal conductivity increased by up to approximately 15% as the ambient relative humidity increased from 0% to 90%. However, when the aerogel blankets were placed in a humid environment, it took hours for the moisture to diffuse towards the material core.

## EXPERIMENTAL STUDIES

### Comparison of existing products

Figure 2 shows the thermal conductivity values declared by the manufacturer for different aerogel blankets currently on the market. The results are particularly promising, especially at the temperature typically incurred in the building sector.

To help comparing several products, the authors performed hygrothermal tests in the Building Science Lab at Ryerson University. In particular, after exposing the different blankets to the same hygrothermal conditions, the thermal conductivity values for different aerogel blankets were measured using the heat flow meter apparatus HFM 436 Lambda. The temperature difference between the hot and cold plates was set to 20 °C, while the temperatures ranged from -20 °C to +50 °C. Figure 3 reports the results for four aerogel-enhanced blankets.

Figure 2. Thermal conductivity values across the temperature for different aerogel blankets (this figure was drawn using the values declared by the manufactures).

Figure 3. Thermal conductivity values across temperature for different aerogel blankets (these values were measured by the authors after having normalized the hygrothermal conditions).

### Development of a new aerogel-enhanced blanket

The synthesis of silica aerogels is typically carried out in three phases: gel preparation, aging, and drying. In particular, three methods for drying the aerogels can be used: supercritical drying (SCD), ambient pressure drying (APD) and the freezing drying. SCD reduces capillary tension but comports higher costs. On the other hand, APD is more cost-effective but involves increased capillary tension which can lead to shrinking and possible fractures, therefore SCD is generally used for silica aerogels. The cost of the SCD process represents a limiting factor to obtain a competitive price for the aerogel. To lower the price of the blankets by avoiding to perform a SCD, the authors have obtained aerogels and aerogel-enhanced blankets drying the materials in a vacuum oven for 24 hours (Fig. 4).

Figure 4. Authors' produced aerogel granules (left) and aerogel-enhanced blankets obtained embedding a fiberglass panel with precursor aerogel before the drying process (right).

The silica aerogels were prepared using the 2-step Stöber process, as adapted from Shlyakhtina et al. (2007), using reagents purchased from Sigma Aldrich. Firstly, 120 ml of isopropanol was added to 123.2 ml of tetraethylorthosilicate in a graduated cylinder. The contents were then transferred to a beaker with a stir bar, set to stir for 30 minutes, and sealed with paraffin to prevent evaporation. Next, 29 ml of 0.1 M HCl was added dropwise, and set to stir for an additional hour until the mixture was completely hydrolyzed into silicic acid. A timer was started, and 28 ml of 0.15 M  $\text{NH}_4\text{OH}$  was added dropwise to initiate the polymerization. The solution was transferred into a cellophane-lined rectangular mould. Pre-cut and pre-weighed fiberglass samples 2 cm thick were dipped into the solution, and then the excess solution was squeezed out. Afterwards, the samples were set to cure, and were transferred to a heated vacuum furnace for 24 hours, similarly to the work of Padmanabhan et al. (2016). The samples were taken out and weighed to determine their final mass and that of aerogel, by subtracting from their initial mass. The thermal conductivity of the aerogel-enhanced blanket shown in Fig.4, tested using the same apparatus and conditions described previously, resulted to **be 0.029 W/(mK) at 0 °C and 0.031 W/(mK) at 20 °C**, generally above that of commercial aerogel-enhanced blankets, although the price of this bat would be extremely competitive and its manufacturing process would not require expensive equipment. In fact, the costs of the aerogel and of the aerogel-enhanced blankets were below \$4/gram and \$30/m<sup>2</sup> respectively.

## CONCLUSIONS

This paper has presented ongoing research activities leading to the manufacture of aerogel-enhanced blankets. An overview of products available on the market has been reported. Meanwhile, a new aerogel-enhanced blanket has been presented. The hope is that soon APD processes could be improved to realize cheap aerogel-blankets with a thermal conductivity of 0.010 W/(mK), a target that would make these products preferable over traditional insulating ones.

## **Hygrothermal Analysis of a Vapour-Open Assembly with Vacuum Insulation Panels**

Brock Conley<sup>1</sup>, Cynthia Ann Cruickshank<sup>1</sup>, Mark Carver<sup>2</sup>

<sup>1</sup>Carleton University, Ottawa, Canada

<sup>2</sup>CanmetENERGY-Natural Resources Canada, Ottawa, Canada

### **ABSTRACT**

The following paper studies the year-long moisture conditions associated with vacuum insulation as the exterior insulation. The exterior insulation of one assembly was renovated by using 50.8 mm (2 inch) of expanded polystyrene (EPS) and represents the baseline performance of current common practice. Another assembly was built with 20 mm (0.7 inch) vacuum insulation panels encased in the equivalent thickness of EPS to represent a high RSI-value retrofit. The thermal performance was evaluated using a guarded hot box facility at Carleton University and the in-situ Building Envelope Test Hut at CanmetENERGY-Ottawa. The temperature, humidity and moisture content in the sheathing measurements from February 2017 to March 2018 are presented. Experimental results were compared to failure criteria outlined by ASHRAE Standard 160 to determine if the proposed building envelope system would be suitable in a cold, humid climate.

### **INTRODUCTION**

In Canada, it is estimated that a single dwelling built before 1980 consumes 25% more space conditioning energy than a dwelling built after 2010 according to the National Energy Use Database (NRCan-OEE, 2016). Considering the disparity in energy consumption between vintages, and that there are 4.5 million dwellings in Canada (Statistics Canada, 2016) built before 1984, there is a significant amount of energy that can be saved by further insulating or improving the energy performance of these existing dwellings. Since space conditioning accounts for the majority of the energy consumption in a residential building, addressing the energy flow through the envelope of the building (e.g., conduction, air leakage) may provide significant benefits. A properly sealed and well insulated envelope, which older homes often lack, can reduce the energy transfer between the conditioned space and ambient environment.

Approximately 60% of existing residential buildings in Canada were constructed before 1984 (Statistics Canada, 2016). Since some of these buildings may be poorly insulated, and/or lacking airtightness and consequently represent a large portion of the energy usage of the residential building stock, that stock is a perfect candidate for retrofit. While these buildings may need upgrades to their envelopes, simply increasing the amount of insulation on the exterior face of the envelope may not be the best practice. Instead, it may be beneficial to use high performance (e.g., high resistance) materials, such as vacuum insulation panels (VIPs), to maintain or limit the increase of wall assembly thickness. While thermal improvements are a main driver of retrofitting the building envelope, the hygrothermal aspects of the wall assembly impact its lifespan and durability.

The paper outlines the investigation of using high performance exterior insulation on two wall assemblies to address the moisture requirements and thermal performance of a building envelope while maintaining the thickness compared to standard constructions.

## WALL ASSEMBLIES

Since the desired wall assembly construction is thin profiled as well as thermally and hygrothermally sufficient for a cold and humid climate, a composite insulation panel using VIPs and Type 2 expanded polystyrene (EPS) as rigid exterior insulation board was proposed. The VIPs were surrounded by the EPS such that the RSI-value of the assembly was higher than an equivalent thickness of EPS. This configuration also mitigates the risk of punctured VIPs during installation, which was a concept previously investigated (Conley, et al., 2016; Carver, et al., 2017).

## Construction

Two wall assemblies used for this study were developed to represent types of construction that could impact Canadian construction. As previously stated, retrofitting the existing building stock that is currently built below the current minimum insulation levels is an area that could provide a large change in national energy consumption. The first wall assembly under investigation was a 2x4 wood stud assembly with 600 mm spacing, filled with RSI-3.3 insulation without any interior vapour barriers and has undergone an exterior retrofit. The exterior retrofit involved removing all materials to the exterior of the sheathing, applying an air barrier, adding the VIP-EPS insulation panel, adding 1x3 strapping and finishing with siding (see Figure 1). The second wall assembly represented a typical new construction in Ottawa, Canada. The wall was construction with 2x6 wood studs with 600 mm spacing filled with insulation, internal vapour barrier, 40 mm of rigid insulation, an exterior air barrier and vinyl siding (similar to Figure 1). For the high performance assembly, the VIP-EPS insulation panel was used as 40 mm of rigid insulation. Both of the wall assemblies described are attempts at creating a durable, robust and high performing assembly that can be utilized in Canadian climates and must be evaluated for their applicability to the climate.

Figure 1: Cross section illustrating materials used for the wall assemblies in the study

## Failure Criteria

For the wall assembly design to be considered a success, the thermal and hygrothermal goals must be met, in totality and in comparison to the baseline assemblies. These criteria were developed from standards such as ASHRAE 160 or voluntary building performance standards. The hygrothermal performance of the wall assembly is an indicator of its resilience to the wetting, and its drying potential. The following criteria is applicable for materials at temperatures between 5°C and 40°C:

1. Maintain the 30-day running average relative humidity at the sheathing below 80%;
2. Maintain the 5-day running average relative humidity at the sheathing below 98%;
3. Maintain the daily average relative humidity at the sheathing below 100%; and
4. Maintain a moisture content below 28% to eliminate the risk of mould and rot.

When the material is at a temperature below 5°C, most deterioration at high humidity levels is non-existent, while condensation and bulk wetting could still be an issue. The relative humidity set-points were developed by ASHRAE (ANSI/ASHRAE, 2016) as guidelines to minimize the risk associated with organic growth within the building envelope assembly. The moisture content of wood limits are based on studies that assessed the robustness or durability of wall assemblies and is related to the surface relative humidity.

### THERMAL PERFORMANCE

The steady-state testing was performed using a guarded hot-box situated at Carleton University with the purpose of determining an accurate RSI-value of the proposed wall assemblies. The guarded hot-box, depicted schematically in Figure 2, is composed of three independently controlled chambers to force one-dimensional heat flow through the wall assembly specimen. The climate chamber is set to simulate the exterior temperature conditions (approximately -20°C) while the metering and guarded chambers have the same set-point, slightly above room temperature around 25°C, thus creating a substantial temperature difference across the specimen.

Figure 2: Schematic of the guarded hot-box at Carleton University

The electric heaters installed within the metering chamber are the only source of energy input to the area, and are therefore accurately monitored for the duration of the test period. Additionally, the interior and exterior surface temperatures are measured during the test period to find the effective RSI-value of the wall assembly through Equation (1), where  $\Delta T$  is the temperature difference between surfaces in °C,  $A$  is the known area of the metering chamber in m<sup>2</sup>,  $t$  is the test period in seconds, and  $E$  is the energy input to the metering chamber in J.

$$RSI = \frac{\Delta T \cdot A \cdot t}{E} \quad (1)$$

The effective RSI-value of the wall assembly can be calculated from the measured data after steady-state is reached. Defined by ASTM C-1363, these test conditions are met when five consecutive test periods:

- The average specimen surface temperature in either chamber did not vary by more than  $\pm 0.25^\circ\text{C}$ .
- The average energy input to the metering chamber did not vary by more than  $\pm 1\%$ .

For this study, the wall assemblies were evaluated in the guarded hot-box and results were compiled into Table 1. The assemblies that were tested performed below the failure criteria previously described, however, the baseline values were improved by increasing the RSI-value by 31% and 21% for new construction and retrofit construction, respectively. It should be noted that the nominal values provided for the baseline assemblies do not incorporate thermal bridges from the vertical framing members, and constitute a highest permissible value, while the values calculated from the guarded hot-box experiments are the effective RSI-values, which would be a lowest possible RSI-value.

Table 1: Summary of steady-state effective RSI-value from guarded hot-box testing

Assembly	New Construction ( $\text{m}^2\text{K/W}$ )	Retrofit ( $\text{m}^2\text{K/W}$ )
Baseline	4.8 (nominal)	4.2 (nominal)
High Performance	6.3 (effective)	5.1 (effective)

## HYGROTHERMAL PERFORMANCE

The hygrothermal assessment of the wall assemblies were conducted at the CanmetENERGY Building Envelope Test Hut (CE-BETH) in Ottawa, Canada. The test facility monitors the moisture and thermal conditions of wall assemblies by controlling the interior conditions and exposing the exterior to ambient conditions for a prolonged period of time. Instrumentation is placed within each specimen to monitor the moisture content, relative humidity, temperature and heat flux at various interfaces and materials within the assembly. The measured values were compared to failure criteria and the durability of the assembly was assessed for the climate. Measurements were taken at 5 minute intervals and averaged over the hour to reduce the number of data points and have a better comparison for weather data. The instrumentation points are shown in Figure 3, which are identical for the new construction and retrofit wall assemblies.

Figure 3: Plan view of instrumentation placed at the sheathing of bottom half of the assemblies

The durability of the wall assemblies were monitored from February 2017 to February 2018, however they were installed at the test facility beginning in December 2016. Therefore, the assemblies were exposed to a heating seasons worth of moisture loads prior to when the data acquisition began. During installation, various sensors were place on the sheathing surface and vertical framing members to assess the moisture content, temperature and relative humidity of the materials.

The interior conditions of the facility have different set-points for the heating and cooling seasons. During the heating season, the facility maintains an indoor air temperature of 24°C and a relative humidity between 35% and 40%. During the cooling season, the indoor air temperature is maintained at 20°C but the relative humidity may reach up to 70%. The lack of dehumidification in the space aligns with ASHRAE 160 interior design humidity for daily average outdoor temperatures 20°C or greater, which is experienced in Ottawa. For the one year test period, the interior temperature and relative humidity of CE-BETH is presented in Figure 4. Note that there were control and power issues during the monitoring program that caused dips in temperature and relative humidity.

Figure 4: CE-BETH interior conditions for the February 2017 through February 2018

During the test period, the moisture content in the sheathing and vertical framing members were measured through resistance based instruments. In Figure 5, the moisture content of four locations in the high performance assembly designed for new constructions were plotted for the duration of the test period. The VIP and EPS labels are moisture content pins in the sheathing aligned to the labelled material outboard. The temperature of the sheathing aligned with a VIP is plotted to show the temperature dependence of the moisture content. The moisture contents in the assembly did not exceed 20%, except for a brief period in November and December, where the temperature decreased rapidly.

The findings suggests that the building envelope would pass the hygrothermal failure criteria outline, however, the assemblies would need to undergo further observation to ensure that the increasing trend of moisture content does not continue over time. An acceptable level of drying potential is shown for the 2017 annum, but with 2018 data, conclusive determinations can be made about the assembly and its feasibility in the environment.

Figure 5: Monitored moisture content within the new construction wall assembly

## CONCLUSION

In conclusion, two wall assemblies with VIPs were evaluated under steady-state and in-situ conditions in Ottawa, Canada. The thermal performance of the proposed assembly increased the thermal resistance by up to 32% compared to the baseline assembly. The hygrothermal parameters of the assemblies were and continue to be monitored and measured. After the first year of data collected, the wall assemblies passed the failure criteria outlined, however, it remains too early to make conclusive determinations about the durability and robustness of the wall assemblies in this climate.

The hygrothermal measurements continue to be logged, while the computer simulations will be used to verify the results from CE-BETH. After the in-situ study in Ottawa is completed and simulations are compared to the experimental data, the wall assemblies will be compared to other climates across Canada to ensure they are sufficiently robust and durable. Afterwards, hygrothermal simulations will be used to determine the sensitivity of the proposed assembly to parameters such as, interior relative humidity, sun exposure and varying weather files.

## Measurements of Temperature Dependency on Thermal Insulation Thickness in Ventilated Attics

Thor Hansen<sup>1,\*</sup> and Eva B. Moeller<sup>1</sup>

### ABSTRACT

The main objective of this paper is by measurements to investigate whether increased thermal insulation thickness reduces the temperature in ventilated attics. With lower heat flux through the ceiling in the winter, the theory is that the temperature in the attic decreases and consequently the relative humidity increases which may cause mold growth. While some simulations support this theory, others do not. To test the theory in practice, measurements were performed in 29 dwellings, mainly older single family houses with ventilated attics and insulation thicknesses varying between 150 and 600 mm (6" and 23"). The temperature was measured for more than one year in the attic, the living space below and outdoors.

All measured attics were ventilated as recommended in guidelines; i.e. with openings at the top and the bottom. The measurements in the attics showed high dependency on the outdoor temperature, while indoor temperature and the thickness of insulation were not significant.

Consequently, the thermal insulation thickness alone cannot explain possible increasing mold problems. However, extra insulation in attics may obstruct the ventilation openings and therefore, reduce the ventilation rate. Measurements of ventilation rates in non-problematic and moldy attics should therefore be the next step.

### KEYWORDS

Ventilated attics, temperature, thermal insulation thickness, heat flux, energy efficiency

### INTRODUCTION

Our recent, paper (Hansen & Møller, 2017) showed some indication that the measured temperature in the attics of the case buildings was independent of the thermal insulation in the ceiling. Another paper (Nielsen & Morelli, 2017) presented simulation results for temperature variation in cold ventilated attics, with insulation thicknesses varying from 50 to 450 mm, where the average temperature in the attic in January was 1.54 °C (50 mm), 0.29 °C (150 mm) and -0.39 °C (450 mm). In April the average temperatures in the attic were 9.7 °C (50 mm), 9.0 °C (150 mm) and 8.7 °C (450 mm). This indicates that an increased insulation thickness from 150 mm and up, has a minor influence on the temperature in a cold ventilated attic during winter time. Hagentoft & Sasic-Kalagasidis (2010) state that additional attic insulation leads to a colder attic space, but does not indicate the magnitude. Geving & Holme (2010) have made simulations with average monthly values of temperature and relative humidity for Oslo; they also conclude that the temperature in the attic decreases with increased insulation, but they do not state how much. However, from the increase in relative humidity the temperature difference can be calculated to be approximately 0.5 °C when the insulation thickness is changed from 100 mm to 500 mm. The outdoor temperature in Oslo in January is approximately 3 °C lower than in Denmark.

The general perception that energy-saving will decrease the temperature in a ventilated attic substantially and consequently increase the risk of mould growth is challenged in this paper. Instead of simulations, measurements of temperature were performed in 29 case buildings with different amounts of insulation on the ceiling against a ventilated attic.

## METHODS

To assess the effect of the insulation thickness on the temperature in a cold ventilated attic, a series of field measurements was carried out in 29 Danish case buildings grouped in three groups depending on the insulation thickness:

- Group A: 7 case buildings with an insulation thickness ranging between 150-250 mm
- Group B: 9 case buildings with an insulation thickness ranging between 300-400 mm
- Group C: 13 case buildings with an insulation thickness ranging between 450-600 mm

The thermal insulation was applied either at construction or later as a part of improving the energy efficiency. When looking at temperature difference, the thermal resistance for the insulation material is the relevant parameter. As the insulation materials used in the case buildings had approximately the same thermal conductivity, the thickness was proportional to the thermal resistance. Most of the case buildings had a vapor barrier installed; some of them were old and probably not tight. However, this article only considers temperatures; the effectiveness of the vapor barriers is therefore not considered.

In each attic, a series of sensors (EL-USB-2+ from Lascar Electronics (Lascar electronics)) were installed in order to register the temperature and relative humidity for at least one year. Measurements were performed from July 2015 to June 2017. Not all houses were measured at the same time, and therefore two winters were covered. Sensor positions are shown in Figure 1. The sensors were controlled for uncertainty of measurements, which was registered to be within the 0.45 °C stated by the manufacturer. The sensors registered the climate every hour. Beside the sensors in the attic, one sensor registered the indoor climate and another sensor measured the outdoor climate.

The data analysis showed that the temperatures at the ridge and at the roof underlay were very much alike; the same applied for the two sensors located on top of the insulation material. The hypothesis that the temperatures in the attic space and above the insulation were the same in the groups was tested statistically by t-tests and test of correlation.

Figure 1. Principle sketch of a cold ventilated attic with sensor location (grey stars). Blue arrows indicate ventilation; red line indicates position of possible vapor barrier.

Ventilation rates in the attic were measured in seven of the case buildings by two passive tracer gasses (Heiselberg and Bergsøe, 1992) placed in attics and living spaces, respectively.

## RESULTS

Data collected from the mounted loggers in the case buildings are presented in Figure 2 and Figure 3. In each group the case building has its own color so the legend in Figure 2 represents both figures. To avoid fluctuating data, moving average for a period of one week, is used for evaluating data.

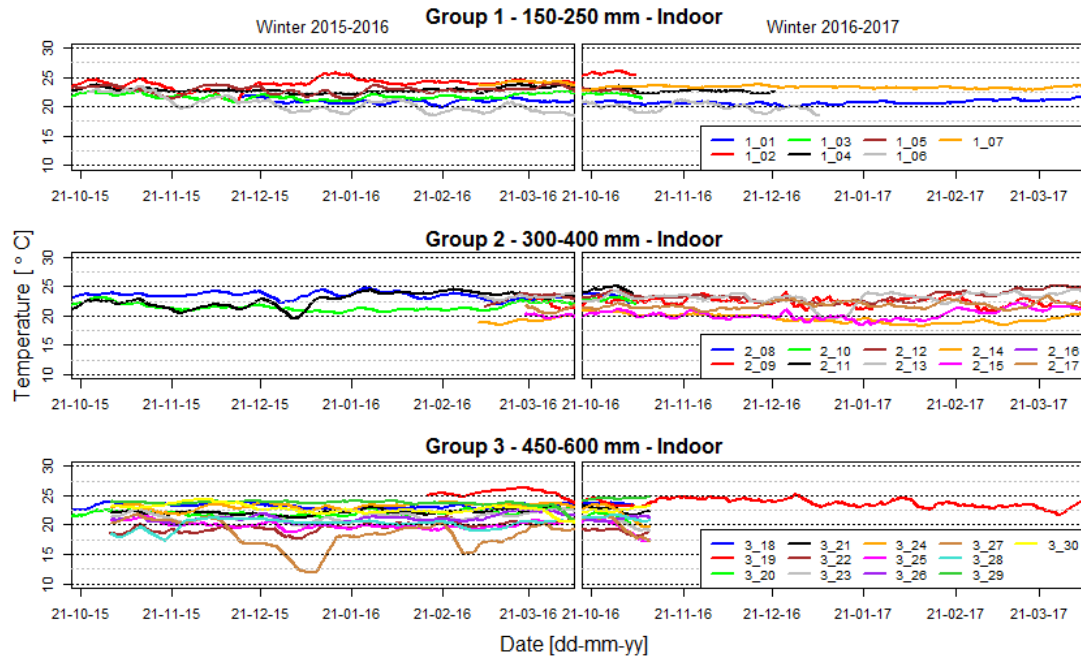

Figure 2. Measured indoor climate in every case building for the two winter periods 2015/16 and 2016/17 (November to March, both included) for the three different groups

Figure 3. Measured attic temperature in every case building for the two winters 2015/16 and 2016/17 for the three different groups, see Figure 2 for legend

Figure 2 and Figure 3 illustrate the measured indoor temperature central in the house, and the average temperatures for the sensors located in the attic space, respectively. In the figures, the measured summer conditions are omitted, as the temperature difference between the indoor climate and the attic space are most significant during the winter period.

Table 1 shows the mean and standard deviation for the measured temperature in the three different groups for both winter periods (from 1 November to 31 March) in the attic and above the insulation. For comparison, the indoor and outdoor temperatures are shown as well.

Table 1. Mean and standard deviation for the measured temperature in the three different groups for both winter periods (from 1 November to 31 March). The numbers in brackets denotes the number of case buildings.

		Group 1 150-250 mm	Group 2 300-400 mm	Group 3 450-600 mm
Winter 2015/2016	Outdoor [°C]	4.9 ± 1.2 (14)		
	Indoor [°C]	22.1 ± 1.4 (6)	22.3 ± 1.5 (3)	21.5 ± 1.9 (12)
	Above insulation [°C]	4.9 ± 0.5 (6)	5.3 ± 0.7 (3)	5.3 ± 0.4 (12)
	Attic space [°C]	4.6 ± 0.4 (6)	4.2 ± 0.5 (3)	4.7 ± 0.4 (12)
Winter 2016/2017	Outdoor [°C]	4.5 ± 1.2 (10)		
	Indoor [°C]	21.8 ± 1.7 (2)	21.4 ± 1.7 (7)	23.6 (1)
	Above insulation [°C]	4.7 ± 1.2 (2)	5.1 ± 0.6 (7)	5.3 (1)
	Attic space [°C]	4.2 ± 0.6 (2)	4.5 ± 0.7 (7)	4.8 (1)

The ventilation openings were visually inspected; most of the case buildings had the recommended size of ventilation openings of 1/500 of the floor area (Brandt, et al., 2013). Only in one case the ventilation was insufficient. In that case, there was visible mold growth in the attic. Measurements of the ventilation rate in seven houses showed ventilation rates between 1.9 h<sup>-1</sup> and 24 h<sup>-1</sup>. The ventilation rate was not measured in the attic with visible mold growth.

## DISCUSSIONS

The measurements did not support the hypothesis that the attic temperature decreases with higher thickness of insulation. The tendency seems to be the opposite; in the winter 2016/2017 the attic temperature generally increased with higher amounts of insulation material. However, the measurements in Group 3 are only from one case and the indoor temperature was 1.8 °C higher in this building compared with the two Group 1 cases, so this might explain a 0.5 °C higher temperature. Nevertheless, the temperature rise in Group 2 of 0.3 °C compared with Group 1 cannot be explained by a higher indoor temperature as the average indoor temperature in Group 2 was 0.4 °C lower. In the winter 2015/2016, the temperature in the attic space in Group 3 was 0.1 °C higher than in Group 1 although the indoor temperature was 0.6 °C lower.

A series of t-tests shows no significant differences for the mean temperature between the different groups and as shown in Table 2, the temperature in the attics and above insulation were highly correlated within the group and each other. Furthermore, temperature differences of this magnitude in the attic are within the measurement uncertainties. Consequently, the temperatures in the attic space do not differ in the three groups and there is therefore no dependency on the insulation thickness. This corresponds to measured data from a laboratory test building with a controlled indoor climate (Hansen & Moeller, 2016).

Table 2. Correlation coefficients between temperature curves for different sensor positions. Green area indicates significant correlation.

		Out-door	Indoor climate			Above insulation			Attic		
			G1	G2	G3	G1	G2	G3	G1	G2	G3
Indoor	G1	0.59	1.00								
	G2	0.30	0.44	1.00							
	G3	0.06	-0.33	-0.52	1.00						
Above insulation	G1	0.98	0.64	0.30	0.06	1.00					
	G2	0.98	0.61	0.34	0.04	0.99	1.00				
	G3	0.97	0.62	0.28	0.10	0.99	0.99	1.00			
Attic	G1	0.98	0.65	0.34	0.03	1.00	1.00	0.99	1.00		
	G2	0.97	0.59	0.27	0.12	0.99	0.99	0.99	0.99	1.00	
	G3	0.97	0.61	0.29	0.10	0.99	0.99	1.00	0.99	0.99	1.00

As expected, the temperature above the insulation is generally higher than the temperature in the attic space; the tendency was consistent throughout the two winters and the three groups. That the temperature in the attic space is the same as the outdoor temperature might be due to effective ventilation, but the surface temperature of the insulation should be lower in the case of reduced heat flux i.e. high insulation thickness. This was not the case; all temperatures above the insulation increased with increasing insulation thickness. In the winter 2015/2016 the temperature difference above the insulation was 0.4 °C higher in Group 3 than Group 1 despite a 0.6 °C lower indoor temperature in Group 3. There might be a simple technical explanation as to why the temperatures in Groups 2 and 3 are higher than in Group 1; while the insulation material in Group 1 is in general relatively firm plates, the insulation material in Groups 2 and 3 is more often a granulate. Consequently, the data loggers are more likely to sink a little into the insulation material in Groups 2 and 3 and therefore measure in an area where the temperature is higher. However, this cannot explain why the temperature above the insulation is higher in Group 3 than in Group 2.

Although some of the temperature differences cannot be explained, they are all small compared with the measurement uncertainties and the tendencies are not significant, therefore, the temperature above the insulation should be regarded as independent of the insulation thickness. This does not support simulations made by others. The reason for this discrepancy might be computational difficulties in the simulation of convection or because the ventilation rate in attics fluctuates, depending on wind speed and direction.

Some practitioners claim to have observed an increased number of attics with mold growth. This study shows that the assumption that a temperature decrease because of higher amounts of insulation in the ceiling is responsible for this is not correct. There must be other explanations. One could be that additional insulation in existing attics obstructs some of the ventilation openings and consequently less moisture is removed by ventilation. In some cases, ventilation openings have consciously been closed because of the wrong assumption that ventilation can be omitted in attics if the roof underlay is open for diffusion.

Knowing the appropriate ventilation rate would therefore be helpful. However, the rate varied considerably and no visual mold growth was detected in any of the attics where the ventilation rate was measured. The needed ventilation rate may also change with the season. Therefore, more studies of sufficient ventilation rates are needed. To test the influence of ventilation rates, WUFI (WUFI, 2018) was used for a series of preliminary simulations with insulation thickness of 150, 350, and 600 mm, simulated with two different ventilation rates:

2 and 15 h<sup>-1</sup>. These showed that the temperature in the attic was influenced by neither the ventilation rate nor the insulation thickness. This supports that higher relative humidity in some attics are not caused by lower temperature. Contrary to the measurements, the simulations of temperature in the top of the insulation layer was influenced by the insulation thickness, winter average was 1 °C higher with 150 mm of insulation compared to 600 mm insulation, regardless of the ventilation rate. This illustrates how difficult it is to measure at intersections between materials when sensors have a size of approx. 2 cm.

## CONCLUSIONS

Contrary to our expectations, the measurements showed that the temperature in ventilated attic spaces or just above the insulation material did not depend on the thickness of the insulation material. The assumption that additional insulation in ceilings reduced the temperature, therefore raises the relative humidity, and consequently is responsible for increased mold growth in attics, cannot be corroborated. However, additional insulation may have an influence on the relative humidity anyway e.g. because ventilation openings may be blocked by the additional insulation resulting in insufficient ventilation rates. The consequence of these findings is that if there is no mold problem in an attic, it is possible to increase the insulation limitless if the ventilation is not altered. Measurements of ventilation rates in attics with and without mold growth might bring further insight to why mold growth in attics seems to be an increasing problem.

### **ABSTRACT**

Vacuum insulation panels (VIPs) are high-performance insulating materials constructed by covering a core and adsorbent with an envelope and evacuating the air from the inside. VIPs have used to enhance the energy efficiency of devices including refrigerators, vending machines, and cooler boxes. In order to apply VIPs as heat-insulation materials in buildings and houses, it is necessary to predict the long-term performance of the VIPs and verify the accuracy of the prediction using actual measurements. VIPs using glass fiber as a core material are spreading in Japan, and VIPs using glass fiber core material as the core is also likely to be the mainstream in building applications. Therefore, in this paper, we report the comparison of the measurement results of the long-term performance in the building environment of VIPs using glass fiber and the calculation result. We also describe the calculation method of long-term performance prediction.

### **KEYWORDS**

Vacuum insulation, Thermal conductivity, Long-term performance,

### **1. Introduction**

Vacuum insulation panels (VIPs) are high-performance insulating materials constructed by covering a core and adsorbent with an envelope and evacuating the air from the inside. The VIP core is composed of glass fiber core or fumed silica core and covered by a laminated film. Upon evacuating the air from the VIPs, the gas thermal conductivity can be reduced to near zero, resulting in good thermal performance. Because it has high insulation performance, it is expected to be able to reduce wall thickness and enhance energy-saving when used for building applications. However, in many studies, long-term performance of VIPs under a constant environment had been discussed, but the long-term performance of VIPs itself in the building environment was not measured. Since there is no actual measurement data, accuracy of long-term performance prediction in the building environment cannot be confirmed. In addition, most of these studies are fumed silica core, and there are few studies on glass fiber core [1-6]. In order to solve this problem, we have been started to measure the thermal conductivity of VIPs that installed under the raised floor of a building. Glass fiber was used as the core material. VIPs was taken out from under the raised floor once every three months and measured the thermal conductivity by heat flow meter method. Furthermore, we measured the temperature and humidity of the front and back of VIPs, and examined the influence of environmental condition on long-term performance of VIPs.

### **2. Aging model<sup>[7-10]</sup>**

The parallel model is widely used to predict thermal conductivity. Heat transfer in the core material can be expressed as the conduction through solid and through gas in case of its presence and radiation:

$$\lambda_{cop} = \lambda_s + \lambda_g + \lambda_r, \quad (1)$$

Where  $\lambda_{cop}$  is the thermal conductivity of the center of panel,  $\lambda_s$  is the thermal conductivity of the solid skeleton,  $\lambda_r$  is the radiative thermal conductivity, and  $\lambda_g$  is the thermal conductivity of the gas within the pores. The units for all variables are provided in the Symbols section at the end of the paper. The thermal conductivities of the solid and gaseous components of the VIP are affected by the internal pressure and adsorption of water vapor on the core material.

### 2.1. Thermal conductivity of the VIP with desiccant

The thermal conductivity of the VIP containing desiccant can be expressed as,

$$\lambda_{cop} = \lambda_{sr,ini} + \lambda_{g(P_a,T)} = \lambda_{sr,ini} + \lambda_{ga}. \quad (2)$$

### 2.2. Permeability of dry air

Based on the mass-balance equation for air permeation into the VIPs and the state equation of an ideal gas ( $P_i V_{eff} = m_i / M_i R T$ ), the change in internal pressure resulting from the permeation of dry air can be expressed b

$$\frac{dm_a}{dt} = \frac{M_a \cdot V_{eff}}{R \cdot T} \cdot \frac{dP_a}{dt} = K_{a,total} \cdot (P_{a,atm} - P_a) \quad (3)$$

$$P_a = P_{a,atm} - (P_{a,atm} - P_{a(0)}) \exp\left(-\frac{K_{a,total} R T}{M_a V_{eff}} t\right) \quad (4)$$

### 2.3. Relation of dry air pressure and thermal conductivity

Since the thermal conductivity of the VIPs relate to the internal pressure of VIPs, it can be expressed as follows using the Eq.(2) and (4).

$$\lambda_{cop} = \lambda_{sr,ini} + \lambda_g = \lambda_{sr,ini} + \frac{\lambda_{ga,0}}{1 + \frac{P_{1/2}}{P_a}} \quad (5)$$

$$\lambda_{cop} = \lambda_{sr,ini} + \frac{\lambda_{ga,0}}{1 + \frac{P_{1/2}}{P_{a0} + P'_{a,t} \cdot t}} \quad (6)$$

### 2.4. Thermal conductivity owing to difference in dimensions (metallized film)

Unlike the aluminum foil VIPs, considering the transmittance from the surface, the transmittance of the metallized VIPs is expressed as

$$K_{a,total} = K_{a,A} \cdot A + K_{a,L} \cdot L \quad (7)$$

From the time rate of the internal pressure, the relation of time rate of thermal conductivity can be obtained. Based on the measured value at a certain dimension, for a surface area  $A_{ref}$  and perimeter length  $L_{ref}$ , the change in internal pressure is expressed as

$$\frac{dP_{Aref,Lref}}{dt} \cong (P_{a,atm} - P_{a(0)}) \frac{K_{a,total(ref)} R T}{M_a V_{eff(ref)}} \quad (8)$$

$$\begin{aligned} \frac{dP_{A,L}}{dt} &\cong (P_{a,atm} - P_{a(0)}) \frac{K_{a,total} \cdot L_{ref} R T}{M_a V_{eff(ref)}} \\ &\cdot \frac{V_{eff(ref)}}{V_{eff}} \cdot \frac{K_{a,total}}{K_{a,total}(A_{ref}, L_{ref})} \end{aligned}$$

$$= \frac{dP_{A_{ref},L_{ref}}}{dt} \cdot \frac{V_{eff}(ref)}{V_{eff}} \cdot \frac{K_{a,total}}{K_{a,total}(A_{ref},L_{ref})} \quad (9)$$

$$= \frac{dP_{A_{ref},L_{ref}}}{dt} \cdot \frac{V_{eff}(ref)}{V_{eff}} \cdot \frac{K_{a,total}}{K_{a,total}(A_{ref},L_{ref})} \quad (10)$$

### 2.5. Estimation of transmittance under different conditions (Arrhenius plot)

Supposing that the temperature and pressure of the environmental conditions to be found are  $T_{ex}, P(T_{ex})$ , from Eq. (8), the gas permeability  $K_{a,total}$  of dry air is as follows:

$$K_{a,total} = \frac{1}{(P_{a,atm} - p(0))} \cdot \frac{M_a V_{eff}}{RT_{ex}} \cdot \frac{dP(T_{ex})}{dt} \quad (11)$$

When calculating the time rate of internal pressure from the measurement result of the thermal conductivity, it is necessary to convert by the average temperature at the time of measuring the thermal conductivity and the pressure ( $\lambda_c, P(T_c)$ ).

$$P(T_{ex}) = \frac{P(T_c)}{T_c} T_{ex} \quad (12)$$

Substitute this equation into Eq.(11),

$$K_{a,total} = \frac{1}{(P_{a,atm} - p(0))} \cdot \frac{M_a V_{eff}}{RT_c} \cdot \frac{dP_a(T_c)}{dt} \quad (13)$$

## 3. Long term performance

In order to confirm the gas permeability ( $K_{air\_total}$ ) of the dependence of temperature and humidity, we carried out the aging test with thermostatic chamber. The Arrhenius plot was obtained based on Eq. (13). The details of the experimental VIPs are shown in Table 1. The Arrhenius plot does not consider the gas absorbed by the getter material.

### 3.1. Long-term performance in a thermostatic chamber

The VIPs was removed from the thermostatic chamber and cured at room temperature. The thermal conductivity was then measured using a heat flow meter (HC074 600, EKO instruments), and the results are shown in Fig. 3. The results of Arrhenius plot obtained from Eq.13 and experimental results are shown in Fig.4. The Arrhenius plot confirmed the temperature dependence of the VIPs air permeability under the tested aging conditions (23°C 50% RH and 50°C). The comparison of the aging conditions of 50°C and 50°C with 70% RH confirmed that the gas permeability increased by approximately 6% shown in table2. The transmittance of dry air increased with relative humidity, which may be influenced by the material of the film. The metallized film is provided with a vapor deposited layer based on Ethylene vinyl alcohol (EVOH), probably because the barrier property of the EVOH layer decreased under high temperature and high humidity. When estimating the transmittance using Arrhenius plot, it is also necessary to consider film properties of EVOH.

### 3.2. Long-term performance in a building condition

The VIPs were constructed on the concrete slab under the raised floor of a new building, the details of VIPs are shown in Table3. The VIPs were removed from under the floor every three months, and thermal conductivities were measured before reinstallation (Fig.5). The construction period and measurement period are shown in Table4. Thermo-hygrometers were installed on the front and back of each VIP to measure the temperature and humidity (Fig.7 and 8). Half of the VIPs installed in Room 2 (VIP01) was placed in the reverse of the front and back, and the effect of the orientation of the MF surface on the long-term VIPs performance was evaluated. First of all, we obtained the total gas permeability ( $K_{air\_total}$ ) based on the values of internal pressure which is calculated from measurement value of thermal conductivity. Secondly, Table5 shows a comparison of the internal pressure obtained from the time rate of thermal conductivity " $\Delta P_m$ " and the time rate of temperature data " $\Delta P_{cal}$ ".  $\Delta P_{cal}$  was obtained total gas transmittance on site conditions which is calculated from Arrhenius plot and average temperature every 2 hours. As the result of calculating the among  $\Delta P_{cal}$  obtained using the temperatures on the upper and lower surfaces of the VIPs in the room2, the error from the measured value was smaller in the result calculated by referring to the temperature on the metallized film's side than the aluminum foil's side. This is attributed to the higher temperature dependence of the transmittance of dry air on the metallized film compared to that on the aluminum foil. However, the error of this result should also consider that the exposure environment during the measurement period is ambiguous. In order to prevent errors, for example, it can be solved if pressure of inside the VIPs can be directly measured at the real building environment.

Table3. Characteristics of VIPs used in the test of building condition

#### 4. Summary

We constructed a VIPs under the raised floor of the building and periodically measured the thermal conductivity and the weight increase and the environmental conditions. We compared

the time change of internal pressure which was calculated by the relationship of thermal conductivity and internal pressure (Eq.6) using measurement result of thermal conductivity with calculated data which was obtained by temperature of environmental condition and Arrhenius plot (Eq.13). The results were roughly in agreement with the calculation results, but the prediction result of about 10% error as a whole at 227days increased further by 10% or more at 381 days (Fig.6). We consider the following three reasons why errors occurred.

- (1) It is necessary to separate the gas permeation of surface and edge.
- (2) Since the actual measurement range of Arrhenius plot is 23°C to 50°C, it is necessary to confirm the accuracy at 23 ° C. or less.
- (3) The influence of humidity in the actual measurement environment is expected to be low from the Arrhenius plot, but in order to make more accurate prediction it is necessary to consider the influence of humidity.

## 5. Future work

We will continue to measure and continue to verify whether long-term performance can be predicted from the measurement of environmental conditions. Meanwhile, we plan to develop a method that can be measured while it is being constructed on site. Specifically, we will consider improving the accuracy of prediction of durability by comparing it with the result of thermal conductivity measurement using VIPs equipped with micro pressure sensor. We will discuss the relation between external environment and internal pressure. And we will also study the influence of getter material, folded edges on gas permeability calculation, time rate of transmittance due to material deterioration, and another size of VIPs.

## Super insulation material in district heating pipes

### ABSTRACT

In Swedish district heating systems, 10% of the produced energy is lost at the distribution network. It is of interest to lower the energy losses both for economic and environmental reasons. Since 2011 the feasibility of using superinsulation material for insulation of the district heating pipes were studied. Apparent thermal conductivity and long term performance of vacuum panels has been identified as the crucial challenge for using vacuum insulation panels. The estimated life time of a vacuum panel in building applications at 90 °C is about 50 years. The life time estimation is based on the climate condition valid for building application. However, peak temperature in a district heating system can be about 140°C.

Hybrid insulated pipes with a Vacuum Insulated Panel (VIP) have been tested and evaluated by laboratory and field measurements. The results of numerical analyses of the measured data indicate a possible small degradation of the VIP at a similar rate as building application, even though the operative temperature is between 80-100 °C. In the laboratory a hybrid insulated pipe has withstood exposure to one sided heating at 115°C for over 5 years. The results indicate that hybrid insulated district heating pipes reduce heat losses by 20-30% for a twin pipe and with more than 50% in a single pipe. It can be concluded that VIP shows promising performance in district heating pipe applications.

### KEYWORDS

Vacuum insulation panels, district heating pipe, heat losses, long-term performance

### INTRODUCTION

More than 5000 district heating system are in operation within the European Union. Transferring heat and cold efficiently in urban areas is the main goal of district heating. Sweden is one of countries where more than 50% of heat demand of the building stock is covered by district heating systems. At present there are approximately 24,000 km of district heating network (DHN) in Sweden. The heat losses in DHN is 5-6 TWh (Swedish Energy Agency, 2017). There are a number of measures for reduction of heat losses e.g. a) using twin pipes instead of two single pipes, where the supply/carrier pipe and the return pipe are placed within the same insulation pipe, b) reduction of temperature level in DHN i.e. low temperature system, c) enhancing thermal properties of insulation material of the pipes.

In Nordic countries, the twin pipe concept has been used since the 1990's and utilization of low temperature district heating systems are under investigation in Sweden. However, the low temperature system was used in Denmark. Enhancing the insulation material in a DHN has been studied since the introduction of district heating systems and different types of insulations material, e.g. glass wool, mineral wool, stone wool and polyurethane (PUR), were used.

PUR is most common insulation material in new district heating pipe generation. The thermal conductivity of PUR is about 26 mW/mK at 50 °C. Research and development concerning

improving PUR insulation is ongoing. However, it is very difficult to achieve major improvements. An alternative is to replace a part of PUR insulation with Super Insulation Materials (SIM) which have 2-4 time lower thermal conductivity than PUR. Combining PUR and SIM, hybrid insulation, is the most technically feasible solution for development of high thermal performance district heating pipes.

Research related to hybrid insulation of the pipes, initiated in 2011 at Chalmers University of technology, department of Architecture and Civil engineering where a layer of SIM was added close to supply pipe. Two type of superinsulation material, aerogel blanket and vacuum insulated panels (VIP) were investigated as alternatives for hybrid insulation, see Figure 1.

Figure 1. Hybrid insulation district heating (single/twin) pipe with VIP (left). In a VIP, the core material is enveloped by a diffusion barrier (right)

Samples and prototypes of hybrid insulation pipe were produced for investigating compatibility of SIM with polyurethane and investigating mechanical and thermal performance of the final product. Both types of selected SIM fulfilled the essential function described in (EN253, 2009). However, thermal performance of VIP was higher than aerogel blanket thus VIP was selected for further investigation.

Apparent thermal conductivity of VIP in a cylindrical geometry and expected lifetime of a VIP at a high temperature district heating network are of special interest for using VIP in district heating pipes. According to VIP manufacturer the maximum operative temperature of an ordinary VIP is about 80-90 °C which is lower than the peak temperature in a high temperature district heating system.

The aim of this paper is to present how the apparent thermal conductivity of a VIP can be determined and also present the results of analyses related to lifetime estimation of VIPs by measurement at laboratory and in operational environments.

### APPARENT THERMAL CONDUCTIVITY

District heating pipes, single and twin pipe, vary in diameter thus the estimation of thermal performance of a hybrid insulated pipe with VIP needs determination of the apparent thermal conductivity of VIP for each pipe size. The thermal conductivity in the center of a VIP is declared to be between 3-5 mW/mK. To obtain the vacuum in a VIP, the core material is enveloped by an air and moisture diffusion barrier, see Figure 1, which is commonly a metalized polymer laminate or an aluminum laminate with a thermal conductivity 50-250 times higher than the center of VIP. The different thermal conductivities of the materials lead to thermal bridging effects at the edges of the panels. The linear thermal transmittance values for the edges of a plane panel can be calculated by procedures described in (ISO-102011, 2007). The influence of thermal bridges varies with the geometry of the panel, the core material and the type of diffusion barrier. The liner thermal transmittance of a number of different geometries for a plane VIP were calculated in (Sprengard & Holm, 2014). However, the VIP in district heating pipes are cylindrical with a special formation on one surface, see Figure 3a. The non-

regular boundary between VIP and the pipe makes numerical calculation related to influence of thermal bridges on the overall thermal conductivity very difficult and uncertain. Thus, apparent thermal conductivity of VIP has been calculated in combination with measurements using the guarded hot pipe method (EN253, 2009).

The results of thermal and mechanical (fulfilling shear stress capacity caused by thermal expansions of different layers of the pipe) measurement indicates that a 10 mm thick VIP is the most reasonable thickness for a district heating pipe. Thus, the apparent thermal conductivity was determined for 10 mm thick VIP. Furthermore, manufacturing parameters related to production of a district heating pipes restrains the length of the VIP to 1 meter. The width of the panel is equal to the circumference of the supply pipe. The mounting of VIP around a supply pipe can be done in two ways 'edge to edge' or with overlapping, see Figure 3b.

Five measurements were performed for determination of steady state heat flow by the guarded hot pipe method. The first measurement, reference measurement, was performed in order to determine thermal properties of the pipe insulated by pure PUR. Two measurements were performed on hybrid insulated pipe for each mounting procedure. The pipes in the measurements were single pipe DN80/180 (supply pipe diameter/casing pipe diameter). The VIP insulation surrounding the supply pipe, see figure 1. The temperature of the supply pipe was about 80 °C and the temperature of casing pipe was about 22 °C.

Figure 2. a) Surface of a cylindrical VIP b) overlap mounting of VIP

The apparent thermal conductivity of the VIP can be calculated by using the measured heat flow and equation 1.

$$q = \frac{\Delta T}{\sum_{i=1}^N \frac{\ln(\frac{r_{i+1}}{r_i})}{2\pi \cdot \lambda_i}} \quad (1)$$

Where  $q$  (W/m) is heat flow,  $\Delta T$  (°C) is the temperature difference cross insulation material,  $r$  (m) is the radius of each layer and  $\lambda$  (W/mK) is thermal conductivity of each layer.

The calculated apparent thermal conductivity of a 10 mm thick VIP with a length of 1 m and a width of 0.28 m (edge-to-edge) is presented in Table 1.

Table 1: Measured heat flow and calculated thermal conductivity for the pipes and apparent thermal conductivity of VIP for two different mounting procedures.

Sample	$q$ [W/m]	$\lambda_{50}^{Pipe}$ [mW/m.K]	$\lambda_{90}^{vip/Apparant}$ [W/m.K]
Reference	14.7	28	-
Edge-to-Edge	10.8	19	12
Overlap	9,2	17	9

The results presented in Table 1 indicate that the thermal performance of the hybrid insulated pipe is 30-60% better than the reference pipe. However, it should be mentioned that the thermal conductivity of PUR insulation in this test is higher than ordinary PUR insulation. One reason is that the PUR in these measurements are handmade. In further investigations overlapping the edges of the VIP will be used. Furthermore, apparent thermal property of VIP was about 9 mW/mK which will be used for calculation of thermal performance of single and twin pipes.

### LIFETIME ESTIMATION OF VIP

The hybrid insulation of the pipes was based on replacing 10-20 mm of PUR by VIP. As long as the VIP is not penetrated the thermal performance of the hybrid pipe will be better than a pipe insulated by pure PUR. If the VIP is penetrated for any reason, aging or damaged during production, then thermal conductivity of VIP will be around 21 mW/mK which is still better than thermal conductivity of PUR. Thus, the pipe will still fulfil its thermal performance.

According to manufacturer of VIP the maximum operating temperature of a VIP is around 80-90 °C. However, the declared values are based on laboratory measurements when all sides of a VIP is exposed to uniform temperature level. In a pipe the temperature will not be evenly distributed throughout the cross section of the insulation, but will rather form a gradient. Thus, laboratory and field tests concerning lifetime estimation of a hybrid insulated pipe and related temperature levels were initiated in 2012.

### Laboratory test

The laboratory test was initiated at the end of 2012 and it is still ongoing. The tests were designed for mean temperature of 90°C over cross section of VIP in a hybrid insulated pipes (80/180) i.e. a supply pipe temperature of 115 °C and backside temperature of VIP 65°C. A hypothesis is that the sealing of the VIP envelope is the weak point of the diffusion barrier. Thus, the joints (sealing in a VIP) were folded around the edge making the distance to the service pipe as long as possible. Temperature gauges were installed inside the pipe, on backside of the VIP (center part) and on the service pipe, and on the casing pipe.

Using measured data and equation 2 make it possible to find a relation between thermal conductivity of PUR and thermal conductivity of VIP. Assuming that the ageing of PUR is negligible, it is possible to indicate the changes in thermal conductivity of the VIP.

$$\frac{\lambda_{PUR}}{\lambda_{VIP}} = \frac{\Delta T_{VIP}}{\Delta T_{PUR}} \cdot \frac{\ln(\Delta r_{PUR}/r_{0,PUR} + 1)}{\ln(\Delta r_{VIP}/r_{0,VIP} + 1)} \quad (2)$$

Where  $\Delta T_{VIP}$  and  $\Delta T_{PUR}$  are temperature gradients over the cross section of VIP and PUR,  $\Delta r_{VIP}$  and  $\Delta r_{PUR}$  are thickness of VIP and PUR respectively.  $r_{0,VIP}$  and  $r_{0,PUR}$  are internal radius of VIP and PUR in a cylindrical coordinate system.

The supply pipe temperature was controlled to be  $115 \pm 3$  °C. The ambient temperature in laboratory varied between 21 and 27 °C. The measured results of five last years (2013-2015) were analyzed in order to determine a time dependent degradation coefficient for thermal conductivity of VIP. The results of the analyses are presented in figure 3. A decrease of the ratio indicates that the thermal conductivity of VIP increases.

The ratio is decreased during the first 13 weeks and between weeks 13-78 the ratio is stable around a mean value of 3.95. This means that the VIP has a thermal conductivity which is about 4 times better than PUR. The mean temperature of PUR is about 40°C, thermal conductivity of

PUR at 40 °C is about 27 mW/mK thus the center of VIP has a thermal conductivity of about 7 mW/mK in this setup.

A failure in the devices which maintain the supply pipe temperature lead to losing data for a number of weeks, see figure 3. The failure has no influence on the pipes and thermocouples. The measurements started again at week 86. The mean value of the ratio between week 86 to 260 is 4.25 i.e. 7% higher than the ratio before failure. There is no reasonable explanation for the increasing ratio before and after failure.

Figure 3. Variation of the ratio of thermal conductivity PUR and VIP in time.

There is a slight increase of the ratio observed between weeks 112 to 260, see figure 3. It is expected that both VIP and PUR will be degrade. It is difficult to determine the level of the degradation in each material. However, the results indicate a faster degradation of PUR than VIP.

### Field measurement

Performance of the hybrid insulated pipes should be investigated in an operational environment. In field measurements the boundary condition of the pipes are quite different compared to laboratory tests i.e. the pipes lay about 1 meter below ground surface and they can be exposed to ground water flow. Furthermore, the pipes in the field station are generally twin pipes. The boundary conditions and the type of the pipes increases the complexity of analysing thermal performance of the hybrid insulated pipes.

Since 2013 five field stations were initiated in Sweden. The total length of pipe in each station is 6 meter. The pipe was divided in two parts, hybrid insulated pipe (3m) and reference pipe insulated by pure PUR (3m). The thickness and length of VIP were 10 mm and 1 meter. The VIP insulation enclosed the supply pipe. The size of the twin pipe was matched to size of the pipe in DHN. A number of thermocouples were imbedded in both parts of the pipe and on the casing pipe. The thermocouples in the reference pipe were placed in positions that they can be compared to the hybrid insulated pipe i.e. thermocouples S-VIP and S-PUR, see figure 4.

The temperature of the supply pipe follows the temperature level of DHN in the area. The results obtained from field measurement were used for validation of a numerical model. The numerical model and the results based on measurements during 2013-2016 were presented in (Berge,

Hagentoft, & Adl-Zarrabi, 2016) and (Berge A. & Adl-Zarrabi, 2014). The results of the numerical analyses showed that a total reduction in the energy loss between 20% and 30% compared to pipes of the same size with pure PUR insulation. Furthermore, the losses from the supply pipe decreased by up to 56%

Figure 4 Position of VIP (dashed lines) and thermocouples in the twin pipe. PU1, PU2, VIP1 and VIP 2 sections where thermocouple positions were mounted.

The simulations also show that a slower deterioration process could be hidden in the responses to other variations in the system (Berge et al., 2016). The measured results during 2017-2018 were analysed and the results supported the same conclusions as presented in 2016.

## CONCLUSIONS

The apparent thermal conductivity of a VIP in district heating pipes varies with dimension and type of the pipe. The apparent thermal conductivity of a 10 mm thick VIP at 50 °C used for insulation of a 40 mm supply pipe is about 9 mW/mK which can be used as a benchmark. Hybrid insulated district heating pipes reduce the heat losses by 20-30% for a twin pipe and by more than 50% in a single pipe. The results of field measurements show that hybrid insulated pipes using VIP fulfil their function after five years in an operational environment. Thus, hybrid insulated pipes by VIP have potential to improve long-term thermal performance of the district heating network.

## **Super insulation materials in the building sector: Field studies and future challenges**

Pär Johansson<sup>1,\*</sup> and Bijan Adl-Zarrabi<sup>1</sup>

<sup>1</sup>Chalmers University of Technology, Gothenburg, Sweden

*\*Corresponding e-mail: par.johansson@chalmers.se*

### **ABSTRACT**

The global rate of improvement in energy efficiency have to be increased to reach the UN sustainable development goals by 2030. Super insulation materials (SIM) can maintain the same thermal transmittance with a thinner insulation layer compared to conventional insulation materials. Recommendations and experiences from practical applications are needed to raise the knowledge and awareness of using SIM in buildings. Evidences related to real-condition performance need to be presented and independently assessed. The aim of this paper is to describe the state-of-the-art in the area of SIM in building applications based on monitoring data related to long-term performance of vacuum insulation panels (VIP). Both VIP and advanced porous materials (APM) have been successfully installed over the past 15 years in buildings. This paper presents a case study where the temperature and relative humidity of a wall were monitored for seven years. The results of the monitoring indicate that the VIP fulfil its function with no sign of degradation. By continuous product development, the performance of the SIM are improved for every generation which gives a promising outlook for the wider implementation of SIM in the building envelope.

### **KEYWORDS**

Super insulation material, aerogel, VIP, renovation, energy efficiency, building

### **INTRODUCTION**

There is presently a focus in the European Union to decrease the carbon dioxide emissions from the built environment. On the global arena, the UN sustainable development goals put focus on integrating climate change measures. By 2030 the global rate of improvement in energy efficiency should be doubled. This requires new and more energy efficient materials to be developed and evaluated. Conventional insulation materials require a certain thickness to reach a sufficient thermal transmittance. Super insulation materials (SIM) can maintain the same thermal transmittance with a thinner insulation layer. Products are available on the market which offer down to one tenth of the thickness required for conventional insulation materials. This is especially interesting in retrofit applications and in areas with limited land accessibility.

In many of the field studies reported in the literature only the thermal performance of the assembly was investigated (Johansson, 2012). However, also other parameters, such as the moisture performance, is important to consider. Recommendations and experiences from practical applications are needed to raise the knowledge and awareness of using SIM in buildings. Evidence related to real-condition performance needs to be presented and independently assessed. Full scale experiments provide knowledge of practical and technical difficulties as well as data for service life estimation. For certain conclusions to be drawn from case studies, long-term monitoring is needed. Unfortunately, monitoring is only performed in few case studies reported in the literature.

One of the International Energy Agency's (IEA) Energy in Buildings and Communities (EBC) Programme's objective is to enable research and development programmes (Annex) on the building envelope among its 24 member countries. During 2014 the Annex 65 'Long Term Performance of Super-Insulating Materials in Building Components and Systems' was initiated. The work was divided in 4 tasks where task 3 concerned field scale performance of SIMs. The focus of the work was to define the application areas of SIMs and to describe the conditions of the intended use of the products having building retrofit in mind (Adl-Zarrabi & Johansson, 2018).

The aim of this paper is to build on the conclusions of the Annex based on monitoring data related to real-life performance of VIP in buildings. By presenting the state-of-the-art in SIM applications in buildings and a case study with 7 years of monitoring data of a VIP wall installation, future research directions and recommendations for further actions are presented in the area of SIM in building applications.

### SUPER INSULATION MATERIALS

Conventional insulation materials use entrapped air as insulator inside a porous matter. Examples of these are mineral wool, expanded polystyrene and polyurethane. By using different additives, the thermal conductivity can be reduced by targeting the three main heat transfer mechanisms presented in Figure 1 (Berge & Johansson, 2012).

Figure 1. Thermal conductivity in porous materials divided into the three main heat transfer mechanisms (adapted from (Simmler et al., 2005)).

The total thermal conduction can be reduced down to a minimum around 30 mW/(m·K), which can be compared to stagnant air which has 25 mW/(m·K). Therefore, in this paper SIMs are defined as materials having a thermal conductivity lower than stagnant air ( $\lambda = 25 \text{ mW/(m·K)}$ ). To reduce the thermal conductivity further, the heat transfer through the gas has to be reduced. This can be achieved by a) hindering the gas movements in the pores by reducing the pore size, b) removing the gas, or c) a combination of both a) and b) (Berge & Johansson, 2012).

In the context of Annex 65, SIM were divided in advanced porous materials (APM) and vacuum insulation panels (VIP). APM are materials where the heat transfer through the gas is hindered significantly by the fine pore structure. These can further be divided in two groups, porous silica, e.g. based on fumed silica, and aerogels. APM have been installed since the early 2000s in buildings (case studies) and assemblies. The products available on the market are more

similar to conventional insulation materials in most aspects. However, knowledge related to behavior of AMP are needed for performance prediction at the material, component and building scale. The aerogel based products, such as blankets, are in general vapor permeable and hydrophobic.

The second group of products is VIP. Here the contribution of heat transfer through the gas is suppressed by evacuation. These can be further divided in different core materials (fumed silica, glass fiber, polyurethane, expanded polystyrene and others), different envelopes (metalized film, aluminums laminate, stainless steel, glass, or combinations), and with or without a getter and/or a desiccant. Since VIP have less similarities to conventional insulation materials these products will be the focus of this paper.

Generally there are a number of challenges remaining when using VIP in buildings. The first challenge is the cost versus performance ratio. The thermal performance of VIP is practically 5 times better than conventional materials while the price is generally around 10 times higher. There are applications where the high performance and cost can be reasonable. The second challenge is the long-term performance of VIP. The service life of a building is 25-100 years while the VIP for building applications have been developed in the recent decades. The third challenge is that the construction market is a conservative market, regulated by numerous codes and standards, and thus, introducing new products takes a long time. The fourth challenge is knowledge and awareness among designers concerning using VIP. To provide answers to these challenges, field studies can provide insight on how the materials perform during normal use conditions (Adl-Zarrabi & Johansson, 2018).

During the years several research projects have focused on evaluating VIP in the field. The possibilities to use VIP in buildings was investigated during 2002-2005 by Binz et al. (2005). They studied in total 20 constructions with focus on the energy use, thermal bridges and moisture performance. In a study Heinemann and Kastner (2010) used infrared thermography to investigate the performance of the VIP after some years of use in the buildings. They concluded that as long as the VIP is not damaged at installation, about 95% of the VIP will maintain the vacuum several years. One of the most predominant building elements where VIP have been used is in flat roofs. At Empa in Switzerland researchers have monitored a roof construction containing VIP since 2004. Brunner and Ghazi Wakili (2014) measured the thermal conductivity of the VIP which had increased to 6.6-7.0 mW/(m·K) after 9 years. This is an increase of 65-75% from the initial thermal conductivity of 4 mW/(m·K). However, it is still well below the thermal conductivity of conventional insulation materials and the thermal conductivity of the core material at atmospheric conditions, 20 mW/(m·K).

## **CASE STUDIES USING VIP**

Full scale experiments provide knowledge of practical and technical difficulties as well as data for service life estimations. For certain conclusions to be drawn from existing case studies, long-term monitoring is essential. Unfortunately, monitoring is only performed in few case studies. In total 22 case studies using VIPs, spread over 10 countries on 3 continents, were collected within Annex 65. The design process, practical aspects and results were described for each of these case studies. Of the 22 case studies only 4 were monitored and of these 2 were laboratory setups and 2 were field test of an external wall. The installation of the VIPs is the critical process which calls for inspection of the VIPs at the construction site before installing them. Considering the large amount of installed VIPs in case studies reported in Annex 65 in different countries (Figure 2) it is a pity that not more cases have been followed up.

Figure 2. Installed VIP (m<sup>2</sup>) in case studies in Annex 65 (Adl-Zarrabi & Johansson, 2018).

In an ongoing study in Gothenburg, Sweden, a renovated building was monitored for 7 years with data presented for each year. The case study building was a listed building from 1930 which was insulated on the exterior with 20 mm VIPs. The calculated energy use for heating decreased by 24% (Johansson et al., 2014). Temperature and relative humidity sensors were installed in the test wall and in a neighboring (non-retrofitted) wall as reference, see Figure 3.

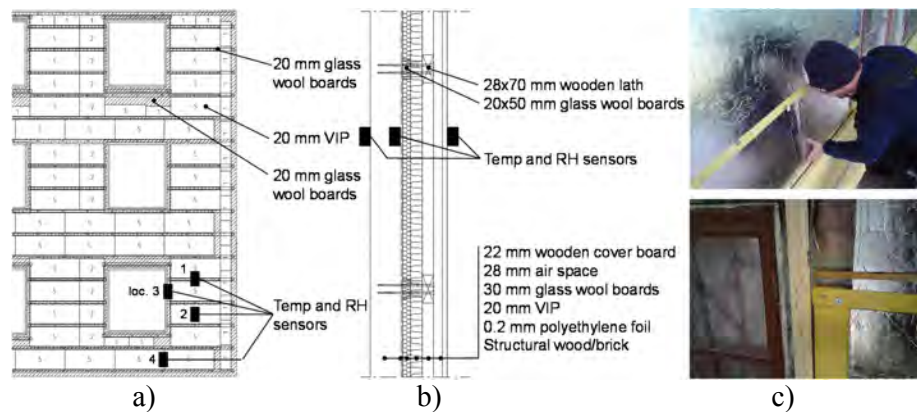

Figure 3. a) wall layout after retrofitting with 20 mm VIP and 30 mm glass wool boards, b) section of the wall layout with the location of the temperature and RH sensors in the wall marked by the black boxes (not in scale), c) installation of the VIP layer with the glass wool boards creating a thermal bridge between the VIP themselves and between the VIP and windows.

The hygrothermal performance was monitored by sensors integrated in the construction. The monitoring results for first 5 years were presented in (Johansson et al., 2016). The temperature and RH in the wall was recorded during 5 years, from January, 2011, to December, 2015. The measurements showed no sign of deterioration of the VIP and there was a low risk for condensation in the construction. It was concluded that the hygrothermal performance of the test wall was substantially better than that of the reference wall (Johansson et al., 2016).

The external air space made it impossible to identify the different panels by thermography. Only indirect methods, like evaluation of the measured temperatures in the wall, could be used to follow the long-term performance of the panels. For this analysis the average temperature for January each year 2011 to 2017 was used to calculate the temperature factor, see Figure 4. Unfortunately several sensors have been damaged why only one position can be evaluated for all 7 years.

Figure 4. The temperature factor of January 2011 to 2017 for the retrofitted and reference walls. The temperature factor is the percentage temperature decrease over the original wall compared to the total temperature drop over the wall. The error bars show an accuracy of the sensor of  $\pm 0.5^\circ\text{C}$  (adapted from (Johansson et al., 2016)).

In the reference wall about 64% of the temperature drop was over the uninsulated parts. After the retrofitting only about 17-18% of the temperature drop was over that part of the wall. The results indicate that after 7 years there was no sign of decreased insulation performance of the VIP. The results of this case study after 7 years are in good agreement with also the conclusion from several case studies that were collected in Annex 65 (Adl-Zarrabi & Johansson, 2018).

## CONCLUSIONS

During the work of the Annex 65 several questions regarding the long-term performance of VIP and their application on the building scale were identified and discussed. Based on the experiences in the case studies, it was possible to identify application areas and the conditions of the intended use of VIP. It is clear that special care is necessary during installation compared to conventional insulation materials, since the VIP are sensitive to mechanical puncturing of the envelope. Therefore, there may be a need for certification of craftsmen and need of special training.

The building industry is generally conservative to new solutions and materials. The industry is regulated by numerous codes and standards, and thus, introducing new material takes a long time. Results obtained by activities in Annex 65 can be used for convincing the building industry about the performance of SIMs.

The ongoing standardization on the material and product levels may trigger building components with VIP to be introduced on the market. There are valuable savings of space when less area is needed for the building elements which leads to an increased rental income. There can also be technical reasons to select a VIP, i.e. when conventional insulation materials are not a practical alternative or for architectural reasons.

The theoretical investigations and first practical tests showed that VIP, especially those with fumed silica core, are expected to fulfil the requirements on durability in building applications for more than 50 years. Both VIP and APM have been successfully installed over the past 15 years in buildings. However, real experience from practical applications exceeding 15 years for VIPs is still lacking.

The long-term performance (25-100 years) cannot be entirely determined due to lack of data for longer time period exceeding 15 years. However, as seen above and more thoroughly discussed in the report of Annex 65, there were few claims concerning the malfunction of SIM in construction. The products are in continuous development and the VIP that were installed several years ago are no longer available on the market. By continuous product development the performance of the products are improved for every generation which gives a promising outlook for the wider implementation of SIM in the building envelope.

## ACKNOWLEDGEMENTS

The work was financed by the Swedish Energy Agency project 40798-1 and 42856-1. The case studies and conclusions are results of the discussions throughout IEA EBC Annex 65. All the contributors and participants are acknowledged for their contributions.

### **ABSTRACT**

The effect of air pressure on moisture transfer inside porous building materials cannot be ignored in cases in which air cannot escape through the surfaces of the materials; in such cases, the air is compressed by the movement of the moisture. Therefore, in a situation in which most surfaces of a specimen are sealed or treated with surface-protecting materials (a situation that is often encountered in typical water-absorption tests), the experimental results may differ from those without sealed or treated surfaces. In the present study, the influence of air pressure on moisture transfer was investigated quantitatively.

First, the following water-absorption test was conducted. Water infiltrated into a brick through its top surface, whereas the side surfaces were sealed to prevent the transfer of moisture and air. The bottom surface was exposed to the ambient air. The water content was measured two-dimensionally during the experiment using gamma-ray attenuation. Next, to investigate how air pressure affects water infiltration, another experiment was conducted after sealing the bottom surface. The air inside the brick was expected to be compressed by the infiltrating water when the bottom surface was sealed. A water-absorption test was then performed after a small hole was made in a side surface of the bottom-sealed brick to reduce the interior air pressure. Finally, we analyzed the experiments numerically using a three-dimensional calculation model for simultaneous air and moisture transfer, assessing the validity of the model by comparing the calculated and measured water contents.

The experimental and numerical results show that water infiltration is slowed by higher air pressure inside the specimen when it is difficult for air to escape. It is also shown that the hole in the side surface helped limit the rise in air pressure to some extent.

### **KEYWORDS**

Air pressure, Water absorption, Numerical analysis, Gamma-ray attenuation

### **INTRODUCTION**

In water-absorption tests and measurements of water permeability, it is common to seal the side surfaces (and sometimes also the bottom surface) of the specimen to make the moisture transfer unidirectional. In addition, water-absorption tests are widely used to understand how the water-absorption rate and moisture properties are changed by surface treatments such as waterproofing and water-repellent coatings. However, because the sealed or treated surfaces may prevent the movement of not only moisture but also air, moisture infiltration may increase the air pressure in the material, thereby affecting the moisture movement.

Descamps (1997) used water-absorption tests and numerical analysis to study how air entrapment affects moisture infiltration, finding agreement between the measured and calculated sorption coefficient and inflow-surface water content. However, the moisture distribution inside the material and its temporal evolution are yet to be examined in detail. By

comparing the results of water-absorption tests on (i) a brick whose side surfaces were sealed and (ii) one whose bottom surface was also sealed, we found previously that the water absorption was clearly delayed in the latter case in which air could not escape from the brick other than through the top surface where water was absorbed (Fukui et al. 2018). In addition, we analyzed those experiments numerically using a one-dimensional model of simultaneous air and moisture transfer. However, the validity of that numerical model was not demonstrated satisfactorily because we did not consider multidirectional air flow and non-uniform distribution of air pressure in the specimen. Such effects arise from non-uniform material properties and from air bubbles appearing locally and escaping from the water-absorption surface into the water. We expect that drilling a small hole in one of the sealed surfaces would help prevent the increased air pressure from hindering moisture transfer. However, how such a hole affects the moisture transfer inside the material is also yet to be revealed quantitatively.

Therefore, in the present study, we conducted water-absorption tests on a brick to investigate how air pressure affects moisture transfer and how drilling a small hole reduces that effect. We also analyzed the experiments numerically using a three-dimensional calculation model for simultaneous air and moisture transfer, examining the accuracy of the numerical results by comparing them with the experimental ones.

## WATER-ABSORPTION TESTS

### Specimens and method

We conducted three experiments (see Fig. 1) on a rectangular brick of size 210 mm × 100 mm × 60 mm. In the first experiment, the side surfaces were sealed (case 1). The brick was then dried and the experiment was repeated but with the 210 mm × 100 mm bottom surface now also sealed (case 2). Finally, the brick was dried again and a 10-mm-deep hole was made in one of the 100 mm × 60 mm side surfaces of the brick with a 3-mm-diameter drill (case 3). During each experiment, water was absorbed through the top surface.

Figure 1. Schematic specimen cross sections for cases 1 (left), 2 (center), and 3 (right).

In the water-absorption tests, we used gamma-ray attenuation to measure the distribution of water content. Following Nielsen (1972), we determine the volumetric water content from the fraction of gamma rays absorbed as they pass through the brick:

$$\psi_w = -\frac{1}{\mu_{mw}\rho_w d} \ln\left(\frac{I_w}{I}\right), \quad (1)$$

where  $\psi_w$  is the volumetric water content [ $\text{m}^3/\text{m}^3$ ],  $d$  is the specimen thickness [m],  $I_w$  is the gamma-ray intensity after passing through the wet specimen [cps], and  $\mu_{mw}$  and  $\rho_w$  are the mass attenuation coefficient [ $\text{m}^2/\text{kg}$ ] and the density [ $\text{kg}/\text{m}^3$ ] of liquid water, respectively.  $I$  is the gamma-ray intensity after passing through the absolutely dry specimen [cps]. However, because the value of  $\psi_w$  is very low for an air-dried brick, instead of  $I$  we use the gamma-ray intensity after passing through the specimen in equilibrium with the ambient laboratory air. To determine  $I_w$  and  $I$  in Eq. (1), we used a measuring device whose gamma-ray source and detector could be moved vertically and horizontally on a plane normal to the direction of gamma-ray propagation (Fig. 2a). The 210 mm × 100 mm surface of the brick was irradiated

with gamma rays. At each measurement cycle, we measured the water content at 20 points (see Fig. 2b). We set the  $x$  and  $z$  axes as shown in Fig. 2b and the  $y$  axis as the direction of the gamma rays. To reduce noise, we measured for 40 s to obtain each data point. We stopped measuring from time to time to refill the water reservoir above the specimen, maintaining a water depth of 20–25 mm. We weighed the specimen before and after each experiment. We used an air conditioner to maintain the laboratory temperature at around 21°C, but we did not control the relative humidity (which fluctuated between 45% and 70%).

Figure 2. a) Schematic of apparatus used for gamma-ray attenuation. b) Points used to measure water content by gamma-ray attenuation.

## Results and discussion

From observations made when the measurement was suspended, air bubbles appeared on the top surface of the brick and escaped into the water in case 2, whereas no such bubbles were observed in cases 1 and 3. Because air in the brick could escape through the bottom surface in case 1 and from the hole drilled in the side surface in case 3, air compressed by moisture infiltration near the top surface might have moved downward because of the air pressure gradient rather than escaping as bubbles through the top surface.

In Fig. 5, the water content measured in each experiment is shown as the data points, with the calculation results (described later) shown as the lines. Here, the results at  $z = 80$  mm are shown as typical examples. Figure 5 shows only those data obtained during the 8 h after the start of each experiment; the water content changed little after that time. The water content clearly increases later in case 2 compared with case 1. In case 3, the water content increases at almost the same rate as in case 2, indicating that the hole did not completely prevent the rise in air pressure from hindering moisture infiltration. The results were nearly the same in cases 2 and 3 because the air bubbles (case 2) and the hole (case 3) might have suppressed the rise in air pressure inside the brick.

In each experiment, the increase in water content was slowest at  $x = 0$  mm (i.e., the center of the brick), becoming faster nearer the side surfaces (i.e., larger absolute values of  $x$ ). The sealed side surfaces and/or the horizontally non-uniform material property such as moisture diffusivity may have affected the moisture transfer. In case 3, the water content at  $x = 80$  mm increased faster than did that at  $x = -80$  mm. During that experiment, the air in the brick escaped from the hole, thereby lowering the air pressure at the right-hand side of the specimen. Therefore, the movement of moisture in the right half was hampered less than it was in the left half.

## ANALYSIS OF SIMULTANEOUS AIR AND MOISTURE TRANSFER

In this section, we analyze case 1 numerically to estimate the moisture diffusivity of the brick. We then use that moisture diffusivity to analyze cases 2 and 3 to assess the validity of the calculation model for simultaneous air and moisture transfer.

### Basic equations, calculation models, and calculation conditions

In the field of soil science, Green et al. (1970) proposed a model for air and moisture transfer and verified it using a water-absorption experiment. Referring to that model, we use the following two equations based on Darcy's law and mass conservation:

$$\frac{\partial \rho_a \psi_a}{\partial t} = \nabla \cdot \left\{ \frac{k_a}{g} (\nabla P_a - \rho_a g \mathbf{n}) \right\}, \quad (2)$$

$$\frac{\partial \rho_w \psi_w}{\partial t} = \nabla \cdot \left\{ \lambda'_p (\nabla P_w - \rho_w g \mathbf{n}) \right\}, \quad (3)$$

where  $\rho$  is the density [ $\text{kg}/\text{m}^3$ ],  $\psi$  is the volume fraction [ $\text{m}^3/\text{m}^3$ ],  $t$  is time [s],  $k_a$  is the coefficient of air permeability [ $\text{m}/\text{s}$ ],  $g$  is the acceleration due to gravity [ $\text{m}/\text{s}^2$ ],  $\lambda'_p$  is the water permeability due to the water pressure gradient [ $\text{kg}/(\text{m} \cdot \text{s} \cdot \text{Pa})$ ],  $P$  is the pressure [Pa],  $\mathbf{n}$  is the unit vector in the direction of gravity, and the suffixes  $a$  and  $w$  refer to air and water, respectively. Here, we consider the compressibility of air but neglect that of liquid water, it being very small in comparison. We use the finite-difference method in the analysis, and the basic equations are discretized by the central difference for space and the forward difference for time. The spatial differential interval is 1.67, 2, and 1 mm in the  $x$ ,  $y$ , and  $z$  directions, respectively. The temporal differential interval depends on  $P_w$ : for case 1, it is  $10^{-6}$  s for  $P_w < -10^8$ ,  $10^{-4}$  s for  $-10^8 \leq P_w < -10^6$ , and 0.02 s for  $P_w \geq -10^6$ ; for cases 2 and 3, it is  $10^{-6}$  s for  $P_w < -10^8$ ,  $5 \times 10^{-5}$  s for  $-10^8 \leq P_w < -10^6$ , and  $2.5 \times 10^{-4}$  s for  $P_w \geq -10^6$ . Here,  $P_w$  is the water pressure relative to atmospheric pressure.

Figure 3 shows the calculation models. We used the average temperature and humidity over the previous 24 h in the laboratory as the initial conditions of the brick for each experiment (case 1: 20.9°C and 55.8%; case 2: 20.8°C and 49.1%; case 3: 20.8°C and 64.1%). In cases 2 and 3, we took the initial air pressure in the brick to be atmospheric pressure. In case 1, the bottom surface was exposed to the ambient laboratory air (the vapour pressure was in equilibrium with an average temperature of 21.0°C and humidity of 63.5% during the experiment); we set the coefficient of moisture transfer between the bottom surface and the ambient air to  $1.25 \times 10^{-8} \text{ kg}/(\text{m}^2 \cdot \text{s} \cdot \text{Pa})$ .

Figure 3. Calculation models for cases 1 (left), 2 (center) and 3 (right).

Because air bubbles were seen escaping from the top surface of the brick in case 2, the top surface was clearly not fully saturated with water. Therefore, in the calculation model we assumed water flow from the water reservoir to the top surface. We assumed there to be a moisture-transfer layer on the top surface of the brick, for which we used the Robin boundary condition. We set the coefficient of moisture transfer to  $8.39 \times 10^{-7} \text{ kg}/(\text{m}^2 \cdot \text{s} \cdot \text{Pa})$  to ensure that the experimental and numerical results agreed in case 1. In case 2, to simplify the model, we distributed the local air loss due to the air bubbles uniformly across the top surface. Therefore,

the boundary condition for the air at the top surface was again the Robin boundary condition; the external condition was atmospheric pressure and we set the coefficient of air transfer to  $4.0 \times 10^{-10} \text{ kg}/(\text{m}^2 \cdot \text{s} \cdot \text{Pa})$ . In case 3, we modelled the hole as a rectangular parallelepiped that was 9.17 mm long, 3 mm high, and 2 mm wide, thereby having nearly the same surface area as the actual hole. We took the air pressure at the hole surface to be atmospheric pressure, and we neglected any flow of moisture through the hole.

### Material properties used in calculation

Figure 4a shows the adsorption isotherm of the brick, which we estimated from Kumaran (1996). However, we determined  $\psi_w$  at saturation by the mass of absorbed water in case 1. According to Descamps (1997), the air permeability decreases rapidly with water content in areas of high humidity. Therefore, we took  $k_a$  to be a function of  $\psi_w$  as in Fig. 4b. Here, we took  $k_a$  in the dry state to be  $2.95 \times 10^{-9} \text{ m/s}$  so that the experimental and numerical results agreed in case 3. Figure 4c shows the moisture diffusivity  $D_\psi$  by volumetric water-content gradient at saturation as a function of  $x$ , and Fig. 4d shows  $D_\psi$  as a function of  $\psi_w$  at  $x = 0$ ,  $\pm 40$ , and  $\pm 80 \text{ mm}$ . We introduced non-uniformity of  $D_\psi$  in the  $x$  direction because the calculated rate of increase of water content did not agree with the experimental results when the calculation model neglected the non-uniformity of this material property. In addition, the moisture diffusivity of a brick increases rapidly in regions of high water content (Kumaran 1996). We calculated  $\lambda'_p$  in Eq. (3) from  $D_\psi$  by  $\lambda'_p = (D_\psi / \rho_w) \times (\partial \psi_w / \partial \mu)$ , where  $\mu$  is the water chemical potential for free water [J/kg]. In the analysis, we considered no other material properties to be non-uniform other than  $D_\psi$ . We did this (i) because the water content in the steady state is largely the same at all measuring points, as shown in Fig. 5, and (ii) to simplify the model.

Figure 4. Material properties of the brick: a) adsorption isotherm; b) coefficient of air permeability as a function of water content; c) moisture diffusivity at saturation as a function of  $x$ ; d) moisture diffusivity as a function of water content.

### Calculation results and discussion

The time profiles of the calculated water content for the first 4 h are shown in Fig. 5 along with the experimental results. Because the measured water content is the average along the line of the gamma rays, we show numerical results averaged in the  $y$  direction. Because the numerical results for case 1 agree well with the experimental ones (Fig. 5a), we applied the

moisture diffusivity identified in case 1 to cases 2 and 3. In cases 2 and 3, the numerical results (Fig. 5b and c, respectively) also agree reasonably with the experimental ones except for the point at  $x = 0$  mm, where the calculated water content rises slower than in the experiment for case 3. Calculation models that consider non-uniformity in the  $y$  and  $z$  directions may improve such agreement.

Figure 5. Calculated and measured water content for a) case 1, b) case 2, and c) case 3.

## CONCLUSIONS

This study has shown that moisture infiltration in a water-absorption test is slowed considerably when air cannot escape from the specimen. It was also shown that making a small hole in the side of the specimen suppresses the rise in air pressure inside the specimen to the same extent as does air loss due to air bubbles; however, such a hole hardly changes the rate of increase of water content. Furthermore, a three-dimensional model of the simultaneous transfer of air and moisture can predict reasonably well the water content measured in the water-absorption test. Further studies of how the depth, area, and location of the small hole affect the ability of the rise in air pressure in a specimen to hinder moisture infiltration should be conducted.

### ABSTRACT

Phase change humidity control material (PCHCM) is a new kind of composite made of high performance PCM microcapsules and diatomite. The PCHCM composite can moderate the hygrothermal variations by absorbing or releasing both heat and moisture and significantly reduce the peak/valley values of indoor temperature and relative humidity. In this paper, a novel model is developed to evaluate the energy performance of office buildings with PCHCM. The model is validated by a series of experiments, and then applied to investigate the effect of PCHCM on energy consumption in different typical climates worldwide (i.e. Beijing, Paris, Atlanta, and Guangzhou). Results show that high values of energy efficiencies can be obtained in the climates which characterized by a wide amplitude of temperature and humidity difference all day along (Paris and Atlanta). Noteworthy, the highest potential energy saving rate could be up to 19.57% for the office building in Paris.

### KEYWORDS

Phase change humidity control material, HAMT, Enthalpy method, Energy consumption

### INTRODUCTION

Nowadays, increased energy demand has resulted in environmental issues worldwide (International Energy Agency, 2012). Building sector represents about 40% of global energy consumption and produces 30% of global greenhouse gas emissions annually (United Nations Environment Programme, 2009). The energy consumption of heating, ventilation and air-conditioning (HVAC) system accounts for 50% of building energy consumption in developed countries (Dincer, 1998). For this reason, it's essential to reduce the energy consumption of HVAC systems. The application of innovative building materials which can control the indoor hygrothermal condition at a relatively comfortable level is a promising way of energy saving.

The phase change materials (PCM) and porous hygroscopic materials are commonly used to moderate the indoor hygrothermal fluctuations (Barreneche et al. 2013; Evola et al. 2013; Andersen and Korsgaard, 1986; Toftum et al. 1998). However, those two kinds of material cannot simultaneously regulate the indoor temperature and humidity. Therefore, the phase change humidity control materials (PCHCM) that have the capability of both thermal and moisture buffering were prepared by our research group (Chen et al. 2015; Chen and Qin, 2016). The synthesis of novel phase change humidity control material (PCHCM) was achieved by using composite microencapsulated phase change material (MPCM) and diatomite. The PCHCM can moderate indoor air fluctuations of temperature and relative humidity by absorbing or releasing both heat and moisture.

Currently, the coupled heat and moisture transfer (HAMT) model proposed by Künzeli (1995) is the most used and validated model to calculate the coupled heat and moisture transfer

through porous building materials. On the other hand, the enthalpy method that can evaluate the general convection and diffusion phase change process was proposed by Voller et al (1987). However, very few models can be used to calculate the coupled heat, air and moisture transfer with phase change process.

The objectives of this study are: (1) to propose a novel mathematical model for calculating the coupled heat, air and moisture transfer with phase change process; (2) to analyse the energy saving effect of PCHCM in different climates.

## METHODS

### Methodology

The following equations are taken from HAMT model (Künzel, 1995). The heat balance of building envelopes can be described in equation (1):

$$\frac{\partial H}{\partial T} \frac{\partial T}{\partial t} = \frac{\partial}{\partial x} \left( k_w \frac{\partial T}{\partial x} \right) + h_v \frac{\partial}{\partial x} \left( \frac{\delta}{\mu} \frac{\partial(\phi P_{\text{sat}})}{\partial x} \right) \quad (1)$$

where  $H$  is the total enthalpy of material (kJ/kg),  $T$  is the temperature ( $^{\circ}\text{C}$ ),  $t$  is the time (s),  $x$  is the thickness (m),  $k_w$  is the heat conductivity coefficient (W/m·K),  $h_v$  is the vaporization enthalpy of water (kJ/kg),  $\delta$  is the vapor diffusion coefficient in air (kg/(m·s·Pa)),  $\mu$  is the resistance coefficient of moisture,  $\phi$  is the relative humidity,  $P_{\text{sat}}$  is the partial pressure of saturated water vapor (Pa).

The capacity of heat storage can be expressed as:

$$\frac{\partial H}{\partial T} = c_{\text{dry}} \rho_{\text{dry}} + c_{\text{p,vapor}} \omega \quad (2)$$

where  $c_{\text{dry}}$  is the specific heat capacity of dry materials (J/kg·K),  $\rho$  is the density of water (kg/m<sup>3</sup>),  $c_{\text{p,vapor}}$  is the specific heat capacity of water vapor (J/kg·K),  $\omega$  is the water content (kg/m<sup>3</sup>).

Equation (3) describes the mass conservation of building envelopes:

$$\frac{\partial \omega}{\partial \phi} \frac{\partial \phi}{\partial t} = \frac{\partial}{\partial x} \left( D_w \frac{\partial \omega}{\partial \phi} \frac{\partial \phi}{\partial x} \right) + \frac{\delta}{\mu} \frac{\partial}{\partial x} (\phi P_{\text{sat}}) \quad (3)$$

According to the enthalpy method, the enthalpy  $H_{\text{dry}}$  can be expressed as:

$$H_{\text{dry}} = c_{\text{dry}} T + L_{\text{heat}} f_{\text{liq}} \quad (4)$$

where  $H_{\text{dry}}$  is the enthalpy of dry material (kJ/kg),  $L_{\text{heat}}$  is the latent enthalpy (J/kg),  $f_{\text{liq}}$  is the Liquid fraction.

The relationship between the specific heat capacity of dry material and temperature can be described by enthalpy method (Voller et al. 1987):

$$\rho_{\text{dry}} c_{\text{dry}} \frac{\partial T}{\partial t} = \rho_{\text{dry}} \frac{\partial H_{\text{dry}}}{\partial t} \quad (5)$$

The combined equation can be written by plugging the Eq. (2) and (4) into equation (1):

$$\rho_{\text{dry}} \frac{\partial H_{\text{dry}}}{\partial t} + \omega c_{\text{p,vapor}} \frac{\partial T}{\partial t} = \frac{\partial}{\partial x} \left( k_w \frac{\partial T}{\partial x} \right) + h_v \frac{\partial}{\partial x} \left( \frac{\delta}{\mu} \frac{\partial(\phi P_{\text{sat}})}{\partial x} \right) \quad (6)$$

Combining with the moisture transfer Eq. (3), Eq. (6) and Eq. (3) are the whole heat and moisture governing equations of HAMT-Enthalpy (HAMT-E) model.

### Validation

In order to verify the coupled HAMT-E model, a test facility with the PCHCM layer was built in Nanjing University.

Figure 1. Experimental cabin

As shown in Fig. 2, the internal dimensions of the experimental cabin are 3m (depth)  $\times$  2m (width)  $\times$  2m (height). The cabin is made of 30 mm-thick wood boards and covered with an insulating material (thermal/humidity) on its four external sides. The 1m (width)  $\times$  1.2m (height) double-glazed window is equipped in the south wall. The interior floor is covered with a 2 mm-thick PCHCM layer. The phase change temperature range of PCM is 25~27 °C. The tests are performed with a constant air change rate (ACH) of 0.5 h<sup>-1</sup>. The experiments were conducted from July 1st to July 10th, 2017.

The temperature and relative humidity were measured both in the inside and outside space of the experimental cabin. The comparison between the experimental and simulated results is shown in Fig. 2 and Fig. 3. It can be seen that the high coincidence results can be obtained with the HAMT-E model both in thermal and humidity aspect.

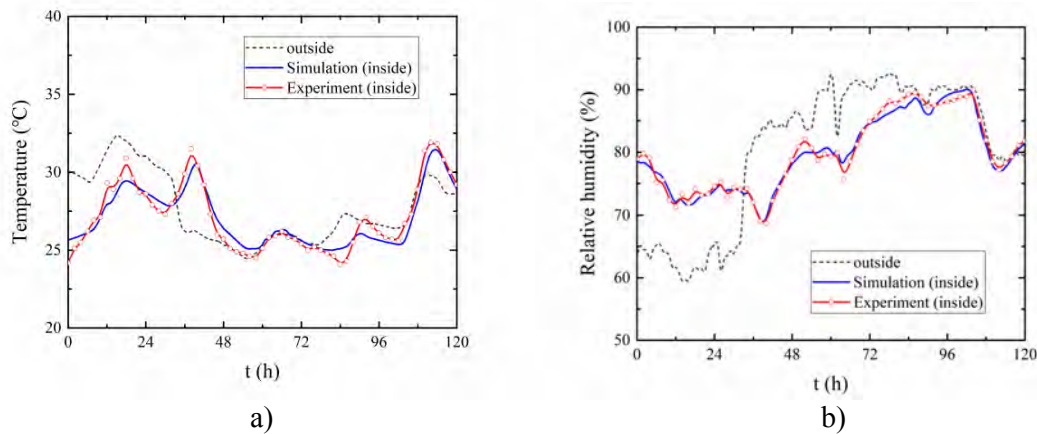

Figure 2. The comparison of simulated indoor temperature and relative humidity with the measured data

## CASE STUDY

The validated HAMT-E model was applied to investigate the impact of PCHCM on building energy consumption under different climates. Four worldwide cities including Beijing, Paris, Atlanta and Guangzhou which characterized by typical urban climates were selected as boundary weather conditions for analysis. The BESTEST base case building (Fig. 3) from the IEA ECBCS Annex 21 was selected as the test office building (Zhang et al. 2017). The physical parameters of building envelopes are listed in Table 1. The simulation settings and boundary conditions can be seen in Table 2 as a office house.

Figure 3. The BESTEST base case building adopted in application examples

Table 1. Physical parameters of different layers in building envelopes.

Construction	Material	d (m)	$\rho$ (kg/m <sup>3</sup> )	$c_p$ (J/kg·K)	$K$ (W/m·K)	$U$ (W/m <sup>2</sup> ·K)

Table 2. Simulation settings and boundary conditions.

Conditions	Office case		
Case ID	Reference	CaseA.1	CaseA.2
PCHCM area (m <sup>2</sup> )	0	63.6	159.6
Heat power (W/m <sup>2</sup> )		15 (occupied period)	
Moisture releasing rate (g/m <sup>3</sup> h)		6 (occupied period)	
Permissible room temperature range (°C)		18-26 (occupied period)	
Permissible max relative humidity (RH)		≤65% (occupied period)	
Air change rate (ACH)		0.5 (2ACH in unoccupied time)	
Air infiltration		No	
Occupied period (h)		09:00-17:00	
Unoccupied period		The rest of the day	

## RESULTS

In a typical year, the energy consumption and efficiency of PCHCM applied in office building are compared (Table 3). The energy saving quantity and efficiency tend to rise with the

increase of PCHCM's area. It illustrates that PCHCM could effectively moderate indoor hygrothermal environment; and a notable energy saving effect could be obtained.

Noteworthy, higher energy saving efficiency can be achieved in Paris and Atlanta, which have a temperate climate characterized by the wide amplitude of outdoor hygrothermal difference. Guangzhou has a hot and humid climate. It usually has a high temperature and relative humidity condition in the whole day. The high outdoor air temperature restrains the exothermic process of melting of the PCM. Similarly, the high outdoor relative humidity prevents the desorption process of diatomite. Therefore, the residual heat and moisture in PCHCM could not be efficiently discharged by the outside hygrothermal environment. As a result, the cooling loads of air conditioning system cannot be reduced by the efficiency of daily cyclic procedure of PCHCM.

The values of energy saving efficiency strictly follow the conclusions mentioned above. For instance, it can be seen that the utilization of PCHCM achieves the high values of energy saving efficiency in summer typical week. In Beijing, Paris, Atlanta and Guangzhou, the energy saving efficiencies are 10.22%, 19.57%, 17.82% and 8.76% in Case A.2, respectively. Additionally, the highest values of energy saving efficiency can be obtained in Paris with wide hygrothermal difference and the lowest can be obtained in Guangzhou with narrow hygrothermal difference.

Table 3. Energy consumption and energy saving of different cities in office buildings (Beijing, Paris, Atlanta and Guangzhou).

City	Load and efficiency	Area of PCHCM		
		0m <sup>2</sup> (Reference)	63.6m <sup>2</sup> (Case A.1)	159.6m <sup>2</sup> (Case A.2)
Beijing	Total load (kWh m <sup>-2</sup> a <sup>-1</sup> )	78.52	75.41	70.49
	Sensible heat saving(%)	-	0.77	7.40
	Latent heat saving(%)	-	18.98	23.48
	Total energy saving (%)	-	3.96%	10.22%
Paris	Total load (kWh m <sup>-2</sup> a <sup>-1</sup> )	71.12	64.77	57.21
	Sensible heat saving(%)	-	0.87	8.82
	Latent heat saving(%)	-	38.13	58.51
	Total energy saving (%)	-	8.93%	19.57%
Atlanta	Total load (kWh m <sup>-2</sup> a <sup>-1</sup> )	71.13	67.52	58.45
	Sensible heat saving(%)	-	0.72	14.83
	Latent heat saving(%)	-	17.41	26.31
	Total energy saving (%)	-	5.07%	17.82%
Guangzhou	Total load (kWh m <sup>-2</sup> a <sup>-1</sup> )	104.57	102.09	95.41
	Sensible heat saving(%)	-	1.3	10.44
	Latent heat saving(%)	-	3.83	6.84
	Total energy saving (%)	-	2.37%	8.76%

## CONCLUSIONS

This study intends to investigate the application of PCHCM in office buildings as a passive method to reduce energy consumption under different climate conditions. In this paper, a model for analyzing the energy consumption of the PCHCM is developed. The model is implemented in MATLAB-Simulink, and is validated by performing a series of experiments and validation tools. By using the model, the energy saving effect of PCHCM in office building is analyzed.

The research indicates that the application of PCHCM has the potential to reduce the energy consumption of office buildings. Overall, the PCHCM presents a melting point of 25~27 °C, which achieves the energy reduction of sensible heat in a summer typical week. Additionally, the porous structure of PCHCM enables the energy reduction of latent heat in moisture buffering process. From the analysis of energy saving, the overall energy saving potential of Paris with temperate maritime climate is found to be the best while the potential of energy reduction is limited in Guangzhou (located in subtropical humid climate) with high temperature and humidity all day long. Above all, the numerical results indicate that PCHCM is suitable for the areas that simultaneously manifest a wide amplitude of hygrothermal (temperature and humidity) difference.

### **ABSTRACT**

In this paper, series of experiment measurements is carried out in order to study effect of freeze/thaw loading on the change of moisture transport properties of autoclaved aerated concrete. The samples were subjected to 15, 30 and 45 freeze/thaw cycles and subsequently basic physical properties, pore size distribution and water vapor and liquid water transport properties were investigated. The results showed significant changes in material properties of the material. The results of this research can be further implemented into computational models in order to bring the simulation results closer to the reality.

### **KEYWORDS**

Autoclaved aerated concrete, freeze/thaw cycles, moisture transport properties, damage

### **INTRODUCTION**

The effects of natural environment, such as air temperature, relative humidity, and solar and wind factors always vary in time, acting on the surface of building materials. Such effects may cause biological, chemical, or physical degradation of the material (Bertron, 2014; Kordatos et al., 2013; Sandrolini et al., 2007). When the materials are exposed to low temperatures, the ice damage needs to be considered in the first place. It is initiated through the nucleation, growth and interaction of micro-cracks, which usually occur internally. Such processes are manifested by volume expansion during cooling and by macroscopic cracks that develop after repeated cycles of freezing and thawing. (Beaudoin and MacInnis, 1972; Powers and Helmuth, 1953)

The ice damage is usually observed and investigated from a structural or esthetic point of view as usually strength loss of the material, surface cracks or detachment of renders are of interest. However, there exist some additional effects of ice damage, which are not apparent at a first glance. For example, building materials subjected to freeze-thaw loading become more permeable for the liquid water and water vapor due to the presence of micro- and macro-cracks in their structure. For that reason those materials become more vulnerable for the rest of their service life. Therefore, the freeze-thaw effects should be investigated also in this manner in order to analyze the effect of cracks on the change of moisture transport properties of building materials and to increase the credibility of service life analyses.

In this paper a series of experiments is conducted in order to investigate moisture transport properties of autoclaved aerated concrete after repeated freeze-thaw loading. The samples are fully saturated and subjected to different number of freeze-thaw cycles. Then, after drying process, for each sample the moisture transport properties, namely water vapor diffusion resistance factor and apparent moisture diffusivity, are determined and their dependence on the number of freeze-thaw cycles is investigated and discussed.

## MATERIALS AND METHODS

### Studied material

For the investigation of the effect of micro-cracks on the change of moisture transport properties, an autoclaved aerated concrete (AAC) P1.8-300 produced by company Xella was selected. Its basic physical, thermal and hygric properties (Jerman et al., 2013; Maděra et al., 2017) are shown in Table 1.

Table 1. Basic physical, thermal and hygric properties of studied AAC.

Parameter	Unit
Bulk density $\rho$ (kg/m <sup>3</sup> )	289
Open porosity $\psi$ (%)	86.9
Specific heat capacity $c$ (J/kg/K)	1090
Water vapor diffusion resistance factor $\mu_{dry}$ (-)	15.61
Water vapor diffusion resistance factor $\mu_{sat}$ (-)	6.17
Thermal conductivity $\lambda_{dry}$ (W/m/K)	0.071
Thermal conductivity $\lambda_{sat}$ (W/m/K)	0.548
Apparent moisture diffusivity $\kappa$ (m <sup>2</sup> /s)	$7.02 \cdot 10^{-8}$

For the further laboratory testing, the material was cut and different sets of samples having specific dimensions were prepared. For the measurement of apparent moisture diffusivity, rectangular prismatic specimens with the dimensions of 20 mm x 40 mm x 300 mm were prepared. The water vapor diffusion resistance factor was measured on block samples with the dimensions 100 mm x 100 mm and height of 20 mm (see Fig. 1), which were cut from the original AAC block.

Figure 1. AAC samples for measurement of water vapor resistance diffusion factor.

### Experimental methods

The prepared samples were subjected to the freeze/thaw loading similarly to freeze resistance tests defined by ČSN EN 15304 (2010). First, the samples were dried, then submerged in water for 48 hours and left for another 24 hours in the laboratory in polyethylene bags to reach moisture content equilibration. After that, each sample was loaded by 15, 30 or 45 freeze/thaw cycles in order to create various amount of micro-cracks inside the material. Freezing period

was realized for 8 hours at -15 °C, thawing period 8 hours at 20 °C. The samples loaded by defined number of freeze/thaw cycles were then subjected to particular measurement of water vapor and liquid moisture transport properties. Simultaneously, the pore size distribution function of loaded samples was determined in order to provide preliminary information on changes in material's pore structure.

The apparent moisture diffusivity was obtained through the measurement of water absorption coefficient. The water absorption coefficient was determined by free water intake experiment. The cumulative mass of water in terms of the square-root-of-time rule commonly employed in the diffusion theory (Crank, 1975) can be expressed as

$$i = A \cdot t^{1/2}, \quad (1)$$

where  $i$  ( $\text{kg} \cdot \text{m}^{-2}$ ) is the cumulative mass of water and  $A$  ( $\text{kg} \cdot \text{m}^{-2} \cdot \text{s}^{-1/2}$ ) is the water absorption coefficient. Once  $A$  is known, the apparent moisture diffusivity can be calculated according to basic formula given by Kumaran (1999)

$$\kappa_{app} \approx \left( \frac{A}{w_{sat} - w_0} \right)^2, \quad (2)$$

where  $\kappa_{app}$  ( $\text{m}^2 \cdot \text{s}^{-1}$ ) is the apparent moisture diffusivity,  $w_{sat}$  ( $\text{kg} \cdot \text{m}^{-3}$ ) is the saturated moisture content and  $w_0$  ( $\text{kg} \cdot \text{m}^{-3}$ ) is the initial moisture content.

The water vapor transport properties were determined by means of water vapor diffusion resistance factor. For that reason the cup method was employed (Roels et al., 2004), which is the most frequently used in the practice. The method, defined by ISO (EN ISO 12572, 2001), is based on one-dimensional water vapor diffusion where the diffusion water vapor flux through the specimen and partial water vapor pressure in the air under and above specific specimen surface are measured. Water vapor transition properties of the investigated material are found by placing a specimen on the top of a cup and sealing it. The water vapor diffusion permeability  $\delta$  (s) is calculated from the measured data according following equation

$$\delta = \frac{\Delta m \cdot d}{S \cdot \tau \cdot \Delta p_p}, \quad (3)$$

where  $\Delta m$  (kg) is the amount of water vapor diffused through the sample,  $d$  (m) is the sample thickness,  $S$  ( $\text{m}^2$ ) is the specimen surface,  $\tau$  (s) is the period of time corresponding to the transport of mass of water  $\Delta m$ , and  $\Delta p_p$  (Pa) is the difference between partial water vapor pressure in the air under and above specific specimen surface. Once the water vapor diffusion permeability is known, the water vapor diffusion resistance factor  $\mu$  (-) can be calculated through water vapor diffusion coefficient  $D$  ( $\text{m}^2 \cdot \text{s}^{-1}$ ) as

$$D = \frac{\delta \cdot R \cdot T}{M}, \quad (4)$$

$$\mu = \frac{D_a}{D}, \quad (5)$$

where  $R$  ( $\text{kg} \cdot \text{m}^2 \cdot \text{s}^{-2} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$ ) is the universal gas constant,  $M$  ( $\text{kg} \cdot \text{mol}^{-1}$ ) is the molar mass of water,  $T$  (K) is the absolute temperature, and  $D_a$  ( $\text{m}^2 \cdot \text{s}^{-1}$ ) is the diffusion coefficient of water vapor in the air.

The pore size distribution function was determined using two different approaches. The distribution of pores up to 10  $\mu\text{m}$  was determined using mercury intrusion porosimetry, while the amount of larger pores was calculated from total open porosity obtained by helium pycnometry.

## RESULTS

Following data were obtained using experimental methods described in previous section. The basic physical properties such as bulk density, matrix density and open porosity are shown in Table 2. The distribution of pores is shown in Fig. 2.

Table 2. Basic physical properties of AAC

Sample	Matrix density $\rho_{mat}$ ( $\text{kg}\cdot\text{m}^{-3}$ )	Bulk density $\rho$ ( $\text{kg}\cdot\text{m}^{-3}$ )	Open porosity $\psi$ (%)
unloaded (reference)	$2034.0 \pm 40.7$	$289.0 \pm 4.3$	$85.1 \pm 2.8$
15 F/T cycles	$2060.4 \pm 41.2$	$281.7 \pm 4.2$	$86.4 \pm 2.9$
30 F/T cycles	$2016.1 \pm 40.3$	$292.5 \pm 4.4$	$85.5 \pm 2.8$
45 F/T cycles	$2005.8 \pm 40.1$	$285.0 \pm 4.3$	$85.8 \pm 2.8$

Figure 2. Pore size distribution of studied AAC

The measured water vapor and liquid water transport parameters are shown in Table 3.

Table 3. Water vapor and liquid water transport properties

Sample	Water vapor diffusion resistance factor $\mu$ (-)	Water absorption coefficient $A$ ( $\text{kg}\cdot\text{m}^{-2}\cdot\text{s}^{-1/2}$ )	Apparent moisture diffusivity $\kappa_{app}$ ( $\text{m}^2\cdot\text{s}^{-1}$ )
unloaded (reference)	$15.6 \pm 2.3$	$0.106 \pm 0.005$	$(7.020 \pm 0.351) \cdot 10^{-8}$
15 F/T cycles	$5.7 \pm 0.9$	$0.021 \pm 0.001$	$(2.652 \pm 0.133) \cdot 10^{-9}$
30 F/T cycles	$6.4 \pm 1.0$	$0.020 \pm 0.001$	$(2.450 \pm 0.123) \cdot 10^{-9}$
45 F/T cycles	$6.5 \pm 1.0$	$0.019 \pm 0.001$	$(2.139 \pm 0.107) \cdot 10^{-9}$

## DISCUSSION

The presented results clearly show the change in material parameters of the sample before and after loading by certain numbers of freeze/thaw cycles. When basic physical properties are taken into account, it is obvious that freeze/thaw cycles generated some micro-cracks inside the material manifested by slight decrease of bulk density. However, the change is within the frame of measurement error. The increase of bulk density for the sample loaded by 30 freeze/thaw cycles can be explained by inhomogeneity of the original block from which the samples were cut. In the same way, the total porosity slightly increased. The changes of materials pore structure are evident from Fig. 2, where the amount of largest pores increased with the freeze/thaw loading.

The change of material structure affected the water vapor and liquid water transport properties. When water vapor diffusion resistance factor is discussed, it is evident that the material became more permeable for the water vapor. The values significantly decreased, however it seems that the number of freeze/thaw cycles does not have significant influence on the value change. Therefore, it can be concluded that major changes in material's pore structure appear after 1 to 15 freeze/thaw cycles and the additional loading does not affect the structure in significant way. In order to evaluate the critical number of freeze/thaw cycle that causes substantial change of material's structure, some additional testing should be performed with finer scale such as 1 or 2 freeze/thaw cycles.

The determination of water adsorption coefficient and apparent moisture diffusivity of AAC was very difficult. Basically, the reason for this is a coarse pore structure of the material making the gravity forces an important factor. With increasing pores in the material the absorption coefficient and apparent moisture diffusivity decreases. However, in order to provide more representative view on liquid moisture transport properties of studied material, another series of experiment needs to be conducted. The objective is to eliminate the effect of gravity forces and therefore the experiment should be designed to simulate moisture transport in horizontal position instead of vertical one.

Also, the cooling of material was done for -15 °C according to national standard, however, this temperature might not be sufficient enough. Using the Gibbs-Thompson equation for calculation of freezing point depression in the pores, the size of largest pore where the freezing occur may be calculated as

$$R = \frac{2T_0\gamma_{sl}v_l}{\Delta h_b\Delta T_f}, \quad (6)$$

where  $\gamma_{sl}$  (mJ·m<sup>-2</sup>) is the surface free energy (interfacial tension) of the solid/liquid interface ( $\gamma_{sl} = 31.7 \pm 2.7$  mJ·m<sup>-2</sup>),  $v_l$  (cm<sup>3</sup>·mol<sup>-1</sup>) the molar volume of the liquid ( $v_l = 18.02$  cm<sup>3</sup>·mol<sup>-1</sup>), and  $\Delta h_b$  (kJ·mol<sup>-1</sup>) the melting enthalpy in the unconfined (bulk) state ( $\Delta h_b = 6.01$  kJ·mol<sup>-1</sup>), all quantities taken at the bulk coexistence temperature  $T_0$  ( $T_0 = 273.15$  K).  $\Delta T_f$  (K) is the freezing temperature, i.e.  $\Delta T_f = T_0 - T_{cooling}$ . Based on Eq. (6), the largest pore with affected by freezing has a diameter of approximately 0.02 μm. For that reason, it will be suggested in further experiments to decrease the freezing temperature to at least -30 °C in order to affect the smallest pores (up to 0.008 μm) by ice damage.

## CONCLUSIONS

The water vapor and liquid water transport properties of the autoclaved aerated concrete were investigated in this paper. The samples were first loaded by various number of freeze/thaw cycles in order to induce ice damage to the material. Then, basic physical properties, pore size distribution and moisture transport properties were analyzed. The results proved significant

change in water vapor transport properties as the material become more permeable for the water vapor. The liquid water transport properties described by apparent moisture diffusivity decreased after loading by freeze/thaw cycles. However, the methodology for vertical water uptake was found not suitable for this kind of material due to significant effect of gravity forces. The analysis of pore size distribution revealed significant changes in pore structure of the material supporting the conclusions made in this paper.

### **ABSTRACT**

Continuous exterior insulation is becoming more common in North American above-grade walls in both retrofit applications and new construction, as a means to improve the thermal performance of wall assemblies. Although moisture performance of wood-frame wall assemblies has been studied extensively, the drying capability of wall assemblies with exterior insulation and an interior vapor retarder in cold climates is not well characterized. This study monitored the hygrothermal performance of wall assemblies with and without exterior insulation under high and low interior humidity conditions and with intentional wetting of the wood structural panel sheathing. Moisture content and temperature of standard 38 mm × 140 mm wood framing and 11 mm thick oriented strand board (OSB) sheathing were measured over a two-year period in eight different wall assemblies, each with north or south orientation, in a conditioned test structure in Madison, Wisconsin. Wall configurations differed primarily in the interior vapor retarder (kraft paper or polyethylene film) and the exterior insulation (none, expanded polystyrene, extruded polystyrene, or mineral wool). OSB sheathing was wetted in a controlled manner at three different times of year to investigate drying response. Wintertime moisture accumulation in OSB in the tested climate zone was not a concern except in the wall with no exterior insulation and interior kraft vapor retarder, though rapid drying occurred in springtime. Drying of OSB after controlled wetting events was generally faster during warm weather than cold weather; faster with exterior insulation than without during cold weather; faster with vapor-open exterior insulation than low-permeance exterior insulation during cold weather; and faster with interior kraft vapor retarder than polyethylene.

### **KEYWORDS**

moisture performance, hygrothermal performance, continuous insulation, building envelope, durability

### **INTRODUCTION**

The building envelope is a key component affecting overall building energy use. Continuous exterior insulation is an increasingly common strategy to improve overall thermal performance in North American above-grade wall assemblies in both retrofit applications and new construction. This approach is particularly relevant for wood-frame construction in cold climates. While Performance Compliance Paths in the International Energy Conservation Code (IECC) (ICC, 2015) offer flexibility in the design of exterior walls, the Prescriptive Compliance Path requires wood-frame walls located in cold climates (IECC Climate Zone 6 or higher) to incorporate continuous insulation at a minimum thermal resistance of 0.88 m<sup>2</sup>·K/W (5 h·ft<sup>2</sup>·°F/Btu or “R-5”). This is often implemented with a combination of cavity insulation and continuous exterior insulation.

Long-term moisture performance of exterior wall assemblies is critical because moisture accumulation can lead to degradation of materials and poor indoor air quality. Moisture control strategies for exterior wall assemblies need to address sources of moisture from the interior and exterior of the building and the ways in which moisture migrates, including bulk water intrusion, uncontrolled air leakage, and vapor diffusion (TenWolde and Rose, 1996). In addition, the capacity to dry out when wetting occurs (either during construction or over the service life of the building) can improve the moisture tolerance and reduce the risk of problems, but the drying potential may be a concern for some wall assemblies that are insulated and air sealed to levels required by current model energy codes.

A recent literature review (Trainor and Smegal, 2017) concluded that adding exterior insulation to wood-frame walls in North American cold climates in nearly every case did not increase the risk of moisture-related durability problems. Continuous exterior insulation raised the temperature of wood structural members in exterior walls during cold weather (relative to walls without exterior insulation), thereby reducing the potential for wintertime moisture accumulation (Tsongas, 1991; Straube, 2011). With regard to drying potential, several studies found that walls with vapor-open exterior insulation allowed drying to the outside at a faster rate than walls with exterior foam insulation (Maref *et al.*, 2011; Fox *et al.*, 2014; Trainor *et al.*, 2016). In addition, faster drying rates were observed during spring and summer in exterior insulated walls without an interior polyethylene vapor barrier than in those with polyethylene (Craven and Garber-Slaght, 2014).

The studies mentioned above investigated a variety of wall configurations but did not include 38 by 140 mm framing (nominal 2×6) with 0.88 m<sup>2</sup>·K/W (R-5) exterior insulation, which meets the “R-20+5” IECC Prescriptive Compliance Path in cold climate zones (IECC Climate Zone 6 or higher). For this configuration, the ratio of exterior insulation to cavity insulation is not sufficient to permit the use of only a Class III interior vapor retarder (such as latex paint on gypsum board). The present study was initiated to characterize the moisture performance of 140 mm wood-frame wall assemblies with and without exterior insulation in a cold climate location. Specific objectives were to monitor wall assembly moisture and temperature conditions under ambient environmental conditions with high and low interior humidity conditions, and to characterize wall assembly drying rates after intentional wetting of the wood structural panel sheathing.

## METHODS

Monitoring was carried out in a conditioned test structure located in Madison, Wisconsin (IECC Climate Zone 6). This cold climate has 4,074 heating degree days (18°C basis; 1981–2010 mean); 2015 and 2016 were warmer than normal, both with about 90% of the historic mean heating degree days. The 17.2 m x 4.9 m test structure was oriented with the long dimension running east to west. It had a preservative-treated wood post and beam foundation with an insulated floor. The 38 x 140 mm wood stud walls were refurbished for this study to create eight different north and south facing test bays (Figure 1). Each test bay was 1.2 m wide and 2.2 m high and consisted of three cavities with studs 406 mm on center. Test bays were isolated with a composite trim board on the exterior and by adding a 38 x 140 mm stud separated from the existing stud of the adjacent test bay using an impermeable self-adhering membrane. An entry door was located on the north side of a central area that houses the data acquisition system and heating and cooling equipment. Winter mean interior temperature was 20 °C; mean interior relative humidity (RH) was 42% during the first winter and 34% during the second winter. Summer mean interior conditions were 25 °C with RH between 45% and 55%.

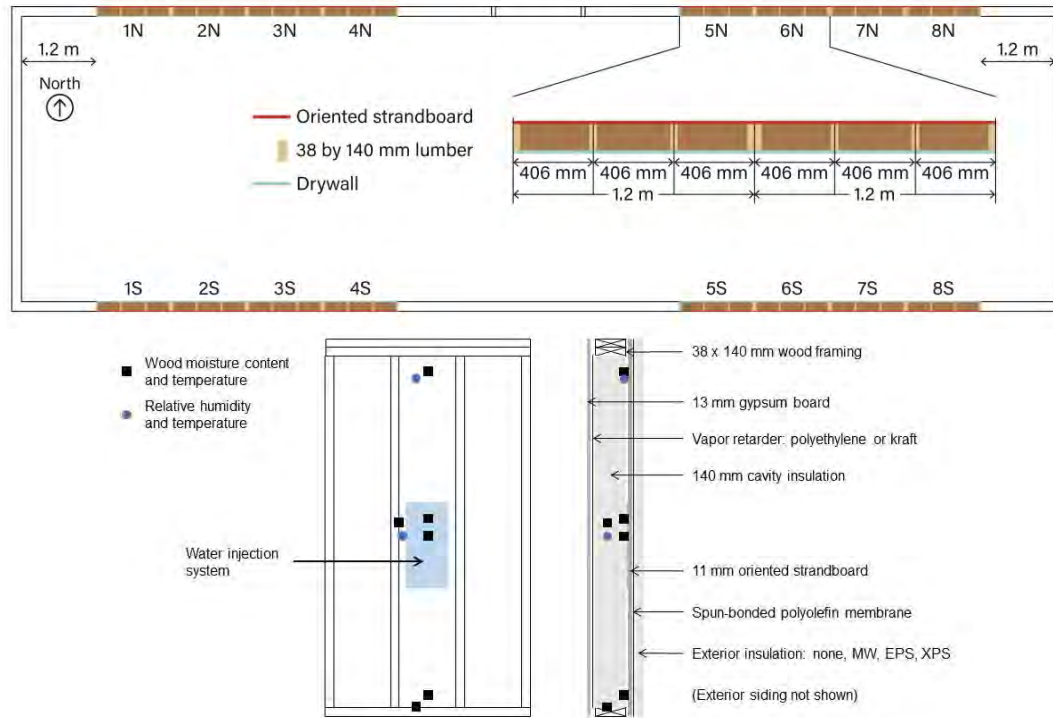

Figure 1. (top) Plan view of test structure with labelled test bays. (bottom) Wall elevation and section showing sensor layout.

All wall assemblies included vinyl siding, spun-bonded polyolefin house wrap, oriented strand board (OSB) sheathing, fiberglass batt cavity insulation ( $3.7 \text{ m}^2 \cdot \text{K/W}$  or R-21), and interior gypsum drywall. Gasketing was installed between the framing and drywall for airtightness, and the drywall was finished with latex primer and latex paint. Test walls differed in the type of interior vapor retarder, water-resistive barrier, and exterior insulation (Table 1). Walls 1 and 2 provided base cases with no exterior continuous insulation (CI); Wall 1 had asphalt-coated kraft paper facing on the fiberglass batt insulation, whereas Wall 2 had 0.15 mm polyethylene sheet (with unfaced batt insulation). The remaining walls included one of the following exterior insulation materials: 38 mm mineral wool (MW) insulation ( $1.1 \text{ m}^2 \cdot \text{K/W}$  or R-6); 38 mm expanded polystyrene (EPS) insulation ( $1.1 \text{ m}^2 \cdot \text{K/W}$  or R-6); or 25 mm extruded polystyrene (XPS) insulation ( $0.88 \text{ m}^2 \cdot \text{K/W}$  or R-5). Walls 1-7 had ordinary spun-bonded polyolefin membrane installed just exterior of the OSB sheathing, whereas Wall 8 used a “crinkled” version of the same material, structured to create vertical channels and a small air gap between the OSB sheathing and XPS insulation.

Table 1. Wall configurations.

Wall	Label	Interior Vapor Retarder	House Wrap	Exterior Insulation
1	No CI, kraft	Kraft paper	Flat polyolefin	None
2	No CI, poly	Polyethylene	Flat polyolefin	None
3	MW, kraft	Kraft paper	Flat polyolefin	38 mm MW
4	MW, poly	Polyethylene	Flat polyolefin	38 mm MW
5	EPS, kraft	Kraft paper	Flat polyolefin	38 mm EPS
6	XPS, kraft	Kraft paper	Flat polyolefin	25 mm XPS
7	XPS, poly	Polyethylene	Flat polyolefin	25 mm XPS
8	XPS, kraft, crinkled	Kraft paper	Crinkled polyolefin	25 mm XPS

Each test bay had an identical set of sensors installed in the central cavity (of the three that make up a bay; Figure 1). Wood moisture content (MC, percentage based on dry mass) and temperature were measured hourly at six locations in each test bay: four sensor pairs were located in OSB sheathing at various heights, one in the bottom plate, and one in a stud at mid-height. MC values in OSB were based on resistance measurements using the calibration of Boardman *et al.* (2017). Two additional sensors measured RH and temperature in the center of the cavity and at the interior surface of the OSB. Indoor RH and temperature and weather conditions were also recorded on site. Further details are given in Boardman *et al.* (2018).

Each wall assembly was subjected to an identical water injection schedule at three different times during the study. A shop towel was fastened to the interior side of the OSB in the center cavity to serve as a reservoir for the injected water (Figure 1), which was introduced through a vinyl tube from the interior near the drywall surface (Van Straaten, 2003). Each injection had a volume of 40 mL, which wetted the shop towel without water running down the OSB sheathing. The first series of injections occurred in late summer, starting August 13, 2015, with one injection per day for three days (total of 120 mL). The second series of injections occurred in late fall, starting November 6, 2015, and lasted five days (total of 200 mL). The last series of injections occurred the following spring, starting May 20, 2016, and lasted 4 days (total of 160 mL).

## RESULTS AND DISCUSSION

OSB moisture content was higher in winter than summer, as illustrated in Figure 2 for north-facing walls (away from the wetting device). Two further trends are noted: first, walls with kraft vapor retarder had higher OSB MC in winter than corresponding walls with polyethylene; second, walls with exterior insulation had lower OSB MC than the base walls. Wintertime moisture contents were highest in the base wall with kraft vapor retarder; the peak was above 30% MC in the first winter and about 23% MC in the second winter, whereas the base wall with polyethylene vapor retarder remained below 16% MC. The difference is a result of water vapor migration from interior humidification through the more permeable kraft vapor retarder. Similar trends were observed in the south-facing walls, though the peak moisture contents were typically not as high as in the north-facing walls. The lower moisture levels in the south walls are due to the slightly higher temperature (as a result of solar radiation), but this effect was small and not consistent in all results. More consistent was the result that walls with exterior insulation had lower moisture levels than the base walls.

The response of OSB moisture content to water injections is depicted in Figure 3 for sensors placed within the field of the wetting device in north-facing walls. All wall configurations had a rapid increase in OSB MC after the water injections. Several observations about drying rates are noted. First, the drying rates in general were faster for the first injection (Aug 2015) and third injection (May 2016) than the second injection (Nov 2015). This was expected because drying is slower at colder temperatures. Second, for all three injections the walls with a kraft vapor retarder dried more rapidly than corresponding walls with polyethylene, consistent with the higher vapor permeance of kraft allowing drying to the interior. Third, for the second injection (in colder weather), walls with exterior insulation generally dried faster than the corresponding base walls, due to the exterior insulation keeping the OSB warmer. Fourth, the walls with exterior MW insulation dried faster than corresponding walls with exterior XPS insulation after the second injection; this is a result of the higher vapor permeance of MW and is consistent with prior research. Further analysis supporting these observations is presented by Boardman *et al.* (2018).

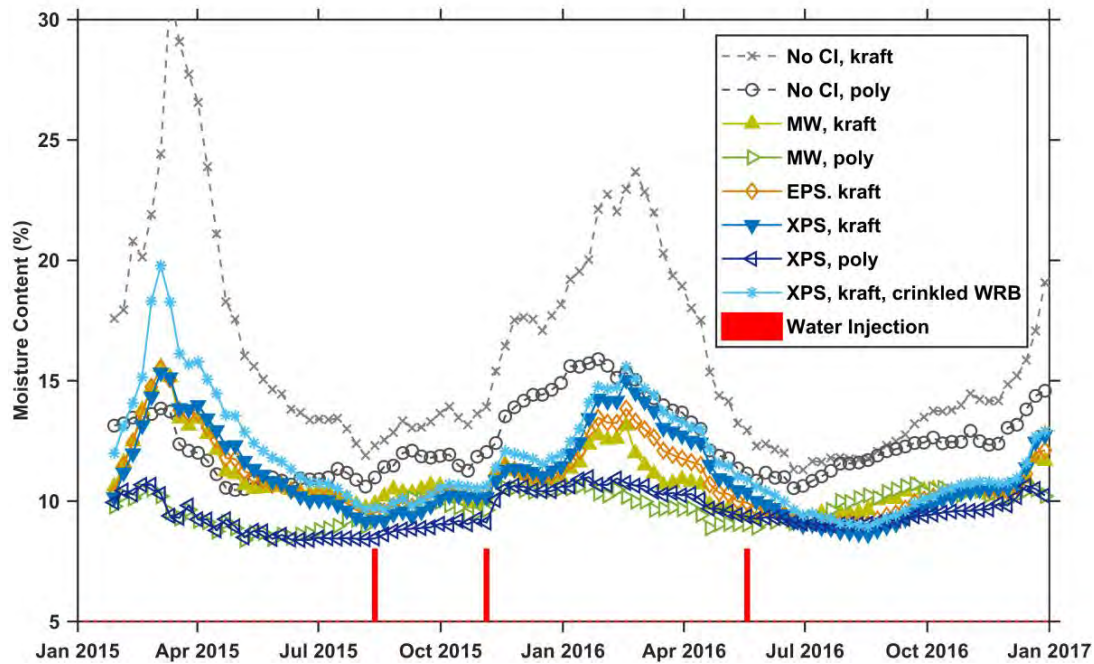

Figure 2. Weekly average moisture content of OSB in north-facing walls (average of sensors in OSB near top plate and bottom plate).

Figure 3. Weekly average moisture content of OSB at mid-height in north-facing walls (average of sensors in the field of the water injection system).

## CONCLUSIONS

This cold-climate monitoring study provides further support to the conclusion that adding continuous exterior insulation lowers the wintertime moisture content in wood structural panel sheathing. The drying rate of a wall with low-permeance exterior insulation and interior polyethylene after modest wetting was similar to a corresponding base wall without exterior

insulation. Drying rates were faster for walls with an interior kraft vapor retarder than polyethylene. In cold weather walls with vapor-open exterior insulation dried faster than base walls and walls with low-permeance exterior insulation. Under cold weather conditions and high interior humidity levels, a kraft vapor retarder did not prevent moisture accumulation in the OSB sheathing in the base wall without exterior insulation, though it dried out quickly in warmer weather. This study did not quantify risk of moisture damage. Further work is ongoing to combine this field study with laboratory and modeling research to develop strategies to minimize moisture risks in energy efficient wood-frame walls.

### ABSTRACT

Moisture retention curves describe the moisture storage property of porous building materials. Currently available experimental methods for measuring moisture retention curves are often demanding in equipment and moreover not always suited for the adsorption process in most of the capillary moisture content range. This paper proposes a novel and simple technique – the psychrometer method – and validates it by the tests on calcium silicate and ceramic brick. In this experiment the moisture content of the samples experiencing adsorption and desorption processes is determined gravimetrically, while the corresponding capillary pressures in the samples are measured with a chilled-mirror dew-point psychrometer. Comparisons are made with results from mercury intrusion porosimetry, pressure plate/membrane and desiccator tests. It is shown that this psychrometer method is simple and reliable for both adsorption and desorption processes for capillary pressures below  $-1 \cdot 10^5$  Pa. When the capillary pressure is around or above  $-1 \cdot 10^5$  Pa, the psychrometer method is no longer very accurate, and other experimental techniques should be employed.

### KEYWORDS

psychrometer, capillary pressure, moisture content, retention curve, porous building material

### INTRODUCTION

Hygic properties of porous building materials are indispensable input parameters for analyzing the hygrothermal performance of building envelopes and the built environment (Defraeye et al. 2013; Zhao and Plagge, 2015). In general, hygic properties can be classified as moisture storage and transport properties, characterizing how much moisture can be stored in and how fast moisture can be transported through a material, respectively. Moisture storage properties are not constant; instead, they depend on the ambient humidity. Moisture storage properties are normally depicted either by moisture sorption isotherms, i.e. moisture content ( $w$ , kg/m<sup>3</sup>) as a function of relative humidity (RH, -), or by moisture retention curves, i.e. moisture content in function of capillary pressure ( $p_c$ , Pa). As RH and  $p_c$  are interchangeable through the Kelvin-Laplace equation, sorption isotherms and retention curves are equivalent. In this paper we use moisture retention curves to describe the moisture storage properties.

Because of hysteresis, moisture retention curves are usually not a single-valued function but process-dependent. As shown in Figure 1, for a complete characterization in the full humidity range, there are at least three important curves: the adsorption curve starting from the dry state, and two desorption curves, starting from the saturated moisture content ( $w_{sat}$ , kg/m<sup>3</sup>) and the capillary moisture content ( $w_{cap}$ , kg/m<sup>3</sup>) respectively.

In the hygroscopic range – where water vapor dominates – the static gravimetric method (e.g. the manual desiccator test (Feng et al. 2013) or the automatic sorption balance (Garbalińska et al. 2017)) is simple and reliable. In the over-hygroscopic range – where liquid water is more important – the currently available experimental techniques are unfortunately less satisfactory. Table 1 summarizes the characteristics of several of these methods. Clearly, none of them can measure the moisture retention curves completely. Even when combined, much information for the adsorption process in the capillary range is still not measurable.

Figure 1. Moisture retention curves.

Figure 2. A schematic chilled-mirror dew-point psychrometer (Leong et al. 2003).

Table 1. Characteristics of several methods for measuring moisture retention curves

Method	Mercury intrusion porosimetry (Roels et al. 2001)	Traditional pressure plate/membrane (Hansen, 1998)	Modified pressure plate (Fredriksson and Johansson, 2016)
Equipment price	Very expensive	Expensive	Expensive
Availability	Common	Common	Rare
Toxicity	High (mercury)	Low	Low
Procedure	Simple	Complicated	Complicated
Data processing	Complicated	Simple	Simple
Applicable $p_c$ range	$0 \sim -2 \cdot 10^8$ Pa	$0 \sim -1 \cdot 10^7$ Pa	$0 \sim -5 \cdot 10^5$ Pa
Applicable process	Desorption from $w_{sat}$	Desorption from $w_{sat}$ and $w_{cap}$	Adsorption
Duration	Hours ~ days	Weeks ~ months	Weeks ~ months
Others	May not suit cement-based materials	Measurements easily fail	Measurements easily fail

To solve these problems, this paper proposes a novel experimental method – the psychrometer method. It features in simplicity, reliability and most importantly, the capability to do both adsorption and desorption measurements in the full humidity range. In the following sections, we will first introduce the principle of the psychrometer method. Then the validation measurements on calcium silicate and ceramic brick are explained. Finally, our experimental results are presented and compared with extra data from other methods.

## METHODS

The key to obtaining moisture retention curves is to determine the corresponding  $w$  and  $p_c$  in the sample. Moisture content  $w$  can be easily obtained through the gravimetric method, while capillary pressure  $p_c$  can be obtained by holding the sample in a sealed chamber and measure the humidity of the air inside caused by the water evaporation from the sample. In the over-hygroscopic range the air humidity is close to saturation, thus the widely used RH sensors are no longer reliable and psychrometers instead become a much better choice. Cardoso et al

(2007) studied different types of psychrometers profoundly, and found that many factors – such as temperature, hysteresis, calibration and equilibrium time – all have an impact on the results. After comprehensive comparisons, the chilled-mirror dew-point psychrometer was recommended.

In this study, we adopted the chilled-mirror dew-point psychrometer for the humidity measurement. The instrument model is WP4C, produced by Decagon Devices, Inc (a schematic is illustrated in Figure 2). It is reported by the manufacturer that this psychrometer has an accuracy of  $\pm 5 \cdot 10^4$  Pa in the range of  $0 \sim -5 \cdot 10^6$  Pa and  $\pm 1\%$  for  $-5 \cdot 10^6 \sim -3 \cdot 10^8$  Pa. More details about the psychrometer can be found in (Leong et al. 2003).

During the test, calcium silicate (density:  $271 \text{ kg/m}^3$ ) and ceramic brick (density:  $1818 \text{ kg/m}^3$ ) were cut into samples with a diameter of 3 cm and a thickness of 0.5 cm. The dry mass of each sample was determined with a balance with a resolution of 1 mg after oven drying at  $70^\circ\text{C}$  for at least one week. For desorption measurements, the samples were first vacuum saturated and then exposed to 97% or 94% ambient RH (controlled by saturated salt solutions) at  $23 \pm 0.5^\circ\text{C}$ . At certain points in time, the desorption process was interrupted by sealing samples into the small sample cups. Trial tests showed that after several hours, the capillary pressure and moisture content distributions within the samples reached equilibrium, indicated by stable psychrometer readings. For this reason, we always carried out the measurements on samples having been isolated overnight. The capillary pressure was measured with the WP4C psychrometer and the wet mass was measured with the balance. Resultantly, the desorption curve starting from  $w_{sat}$  in the capillary range was determined. Reversibly, we measured adsorption curve in the capillary range by putting samples pre-conditioned by adsorption at 97% ambient RH above pure water in a closed container, with a similar process for the determination of capillary pressure and moisture content.

It should be mentioned that for calcium silicate the adsorption progressed very slowly when the humidity is extremely high, while for ceramic brick the adsorption directly from air can hardly result in an observable change in moisture content. For those cases, we applied some tiny water drops directly on the samples for acceleration of the conditioning. To check the applicability of the psychrometer method in the hygroscopic range, we also exposed samples to lower RHs for measurements, as in the desiccator test.

It should also be noted that according to the working principle of the chilled-mirror dew-point psychrometer, an underestimation of  $w$  is inevitable due to the evaporation. However, we estimate the total volume of the sealed chamber at 50 mL. A simple calculation reveals that under our experimental conditions 1.1 mg water vapor could yield 100% ambient RH in such volume. Our sample size is roughly  $3.5 \cdot 10^{-6} \text{ m}^3$  in size, hence the underestimation of  $w$  is just around  $0.3 \text{ kg/m}^3$ , which is completely negligible.

## RESULTS

Figure 3 illustrates the experimental results obtained from the psychrometer method described in the previous section. For calcium silicate it is clearly reflected that both the adsorption and desorption curves have been obtained throughout the full humidity range. The results obtained by applying tiny water drops on the samples for accelerating the adsorption process also seem reasonable. It should be noted that even with the tiny water drops on the samples, the adsorption still progressed very slowly, as the whole adsorption process took more than 6 months. Consequently, for capillary pressures above  $-1 \cdot 10^5$  Pa ( $\log_{10}(-p_c) < 5$ ), we failed to obtain the adsorption curve.

For ceramic brick the general shape of the water retention curves can be observed. However, the data points display large scatters for the desorption process, and the hysteresis phenomenon also seems illogical (the desorption curve should stay above the adsorption curve). This should be explained by the fact that the ceramic brick used in this study has relatively large pores, with a median radius around  $4 \cdot 10^{-6}$  m. Thus, a large drop/rise of the retention curves around  $-3.2 \cdot 10^4$  Pa ( $\log_{10}(-p_c) \approx 4.5$ ) is expected. The psychrometer used in this study has an accuracy of  $\pm 5 \cdot 10^4$  Pa in that range. Consequently, the measured  $p_c$  here are not very reliable.

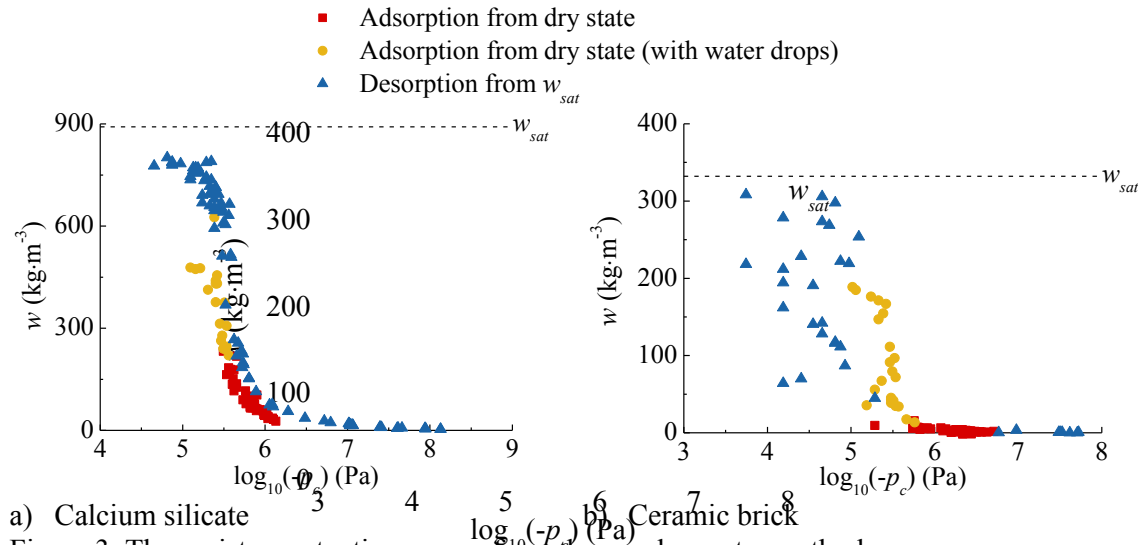

Figure 3. The moisture retention curves from the psychrometer method.

## DISCUSSION

To validate the accuracy of the psychrometer measurements, we performed mercury intrusion porosimetry (Roels et al. 2001), pressure membrane (Hansen, 1998) and desiccator (Feng et al. 2013) experiments on the same batch of calcium silicate for comparison. Pressure plate results were also cited from the HAMSTAD project (Roels et al. 2003). As is clearly reflected in Figure 4.a, in the over-hygroscopic range the desorption results from the psychrometer method are generally close to the results from the other methods, albeit that the deviations around  $-1 \cdot 10^5$  Pa ( $\log_{10}(-p_c)=5$ ) appear to be more significant. Similarly shown in Figure 4.b, in the hygroscopic range for both adsorption and desorption processes the psychrometer method provides slightly different but reasonable results when compared to other methods.

For ceramic brick the situation is less promising. As illustrated in Figure 5, when compared to results from mercury intrusion and pressure plate tests, the psychrometer method results in a cloud of results – scattering irregularly in the range  $\log_{10}(-p_c)=4-5$ , reflecting the limitation of the psychrometer method, due to its limited accuracy in this  $p_c$  range. However, it should be noticed that the results from mercury intrusion and pressure plate tests are neither very close, and it is difficult to judge which method is more reliable here. Further experimental methods – such as the hanging water column method (Plagge et al. 2007) – are hence necessary to be developed and validated for the  $p_c$  range around and above  $-1 \cdot 10^5$  Pa.

Last but not least, in this study we just performed the measurements starting from dry state and  $w_{sat}$ . The principle of the proposed psychrometer method is obviously also valid for the adsorption and desorption processes starting from other initial conditions.

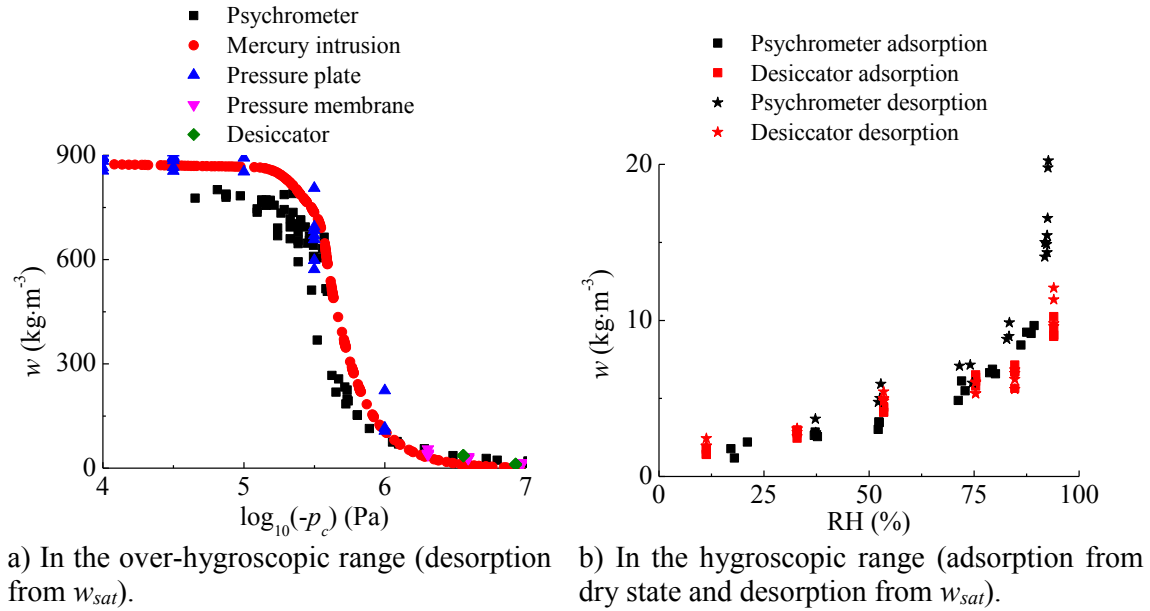

Figure 4. Comparison of the experimental results from different methods on calcium silicate.

Figure 5. Comparison of the experimental results from different methods on ceramic brick (desorption from  $w_{sat}$  in the over-hygroscopic range).

## CONCLUSIONS

This paper proposes a novel experimental approach – the psychrometer method – for determining the moisture retention curves of porous building materials. Measurements on calcium silicate and ceramic brick were conducted and the results were validated by comparing with experimental results obtained from the mercury intrusion porosimetry, pressure plate/membrane and desiccator tests. The psychrometer method demonstrates its simplicity, reliability and wide applicable range for capillary pressures below  $-1 \cdot 10^5$  Pa, covering almost the full humidity range. When the capillary pressure is around or above  $-1 \cdot 10^5$  Pa, other more reliable experimental techniques should be developed and validated.

### **ABSTRACT**

The unsaturated liquid permeability is a crucial hygric property of porous building materials. Its direct measurement is very challenging however, because currently available experimental protocols are either demanding in test facilities, complicated in data processing, or limited in moisture content range. Inspired by the osmosis phenomenon, we study the possibility to apply semi-permeable membranes for directly measuring the liquid permeability of porous building materials. The key principle is studied profoundly and a simple experimental set-up is constructed. Trial tests on calcium silicate insulation and autoclaved aerated concrete are performed. Results show that the experimental set-up can be used to measure the liquid permeability, but strongly underestimates its value in its current form. Based on an in-depth analysis, we believe that the underestimation should be attributed to the pore clogging to the semi-permeable membrane due to the extremely high concentration of salt in the solution. Hence, in a future iteration, we will turn to unsaturated solutions with lower salt concentrations to alleviate the problem.

### **KEYWORDS**

liquid permeability, building material, semi-permeable membrane, hanging water column

### **INTRODUCTION**

Hygric properties are key characteristics of porous building materials. They are indispensable for analyzing the hygrothermal performance of building envelopes and the built environment (Defraeye et al. 2013; Zhao and Plagge, 2015). Of all hygric properties, the liquid permeability ( $K_l$ ,  $\text{kg}\cdot\text{m}^{-1}\text{s}^{-1}\text{Pa}^{-1}$ ) is one of the most important.

Liquid permeability depends on moisture content. For (nearly) saturated samples, the liquid permeability can be easily measured by the water column test (Pedescoll et al. 2011) and the tension infiltrometer test (Zhao and Plagge, 2015). However, if the moisture content is lower, the direct measurement of the liquid permeability becomes rather difficult. One solution is to perform the Boltzmann transformation of the moisture content profiles visualized during a capillary absorption test for obtaining liquid diffusivity and subsequently liquid permeability. However, this protocol requires expensive experimental facilities – such as the X-ray set-up (Roels and Carmeliet, 2006) – and the data processing is complicated with large scatters. The drying test is another option for obtaining the liquid permeability below the capillary moisture content (Zhao and Plagge, 2015). However, this is basically an inverse method, requiring a lot of parameter tuning on the permeability model to approximate the measurement. It is therefore not straightforward and large uncertainties also exist.

From the review above, it's clear that current experimental protocols are either demanding in facilities, complicated in data processing, or limited in the moisture content range. Thus the

simple, reliable and full-range measurement of liquid permeability remains a challenging task. Inspired by the osmosis phenomenon, we investigate the possibility to employ the semi-permeable membrane for directly measuring the liquid permeability of porous building materials in a wide moisture content range. In this method, saturated salt solutions are used to exert a capillary pressure gradient across the sample, and semi-permeable membranes are used to protect against salts' interference. The permeability of the sample can hence be obtained from the measured liquid flux and the capillary pressure difference. Specifically, in the following section we will introduce the osmosis phenomenon. Next, our new experimental set-up with a semi-permeable membrane is described, and trial tests on calcium silicate insulation and autoclaved aerated concrete are explained. After that the experimental results are presented and analyzed. Finally, the future improvement of this method is discussed.

## METHODS

In this section, we will first introduce the osmosis phenomenon. Then our new experimental set-up with a semi-permeable membrane is described, and trial tests on calcium silicate insulation and autoclaved aerated concrete are presented.

### Osmosis phenomenon and the semi-permeable membrane

Osmosis is a common phenomenon in nature and has been widely adopted in many disciplines. As illustrated in Figure 1, when a solution and a pure solvent are separated by a proper semi-permeable membrane, the solvent particles can diffuse through the membrane in both directions while the solute particles are blocked. Due to the concentration difference of the solvent particles, a net flow of solvent from the pure solvent side towards the solution can be observed. This is the so-called osmosis phenomenon (Feher, 2017).

Figure 1. The osmosis phenomenon.

Figure 2. Photo of our semi-permeable membrane set-up

The osmosis phenomenon shows that a semi-permeable membrane exclusively allows the flow of solvent. It is therefore possible to use saturated salt solutions to exert a constant driving force for liquid water flowing through a sample, with semi-permeable membranes to protect the sample against salts' interference. The liquid permeability can thus be derived from the water flux and the capillary pressure difference. By altering the saturated salt solutions, the capillary pressure difference over and the moisture content in the sample can be controlled. This method is therefore in principle applicable to a wide moisture content range.

### Experimental set-up

Based on the principle explained in the previous section, a simple experimental set-up is designed and constructed (Figure 2 and 3). In this set-up, a sample of known cross-sectional area ( $A$ ,  $\text{m}^2$ ) and thickness ( $T$ ,  $\text{m}$ ) is laterally sealed with epoxy to obtain a 1-D liquid flow. The top of the sample is in direct contact with pure water, for which the capillary pressure ( $p_c$ , Pa) is assumed 0 Pa. The sample bottom sits on a semi-permeable membrane in contact with a saturated  $\text{K}_2\text{SO}_4$  solution with an RH of 97% at  $22 \pm 1^\circ\text{C}$  corresponding to a  $p_c$  of  $-3.6 \cdot 10^6$  Pa. The additional water head difference on both sides of the sample, originating from different water levels in the container and burette, is negligibly small relative to the used  $p_c$  difference ( $\Delta p_c = 3.6 \cdot 10^6$  Pa). Consequently, the capillary pressure difference is assumed the only driving force for the water flow through the sample.

When the flow is ongoing, the pure water in the water tank passes through the sample and the semi-permeable membrane, entering the solution tank, where undissolved salt exists and a magnetic stirring system is installed to keep the solution saturated all the time. In this way a constant  $\Delta p_c$  can be maintained and a steady flow can be reached after an initial period. The volumetric flow rate ( $G$ ,  $\text{m}^3 \cdot \text{s}^{-1}$ ) can be easily measured by reading the burette regularly. Given that the burette is part of the container with the saturated solution, the volumetric flow rate thus relates to the inflowing pure water and the additionally dissolved salt.

Figure 3. Schematic of our semi-permeable membrane set-up.

Assuming a certain amount of pure water ( $\Delta m_{\text{water}}$ , kg) passes through the sample and the membrane into the solution tank. The  $\text{K}_2\text{SO}_4$  dissolved by it ( $\Delta m_{\text{K}_2\text{SO}_4}$ , kg) amounts to  $s \cdot \Delta m_{\text{water}}$ , where  $s$  is the solubility of  $\text{K}_2\text{SO}_4$ ,  $\text{kg}(\text{K}_2\text{SO}_4) \cdot \text{kg}(\text{water})^{-1}$ . Consequently, in the solution tank the increased saturated  $\text{K}_2\text{SO}_4$  solution ( $\Delta m_{\text{solution}}$ , kg) occupies a volume of  $\Delta V_{\text{solution}}$  ( $\text{m}^3$ ):

$$\Delta V_{\text{solution}} = \frac{\Delta m_{\text{solution}}}{\rho_{\text{solution}}} = \frac{\Delta m_{\text{water}} + \Delta m_{\text{K}_2\text{SO}_4}}{\rho_{\text{solution}}} = \frac{\Delta m_{\text{water}} + s \cdot \Delta m_{\text{water}}}{\rho_{\text{solution}}} \quad (1)$$

where  $\rho_{solution}$  is the density of saturated  $K_2SO_4$  solution,  $kg \cdot m^{-3}$ . Since previously undissolved  $K_2SO_4$  is now dissolved, its volume ( $\Delta V_{K_2SO_4}$ ,  $m^3$ ) should therefore be accounted for when calculating the net volume change ( $\Delta V_{net}$ ,  $m^3$ ) in the solution tank:

$$\Delta V_{net} = \Delta V_{solution} - \Delta V_{K_2SO_4} = \frac{\Delta m_{water} + s \cdot \Delta m_{water}}{\rho_{solution}} - \frac{s \cdot \Delta m_{water}}{\rho_{K_2SO_4}} \quad (2)$$

where  $\rho_{K_2SO_4}$  is the density of  $K_2SO_4$ ,  $kg \cdot m^{-3}$ . Now we define a coefficient  $c$  ( $kg \cdot m^{-3}$ ) by:

$$c = \frac{\Delta m_{water}}{\Delta V_{net}} = \frac{1}{\frac{1+s}{\rho_{solution}} - \frac{s}{\rho_{K_2SO_4}}} \quad (3)$$

At  $22^\circ C$  we obtain  $c=1009 \text{ kg} \cdot \text{m}^{-3}$ , meaning that  $1 \text{ m}^3$  increase in the net volume of the solution tank (indicated by the burette) reflects  $1009 \text{ kg}$  of inflowing pure water. With the help of the known  $c$ , we can describe the mass balance of the transport process by:

$$G \cdot c = \frac{\Delta p_c}{R_{total}} \cdot A \quad (4)$$

where  $R_{total}$  is the total liquid transport resistance,  $m^2 s Pa \cdot kg^{-1}$ .  $R_{total}$  is the sum of the membrane's resistance  $R_{membrane}$  ( $m^2 s Pa \cdot kg^{-1}$ ) and the sample's resistance  $R_{sample}$  ( $m^2 s Pa \cdot kg^{-1}$ ):

$$R_{total} = R_{membrane} + R_{sample} = R_{membrane} + \frac{T}{K_l} \quad (5)$$

Combining Eq.(4) and (5), the liquid permeability of the sample can be finally derived:

$$K_l = \frac{T}{\frac{\Delta p_c \cdot A}{G \cdot c} - R_{membrane}} \quad (6)$$

After the test, the moisture content of the sample ( $w$ ,  $kg \cdot m^{-3}$ ) can be obtained gravimetrically, while  $R_{membrane}$  can be obtained from similar measurements without the sample in the set-up.

To completely fulfill the measurements in a wide moisture content range, a double-membrane set-up with two semi-permeable membranes separating two different saturated salt solutions on both sides of the sample is needed. At this trial stage, we simplify the set-up to the single-membrane system described above. This set-up restricts the applicable moisture content range to near saturation, but is adequate for preliminary validation. Its success will call for a slightly more complicated double-membrane set-up.

### Trial measurements

As two representative porous building materials, calcium silicate insulation and autoclaved aerated concrete are cut into duplicate cylindric samples, with a diameter of  $10 \text{ cm}$  and a thickness of  $2$  to  $4 \text{ cm}$ . As a reference, falling-head water column tests are also performed for comparison. Due to the page limit of this paper, we will not explain the water column method specifically, and details can be found in (Pedescoll et al. 2011).

## RESULTS

Figure 4 illustrates the experimental results obtained from the semi-permeable membrane approach described in the previous section. Results from water column tests are also included for reference. As is clearly shown, for both calcium silicate insulation and autoclaved aerated concrete, the measured  $K_l$  reflects an expected moisture content dependence – the higher the  $w$  is, the larger the  $K_l$  is. However, it is very noticeable that the measured  $K_l$  values from two methods differ about 4 orders of magnitude. This is far beyond what common experimental errors can explain, and more profound reasons must exist.

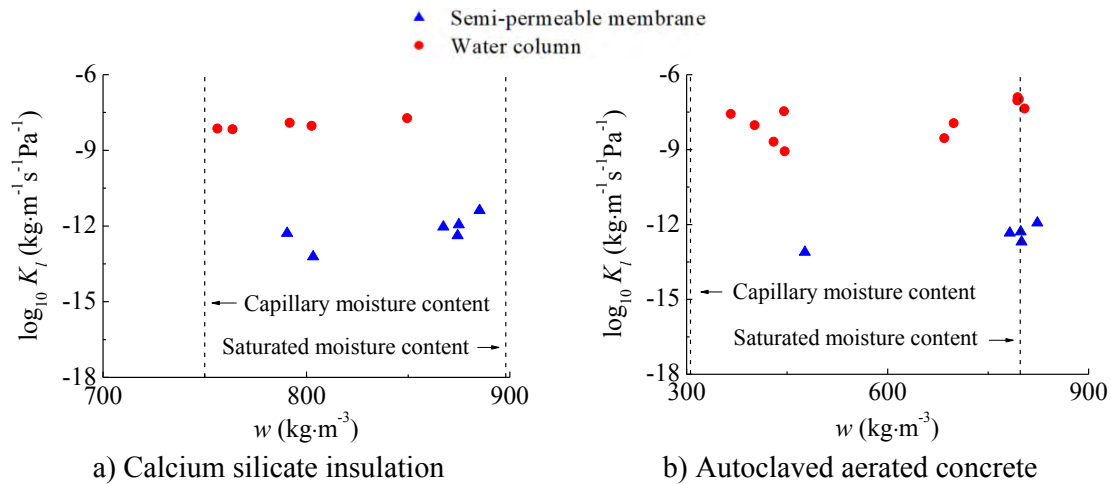

Figure 4. Experimental results of the semi-permeable membrane and water column tests.

## DISCUSSIONS

The water column test is a well-established method. Our water column measurements on other materials agree nicely with other data sources. Thus we believe the water column results in Figure 4 are trustworthy and the semi-permeable membrane approach underestimates  $K_l$ .

The first explanation for the underestimation could be that the transport area of the sample should be corrected for the masked sample edge in the set-up. However, the total diameter of the sample is 10 cm while the unmasked diameter is roughly 9 cm. Simple estimation reveals that the underestimation of  $K_l$  caused by the masked edge should be less than  $1-(9/10)^2 \approx 20\%$ , while from Figure 4 we should focus on the difference amounting to 4 orders of magnitude. Consequently, the masked edge is not a primary reason for the underestimation.

The second possibility is the change of driving force. Ideally no salt can pass the semi-permeable membrane, while in practice a small amount of salt may still penetrate through the membrane and the sample into the tank for pure water, reducing the real driving force and causing the underestimation of the final  $K_l$ . However, reducing the  $\Delta p_c$  to  $1/10^4$  of the assumed original value ( $3.6 \cdot 10^6$  Pa) means that the pure water tank above the sample should almost get saturated. The membrane used in this study has a NaCl rejection capability as high as 99.5%, while the salt used in our test is  $\text{K}_2\text{SO}_4$ , relatively more difficult to pass through the membrane. Consequently, it is unimaginable to assume an almost saturated solution in the upper tank due to the negligible salt transfer through the membrane. Direct measurements of the capillary pressure and electrical conductivity in both tanks also provide support.

Another explanation could be that the overall transport resistance is underestimated due to the existence of air layers on both sides of the membrane, which destroys the hydraulic continuity

of the system. An evidence is that the membrane resistance  $R_{membrane}$ , when measured separately by the semi-permeable membrane method and the water column method, comes to values of  $1.4 \cdot 10^{10} \text{ m}^2\text{sPa}\cdot\text{kg}^{-1}$  and  $1.1 \cdot 10^8 \text{ m}^2\text{sPa}\cdot\text{kg}^{-1}$  respectively. When there is only the membrane without the sample in the semi-permeable membrane set-up, the potential air layer between the membrane and the sample no longer exists, and this clearly reduces the difference between the measured  $R_{membrane}$  values from both methods. To furthermore validate this hypothesis, we turned the presently vertical system into a horizontal one for complete elimination of the air layers. Unfortunately, the newly measured  $R_{membrane}$  remained almost unchanged, indicating that the air layer should not be the most crucial reason.

The last and most plausible reason is that the pore clogging due to the extremely high salt concentration could happen to the semi-permeable membrane and hence increases the overall transport resistance. In our recent trials, we switched to unsaturated  $\text{K}_2\text{SO}_4$  solution, obtaining  $R_{membrane}$  around  $2 \cdot 10^9 \text{ m}^2\text{sPa}\cdot\text{kg}^{-1}$ , 10 times smaller than the saturated case. Encouraged by this supporting evidence, we plan to use unsaturated solutions of different salts and concentrations for further study and hopefully can succeed in the near future.

Albeit the semi-permeable membrane method is still under development, its principle is completely plausible. Theoretically, the liquid permeability below the capillary moisture content could be measured directly with two semi-permeable membranes on both sides of the sample, hence filling the gap of currently available experimental protocols.

## CONCLUSIONS

This paper proposes a novel experimental approach – the semi-permeable membrane method – for determining the liquid permeability of porous building materials. A simple set-up has been constructed and trial tests on calcium silicate insulation and autoclaved aerated concrete are performed. Traditional water column tests are also conducted as a reference. Results show that our current semi-permeable membrane set-up strongly underestimates the liquid permeability, most plausibly due to the pore clogging to the semi-permeable membrane. In the future we are going to use unsaturated salt solutions to solve this problem.

## ACKNOWLEDGEMENT

### ABSTRACT

In this study, investigations on the thermal performance of a solar air heating façade system were carried out. The system consists of a double skin building envelope composed by an opaque internal face, with a novel solar absorbent layer and a glazed external face. This kind of system, particularly suitable to refurbish existing building envelopes, is designed to work as a fan-assisted air supply, which mitigates the heating and ventilation demand during the winter period.

An experimental campaign was set up using a full scale façade module in order to thoroughly characterize its thermal behavior and the air flow rate. This module was also compared with a similar one, having a conventional dark flat surface instead of the above mentioned solar absorbent layer. The system has proven great potential in both reducing the energy demand and maintaining proper the ventilation rates in the winter period. In facts, results show that the cavity air temperature reaches values close to 90°C (unventilated buffer mode) and that, in fan-assisted mode, the air temperature introduced in the indoor environment was up to 25°C higher than the external one. Moreover, the supplied air flow rate was of about 26 m<sup>3</sup>/h, providing about 0.5 air changes per hour (ACH) in a typical residential room (16 - 22 m<sup>2</sup> of floor area).

### INTRODUCTION

Providing feasible solutions to take action against building energy consumption while promoting on-site energy generation through renewable resources is of paramount importance nowadays. Particular effort needs to be put into the energy refurbishment of the existing building stock, since it is largely composed by old, energy-demanding constructions, characterized by high total energy demands, not evenly distributed over time.

According to the Building Performance Institute Europe (BPIE), a deep renovation of the existing buildings could cut the 36% of their energy consumption by 2030 (Building Performance Institute Europe, 2018). Solar air heating façade systems can provide an effective solution: not only they guarantee an improvement in terms of thermal insulation, but they also mitigate buildings heating and ventilation demand by exploiting solar energy. The analysed façade system presents similar technological features of a classic Trombe Wall (Trombe and Michel, 1974), which consists of an external transparent layer and an internal opaque one, separated by an air gap. Usually, the classic Trombe Wall presents two vents installed at the bottom and at the top of the opaque layer. In this way, indoor air flows through the bottom air gap, it heats up due to the greenhouse effect and enters back into the internal environment through the top vent (Özbalta and Kartal, 2010).

Several studies have investigated different ventilation modes of the Trombe Wall. Considering a total of four vents, placed at the top and at the bottom of both the transparent (external) layer and the opaque (internal) layer, there are four main ventilation modes

(Tiantian, et al. 2014): not ventilated wall (Buffer mode); thermal insulation mode; natural ventilation mode (summer cross ventilation); space heating mode.

When the façade component is needed to function mainly as an insulation layer, the buffer or the thermal insulation mode are usually employed. The first mode is applied during the heating season, with all the vents closed, while the second one is used during the cooling season, with both the outer vents opened. It was demonstrated that by using these strategies the façade element was able to significantly reduce the thermal transmittance of the wall (in winter) and to improve solar heat removal (in summer) (Callegari, et al. 2015).

In the natural ventilation mode, the vents at the bottom of the opaque layer and at the top of the transparent part are opened. This ventilation mode results the most efficient during the cooling season (Krüger, et al. 2013; Gan, 1998).

The space heating mode is employed during the heating season in order to supply pre-heated air into the internal environment. In this ventilation mode the vent at the bottom of the transparent layer and at the top of the opaque layer are opened, and it was defined as the best mode during the heating season (Bajc, et al. 2015; Briga-Sá, et al. 2017).

This last ventilation mode is more efficient when the external layer of the opaque component is able to maximise the solar radiation-to-heat conversion, as a solar receiver (López-Herraz, et al. 2017), and it was proved that the application of a high absorption coating on the exterior surface of the massive wall can improve the absorption and storage capacity of the Trombe Wall (Nwachukwu and Wilfred, 2008; Özbalta and Kartal, 2010). Usually, high absorption coefficient values correspond to dark colours. This might lead to have a limited choice of materials and coloured coatings to be used, slowing down the spread of this technology mainly for aesthetic reasons.

In the present study, the fan-assisted solar air heating façade operates in space heating mode. The analysed façade is provided of an outdoor vent, placed at the bottom of the external layer, which enables external air to flow through the entire height of the air cavity. This flow is generated by an axial fan placed at the top part of the opaque layer, connecting the air cavity with the indoor environment. In this way, a controlled rate of air can be introduced in the indoor environment. Moreover, while dark coloured surfaces are used in Trombe walls to enhance the greenhouse effect happening in the air cavity, a novel lightweight and light coloured layer was here used.

## METHODS

During a previous experimental campaign carried out on a façade system called Naturwall® (Callegari, et al. 2015), two types of façade component were installed on the south side of the test apparatus, an outdoor test cell called TWINS (Testing Window INnovative System), in order to evaluate the behaviour of a solar air heating component.

Both components are characterized by a first external transparent layer (6 mm), an air gap and an inner opaque component. The opaque component consists of (from the inside to the outside) an OSB (Oriented Strand Board) layer (1.8 cm), a honeycomb cardboard insulation layer (8 cm) and another OSB panel (1.25 cm).

Module D (Figure 2) is 0.82 m high and 0.82 m wide and it is characterized by having the external OSB layer painted in black, a non-ventilated air gap and a clear glass as the external transparent layer. The original Module A (Figure 3), 3.07 m high and 0.82 m wide was modified by the Authors adding an additional 1.5 cm cellular polycarbonate layer with a particular geometry against the OSB panel face toward the air gap and installing an axial fan at the top of the opaque component in order to guarantee about 26 m<sup>3</sup>/h of air flow rate. Moreover, as external transparent layer a compact polycarbonate panel was chosen.

The main measured entities were the incident solar radiation, the temperatures (both air and surface ones) and the heat fluxes (between the cavity and the internal environment).

Measurements were performed through pyranometers, type T thermocouples and heat flux meter sensors (Figure 2, Figure 3) recorded every 15 minutes through a Datataker. A first set of measurement was aimed at evaluating the effects of the cellular polycarbonate so to assess in the other analyses its influence on the global performance. A comparison between Module A and Module D was thus carried out, making the two modules operating in the same conditions: Module A fan was turned off and the vent was air-tight closed.

Figure 1 – Module A and module D installed on the outdoor test cell (TWINS)

Figure 2- Scheme of the functional layers and the sensors used in Module D

Figure 3 - Scheme of the functional layers and the sensors used in Module A.

In order to provide a quantitative indicator to assess the capability of the ventilated module to mitigate the heating and ventilation loads, solar efficiency ( $\eta_{sol}$ ) was defined considering the heat supplied into internal environment ( $Q_{supply}$ ) and the incident solar radiation measured on the vertical plane ( $Q_{sol}$ ) according to Equation 1:

$$\eta_{sol} = \frac{\sum_n^m Q_{supply}}{\sum_n^m Q_{sol}} \cdot 100 = \frac{\sum_n^m \dot{V} \cdot C_p \cdot \rho \cdot (T_{out} - T_{ext})}{\sum_n^m I_{sol} \cdot A} \quad (1)$$

where  $n$  and  $m$  are respectively the beginning and the ending time of the examined day;  $\dot{V}$  is the air flow rate ( $m^3/s$ );  $C_p$  is the air specific heat ( $J/kgK$ );  $\rho$  is the air density ( $kg/m^3$ );  $T_{out}$  and  $T_{ext}$  are respectively the supply and the external air temperatures ( $K$ );  $I_{sol}$  is the incident solar radiation ( $W/m^2$ ) and  $A$  is the surface area ( $m^2$ ).

## RESULTS AND DISCUSSIONS

Figure 4a shows a sunny winter day characterized by high solar radiation, which reaches values of  $800 W/m^2$ . It is possible to notice that, during the hours of maximum solar radiation, external air temperature ranges between  $10^\circ C$  and  $14^\circ C$ , while the air temperatures in the two cavities are of  $83^\circ C$  and of  $89^\circ C$  respectively for Module A ( $T_{cav\_2A}$ ) and Module D ( $T_{cav\_D}$ ).

Figure 4b shows experimental data from Module A when ventilated by the above described axial fan. Solar radiation was stable throughout the day, with peak values of  $800 W/m^2$  and external air temperature of about  $20-23^\circ C$  between 12:00 and 18:00. At around 14:00 it is

possible to notice that the air cavity temperature at middle height ( $T_{\text{cav\_2A}}$ ) is of about  $51^{\circ}\text{C}$ , at the highest measurement point ( $T_{\text{cav\_3A}}$ ) is  $53^{\circ}\text{C}$  and enters the indoor environment ( $T_{\text{out}}$ ) at  $49^{\circ}\text{C}$ <sup>1</sup>. In these conditions, the solar efficiency for the analysed day (April 8<sup>th</sup>) is of about 20%.

Results shown in Figure 4 show that the cellular polycarbonate layer, although being characterized by a much lower absorption coefficient ( $\alpha$ ), is able to heat up the cavity air roughly as much as the black-painted surface. This is due to its particular geometry, which provides more exposed surface to the solar radiation.

Figure 4 – (a) Experimental data measured of the cavities air temperatures. (b) Module A: experimental data measured of the cavity air temperatures at the different heights and of the outlet temperatures.

When working as a solar air heating façade module (ventilation turned on), it was observed that a significant increase in temperature between the intake and the supply air occurred. Figure 4b shows an increase of about  $25^{\circ}\text{C}$  between external air temperature and the outlet one, meaning that the system was providing  $26 \text{ m}^3/\text{h}$  of air useful for both ventilation and heating purposes. Moreover, the solar efficiency (of about 20%) is in line with that of existing air heating collectors (VijayaVenkataRamana, et al. 2012).

## CONCLUSIONS

In this study the behaviour of an adaptive façade system was investigated through an experimental campaign. As a first step, a comparison between a novel solar absorption layer (the cellular polycarbonate) and a traditional dark surface (typical of Trombe walls) was carried out, demonstrating how both have almost identical effects on the air cavity

<sup>1</sup> It is worthy to mention that the thermocouple used to measure the outlet temperature is placed on the internal side of the opaque component, therefore a little drop in temperature occurs between the air cavity and the outlet temperature.

temperature. Then, assessment in terms of performance and efficiency of the façade system were performed through additional experimental measurements of Module A working in space heating mode (ventilation turned on).

From the obtained results it is possible to state that more aesthetically pleasant solutions for solar air heating façades are possible. Indeed, the use of a lighter material colour with an adequate geometry has demonstrated to be comparable to a flat, black surface in terms of capability of heating the cavity. This outcome could enable similar solutions to arise, resulting in an easier integration of solar air heating façade systems in buildings.

When operating in space heating mode, the façade showed interesting capabilities in rising the air temperature, since a 25°C difference in temperature was observed between external and outlet air. Moreover, the system solar efficiency of about 20% is absolutely comparable with that of existing solar air heating technologies.

Given the great potential of the system to lower building energy need for heating and ventilation, further studies need to be carried out to assess the façade behaviour over a longer period (the entire heating season), also evaluating different technological solutions for both the transparent and the opaque components. Moreover, different control strategies can be explored to best modulate ventilation over time, with potentially great impact on the overall façade efficiency.

### ABSTRACT

The steady state thermal model discussed in this paper is devoted to predict the temperatures and heat fluxes through a naturally ventilated DSF, having solar radiation and environmental temperatures as inputs. It is coupled with a fluid-dynamic model, based on a pressure loop, which takes into account both buoyancy and wind pressure at the openings.

The model has been validated against experimental data, basing on the prediction of the internal surface temperature of the DSF. Results show acceptable accuracy in the prediction of the heat flux towards the inside, even though they reveal a slight heat flux overestimation associated with dynamic effects. These observations lead to further investigate the role of DSF component capacities in order to increase the model accuracy and its applicability.

### KEYWORDS

Building simulation, Airflow measurement, Natural ventilation, Temperature measurements.

### INTRODUCTION

The Double Skin Facade (DSF) is a well-known technology, which might offer interesting adaptive features and improvements in terms of comfort and energy efficiency in buildings with large transparent facades. The evaluation of these benefits is still an open issue, due to reappearing difficulties in prediction of DSF thermal and energy performance as an integrated part of building envelope by means of well-established building simulation tools or recently developed models (Kalyanova et al. 2009; Manz & Frank, 2005).

Highly dynamic performance, initiated by fluctuating boundary conditions explain great complexity of experimental work for double-skin façade performance evaluation and thereby limited number of experimental studies to support validation of new and existing models for double-skin facades. Furthermore, existing experimental investigations (Kalyanova et al. 2007; Marques da Silva et al. 2015) underline multiple challenges related to investigation of DSF performance. Airflow measurement in a naturally ventilated cavity, measurement of the temperature under the strong solar exposure, as well as lack of standard, well-studied experimental methods for the measurement of the surface temperatures (with and without solar exposure) are found among the challenges. Experimental work carried in the of IEA ECBCS ANNEX 43/SHC Task 34 (IEA, 2007) had addressed some of these challenges in order to assemble a data set for empirical validation of building simulation software tools when double-skin façade performance evaluation is in question. This data set is applied for the validation of the model in this publication.

The thermal model discussed in this paper is an extension of a model already presented (Angeli et al. 2015, Dama et al. 2016 and 2017) in which the thermal and fluid dynamic ‘core’ of the ventilated cavity was validated having the channel surface temperatures as boundary conditions. In this work a suitable thermal network has been implemented to simulate the DSF having wind, solar radiation and environmental temperatures as inputs.

## EXPERIMENTAL SETUP

The Cube is an outdoor full-scale test facility located near the main campus of Aalborg University, Denmark. A photo of Southern and Northern façade of the facility is shown in Figure 1.

Figure 1. The Cube. Photo of Southern façade (left) and photo of Northern façade (right).

The double-skin façade is facing South and consists of an internal double-glazed layer (4-Ar16-4) and a single-glazed exterior layer. Specifics of the material properties of all constructions in the Cube can be found in (Larsen et al. 2014). The experiments are performed in the external air curtain functioning mode, i.e. with naturally ventilated air cavity.

Particularly relevant to the task of this paper is to mention the procedures for the measurement of air and surface temperatures when the sensors are exposed to direct solar radiation, as well as the measurement of incident solar radiation. In (Kalyanova et al. 2007) it is explained that the presence of direct solar radiation is an essential element for the façade operation, but it can heavily affect measurements of air temperature and may lead to errors of high magnitude using bare thermocouples and even adopting shielding devices. Taking this into consideration, the thermocouples in DSF cavity were protected from the influence of direct solar radiation. The air temperature was measured using the silver coated and ventilated tube to reduce the impact of incident solar radiation. Meanwhile, surface temperature was measured by attachment of the thermocouples (type K) to a surface, using highly conductive paste and then fixed to the surface using the transparent tape. Surface temperature sensors were also protected from the impact of incident solar radiation, using two following strategies, depending on position of the sensor (Figure 2):

- Highly reflective film of apx. size 20x20 mm shields the thermocouple 1.
- Highly reflective shield made out of thin aluminum foil has the dimensions to ensure shielding both thermocouples 2 and 3.

Figure 2. Shielding strategy from incident direct solar radiation. Left: Plan of DSF cavity. Right: Section of DSF cavity.

Thermocouples for the air temperature measurement were placed in the DSF at six different heights. Surface temperature is measured in the center of each glass pane. Uncertainty of equipment for the temperature measurement is estimated to maximum  $\pm 0.14$  °C, this uncertainty, however does not address the issues of the solar exposure, as well as the limitations of the surface temperature measurements related to attachment of the sensor to the surface.

### MODEL DESCRIPTION

The thermal model developed is based on steady state energy balance equations. It considers both convection and long wave radiation. The convection inside the channel is modelled by a simplified integral approach employing average bulk temperatures and superficial heat transfer coefficient correlations. The thermal model is coupled with a fluid-dynamic model, based on a pressure loop which takes into account both buoyancy and wind differential pressure at the openings as described by Dama (2017). Figure 3 describe the implemented DSF thermal network.

Figure 3. Thermal network of the ventilated channel.  $\phi_1$ ,  $\phi_2$  and  $\phi_3$  correspond to the solar radiation absorbed respectively by the glass of the outer skin, the external glass and the internal glass of the inner skin (double glazed unit).

Table 1 shows a summary of the correlations used for the surface heat transfer coefficients. A fictitious thermal resistance,  $R_v$ , is introduced to couple the air in the channel with the outdoor air, and is defined as in the follow:

$$R_v \equiv \frac{T_f - T_{in}}{\phi_v} \quad \phi_v \equiv \frac{\Phi_v}{H \cdot L} = \frac{L \cdot s \cdot \rho \cdot v \cdot c_p \cdot (T_{out} - T_{in})}{H \cdot L} \quad (1)$$

where  $T_f$  is the air bulk temperature inside the channel,  $\phi_v$  is the heat per unit area removed by ventilation,  $T_{in}$  is the inlet air temperature and  $T_{out}$  the outle

Using the definition in Equation 1 is possible to derive the following expression for  $R_v$ , which depends only on the air velocity and on the surface heat transfer coefficients:

$$R_v = \frac{e^{-kH} + kH - 1}{(h_{cv1} + h_{cv2})(1 - e^{-kH})} \quad k \equiv \frac{(h_{cv,1} + h_{cv,2})}{s \cdot \rho \cdot v \cdot c_p} \quad (2)$$

The complete angular characterization of the DSF glazing systems was obtained from LBNL Window. Table 2 reports the normal incidence properties of the glazing adopted in the experiments and in Window calculation. The Window optical characterization provides the inputs for Equation 3, which describes the heat absorbed by each glass.

$$\varphi_i = \alpha_i(\theta)G_{beam}(\theta) + \alpha_i^{diff}G_{diff} \quad i = 1,2,3 \quad (3)$$

## RESULTS AND DISCUSSION

An experimental validation of the thermal and fluid dynamic model of the ventilated channel using as boundary condition the glass surface temperatures was already presented (Dama et al. 2017). This work focuses on the thermal network implementation, which employs as input the environmental temperatures and the solar irradiance and allows to calculate the convective and radiative (long wave) heat transfer through the DSF towards the interior. This flux strictly depends on the surface temperature of the internal glass of the inner skin (double glazed unit). Figure 3 shows the measured and modelled internal surface temperature (position 3 in the drawing of Figure 2) during the 15 days of the experimentation. Table 3 reports the daily integrated values of the surface heat fluxes from the DSF toward the inside of the Cube, separating the positive contributes to negative ones.

Figure 4. Internal surface temperature of the inner skin, model versus measurements ( $T_{si\_model}/T_{si\_exp}$ ).  $T_{int}$  – internal air temperature.

The results show that the internal surface temperature is predicted with acceptable accuracy, even though a general overestimation is observed when solar irradiance heats up the DSF. For outward heat fluxes, the daily relative errors are below 6% during night time and around 12% in cloudy days. For inward fluxes the average overestimation is about 25%, and reduces to 15% in the last three days of the experimentation, with more stable solar and wind conditions. In order to have better picture of model predictions versus measurements, Figure 5 shows also inlet and outlet air temperatures and surface temperature of the glasses facing the channel. It can be noticed that, while the internal surface temperature is slightly overestimated, the outer surface temperatures, facing the ventilated channel, are underestimated.

It can also be observed that, while the modelled temperatures have the same dynamic profile, which instantaneously responds to the solar irradiance, the measured values show a bit more complex dynamics. The internal surface temperature increases slower than modelled and the surfaces temperature 1 and 2 (respectively of outer glass and external surface of the inner skin) decrease slower than modelled. Component capacities are often omitted when modelling DSF performances, in this case it might have led to an overestimation of the heat transmitted to the inside. Further investigation is therefore advisable first of all to identify the exact origin of heat gain overestimation and then to evaluate significance of the heat capacity of the glazing for better prediction of complex dynamic processes in the DSF and thereby increasing the accuracy and the applicability of the model.

## CONCLUSIONS

A thermal model for simulating naturally ventilated Double Skin Facades under variable boundary conditions – wind, solar radiation and environmental temperatures - has been implemented and results have been compared with measured data from a full scale test facility.

The validation, based on the prediction of internal surface temperature of the DSF, has showed acceptable accuracy even though an overestimation is observed when solar irradiance heats up the DSF. This leads to an overestimation of the heat transmitted inwards of about 15%, limiting to the three days with more stable wind and irradiance, and around 25% averaging over the 15 days of the experimental campaign.

The presence of dynamic effects, which might be associated to the DSF component capacities, has been observed and will be furtherly investigated in the future model implementation in order to increase its accuracy and applicability in the frame of building performance simulation.

### **ABSTRACT**

Relative humidity and temperature were measured in cold attic spaces under the eaves with diffusion-open roofing underlay to investigate different ventilation strategies, the influence of infiltration, and exterior insulated roofing underlay. The project was carried out as a full-scale experimental setup in the cool, temperate climate in Lyngby, Denmark. The objective was to test if the best practice recommendations concerning design of the cold attic space will prevent damaging moisture levels in the attics. Measurements do however indicate that complying with recommendations will not ensure satisfactory moisture levels in the attic spaces. A comparison of the passive ventilation strategies in combination with varying infiltration rates, for attic spaces fitted with diffusion-open roofing underlay, indicate that attic ventilation increases moisture levels. The exterior insulation of the attic space improved the hygrothermal performance.

### **KEYWORDS**

Cold attics, ventilation, diffusion-open roofing underlay, insulated roofing underlay, moisture

### **INTRODUCTION**

Recommendations regarding design of cold attics in cold, temperate climates are to ventilate moisture away using outdoor air, and to ensure air- and vapour tightness towards the conditioned spaces. Previous studies by the Technical University of Denmark (DTU) (Bjarløv et al., 2016) and other studies (Fugler, 1999; Harderup & Arfvidsson, 2013; Roppel & Lawton, 2014) do however indicate that moisture induced damages can be found in attics even when constructed in compliance with local best practice recommendations. Some studies (Essah et al., 2009; Harderup & Arfvidsson, 2013; Ojanen, 2001; Uvsløkk, 2005) have investigated the use of diffusion-open roofing underlay as an alternative to passive ventilation, indicating a lowering of the diffusion resistance may reduce moisture levels in the attic space. Single-sided passive ventilation with one or two ventilation valves have previously been investigated by DTU (Bjarløv et al., 2016; Pold, 2015) for attics with diffusion-open roofing underlay in a cool, temperate climate. Here reported results indicated that single-sided passive ventilation had a detrimental effect and led to an increase in humidity of air by volume. The authors hypothesized that the observed detrimental effect was a result of a lower air tightness allowing for more air to infiltrate from the conditioned interior. Simulations by Essah et al. (2009) for attics with diffusion-open roofing underlay suggests an increase in moisture levels

due to eave-to-eave ventilation. Meanwhile experimental studies by Hagetoft & Sasic Kalagasidis (2010) have investigated attics fitted with adaptive ventilation, indicating superior performance compared to eave-to-eave ventilation. Simulations by Nik et al. (2012) support these indications for adaptive ventilation, as well as suggest superior performance compared to attics with eave- and gable ventilation, and insulated roofing underlay. Furthermore, experimental studies including (Harderup & Arfvidsson, 2013) have investigated the influence of long-wave radiation, and observed lower temperatures in the attic construction than in the outdoor air, increasing the risk of condensation on the roofing underlay.

The objective of the research project was to test the best practice recommendations concerning design of the cold attic space. Especially whether compliance with the Danish building regulations (TBST, 2018) regarding the airtightness of the building envelope (less than 1 l/s per m<sup>2</sup> heated floor area at 50 Pa pressure difference) will prevent damaging moisture levels. According to official Danish guidelines, appropriate ventilation of the attic is recommended and this may be achieved with attic using “pressure equalization” (based on stack effect ventilation) (Brand et al., 2009). However, (Brand et al., 2013) state “It cannot be expected that a diffusion-open roofing underlay (Z-value < 3 GPa m<sup>2</sup> s/kg) will to a sufficient extent remove moisture from the attic rooms and attic rooms under the eaves (when the floor width > 1 m). Unless the vapour retarder toward the indoor climate is perfectly installed, these attics will need some degree of ventilation.” Therefore, the guidelines suggests to ventilate the attic using two ventilation valves. Measurements of relative humidity and temperature will be presented for different attic designs, as well as temperatures in the roofing underlay. Results are expected to contribute to enhancing the current best practice recommendations for design of cold attic space under the eaves, to reduce the risk of moisture induced damages.

## METHODS AND MATERIALS

The experimental setup consisted of a 45° single sided pitched roof, constructed on top of a 40-foot reefer container, conditioned to 20 °C and 60% relative humidity (corresponding to an indoor climate class 3 (Brand et al., 2013)). The roof was subdivided into nine attics with the interior dimensions (LxWxH) 1.25 m x 1 m x 1 m, each with different design variations, of which seven are presented in this paper. Special care was taken to reduce potential sources of error like unintentional transport of heat, air, moisture and mould spores. Thus, hygric- and thermal decoupling were established between the attic spaces and to the conditioned spaces, using vapour retarders and thick layers of mineral wool. The attic spaces were fitted with a diffusion-open roofing underlay, with a vapour diffusion resistance, Z, of 0.1 GPa·s·m<sup>2</sup>/kg.

**Figure 1 Vertical section of the cold attic space under the eaves**

The attics were constructed as north facing, cold attic spaces under the eaves, as this represents the worst-case scenario, since the roof surface receive only a limited amount of solar radiation. A conditioned loft corridor was constructed on the southern side. The experiment was conducted at the test site of the Department of Civil Engineering at DTU in Lyngby, Denmark (55.79°N, 12.53°E). The experiment consisted of three series of variations, representing different structural roof scenarios. The series were infiltration rate, single-sided passive ventilation strategies, and exterior insulation. Two different infiltration scenarios were investigated: 1) 3.4 l/s at 50 Pa pressure difference; 2) No infiltration from the conditioned spaces. It is easier to construct tight walls, ceilings and floors than it is to construct tight joints. Leaks are therefore often found where the ceiling meets the walls. This means that attic spaces under the eaves are in risk of being subjected to (local) infiltration rates well above 1 l/s per square meter attic space at 50 Pa pressure difference over the building envelope that is allowed by BR18. The 3.4 l/s at 50 Pa pressure difference used in this experiment is used to approximate the effects of infiltration in an assumed worst-case scenario. Infiltration was established by fitting several attics with PVC tubes connecting the attics and the conditioned spaces. Three different ventilation strategies: 1) Un-ventilated (UV), in which attic spaces were not fitted with ventilation valves; 2) Pressure equalization (PE), in which attic spaces were fitted with a valve in the top corner. 3) Single-sided ventilation (SSV), in which attic spaces were fitted with two valves, diagonally in the top and bottom corners. The third series compared an unventilated attic space with infiltration, to an identical attic, fitted with a 50mm polystyrene insulation on the exterior side of the ventilated cavity. This series investigated the influence of long-wave radiation. An overview of the attic variations is presented in **Table 1**.

**Table 1 Overview of attic variations**

Attic space	B1	B2	B3	B4	B5	B6	B7
Infiltration rate at 50 Pa	-	-	-	3.4 l/s	3.4 l/s	3.4 l/s	3.4 l/s
Ventilation strategy	UV	PE	SSV	UV	PE	SSV	UV
Exterior insulation	-	-	-	-	-	-	+

Temperature and relative humidity sensors were installed in the attic spaces (two in each), outside, and inside the conditioned container, while temperature sensors were installed in the roofing underlay (see Figure 1). The presented results are based on measurements logged every 10 minutes from November 2014 to May 2017. Note that measurements from the two sensors in the attic spaces were averaged. The accuracy of the sensors is shown in **Table 2**.

**Table 2 Accuracy of sensors**

Instrument	Measurement	Accuracy	Range
Rotronic HygroClip	Temp.	± 0.1 K at 23 °C and 10, 35 and 80% RH	-50 to 100°C
2 S	RH	± 0.8 % at 23 °C and 10, 35 and 80% RH	1 to 100 %
Thermocouple type T	Temp.	± 0.5 K at 0 °C	-200 to 350 °C

## RESULTS

In the following, the measured temperature and relative humidity in the attic spaces are presented as 15-days moving average of the derived daily average values, using 7 days before and after the current date (Figures 2-3). Figure 2 shows the relative humidity for attics without infiltration (B1-3) and with infiltration (B4-6), where higher relative humidity is seen for the cases with ventilation and/or infiltration. The highest relative humidity is seen for the PE attic (B5). Figure 3 shows the temperatures in the attic spaces. Since the measured temperatures were almost identical for attics B1-4, the measurements are shown in combination, against the PE attic (B5) and the SSV attic (B6). Slightly higher temperatures were seen for B5 and B6 during the cold periods (highest for B5,) and slightly lower during the warm periods.

**Figure 2 Relative humidity in the attics spaces, indoor, and outdoor.**

**Figure 3 Temperatures in selected attic spaces, indoor, and outdoor.**

Figure 4 shows the difference in temperatures measured in the roofing underlay and outdoor air, when the temperature in the roofing underlay is lower than the outdoor air. Temperatures are presented as hourly averages of the logged data. The difference in temperatures is the effect of the exterior insulation mounted on attic room B7 preventing heat loss by long-wave radiation. Heat losses from radiation will be greatest during cold nights with clear skies. Focus in the presented data is therefore on cold periods. November 1<sup>st</sup>, 2016 to May 1<sup>st</sup>, 2017 was chosen, as the lowest temperatures were observed during this winter period. Tendencies were similar for the other winter periods. In Figure 4 the roofing underlays are seen to experience temperatures several degrees below that of the outdoor air. The uninsulated underlay (B4) is seen to frequently experience the largest temperature difference to the outdoor air (when  $B4 > B7$ ). Furthermore, the humidity of air by volume was calculated for the attics, and the insulated attic was seen to experience an increase of up to  $0.35 \text{ g/m}^3$  during the winter periods.

**Figure 4 Temperature in the roofing underlay relative to the outdoor air.**

## DISCUSSIONS

Considering the humidities of B1 and B4 in comparison to B2-3 and B5-6 in Figure 2, measurements seem to indicate that ventilation of diffusion-open attic spaces under the eaves

in a cool temperate climate using PE or SSV will increase the relative humidity. While a comparison of B1 to B4, B2 to B5, and B3 to B6, indicate that the relative humidity also will increase in case of infiltration from the conditioned spaces. Lastly, a comparison of B1 to B4 and then to B5-6 show the compounding effect of infiltration and the tested ventilation strategies for the attic spaces with diffusion-open roofing underlay, where the relative humidity was observed to increase even further. The PE attic experienced the largest increase in temperature and relative humidity (B4 to B5). A smaller increase in relative humidity was observed for the SSV attic (B4 to B6). We believe that the observed increase in moisture levels is due to untight ceiling and roof constructions allowing a stack effect to cause an updraft of infiltration air. These indications correlate with findings of previous experimental studies by DTU (Bjarløv et al., 2016; Pold, 2015). However, in contrast to Bjarløv et al. (2016) but in agreement with Pold (2015), the ventilation strategy PE (B2 and B5) was shown to result in the largest increase in the moisture levels, compared to SSV (B3 and B6). Simulations by Pold suggested that PE will exacerbate infiltration from the indoor spaces due to negative pressure under the roof cladding, resulting in increased moisture levels. Pold's simulations also suggested that SSV increase moisture levels in attic spaces just to a smaller extent. Findings concerning lowered moisture levels due to reduced attic ventilation for attics with diffusion-open roofing underlay in cool temperature climate, correlate with the experimental studies by Harderup & Arfvidsson (2013) and Ojanen (2001), as well as the simulation results by Essah et al. (2009). Furthermore, as it was the case for these attic spaces, Harderup & Arfvidsson also observed relative humidity favorable for mould growth during the cold periods. In this study, relative humidity favorable for mould growth, was observed between mid-August to mid-April, when considering 75% relative humidity as critical limit as suggested in the best practice recommendations (Brand et al., 2013).

Considering the temperature difference between the outdoor air and the roofing underlays in Figure 4, measurements indicate that externally insulating the roofing underlay reduces the heat loss due to long-wave radiation for these attics. The roofing underlay temperatures in the externally insulated attic (B7) were seen to increase by up to 2.5 °C compared to the uninsulated attic (B4), and 0.5 °C on average. This difference between the two roofing underlays occurred around midnight on May 18<sup>th</sup>, 2017. The roofing underlays were observed to experience temperatures below that of the outdoor air (Figure 4); and despite the focus on clear, cold nights, the largest temperature difference between the roofing underlays and the outdoor air occurred around 14:00 on February 14<sup>th</sup>, 2017: a difference of 6.7 °C for the uninsulated attic and a difference of 6.6 °C for the insulated attic. Roofing underlay temperatures below that of the outdoor air and attic space air is a potential risk, as movement of warmer, moister air to the roofing underlay could lead to condensation on the interior surface. In the summer periods the attic spaces were almost identical. These findings correlate with Harderup & Arfvidsson (2013), who during the cold periods observed the highest temperatures in the externally insulating attics, compared to the uninsulated; also, a small increase in the moisture levels was observed. Finally, our measurements thus seem to indicate that the exterior insulation has both positive and negative effects on the moisture balance in this attic space with the temperature increase in the roofing underlay being good while the increase in the humidity of air by volume in the attic space is not.

## CONCLUSIONS

Measurements from different cold attic spaces under the eaves fitted with diffusion-open roofing underlay, indicate that following the current best practice recommendations regarding passive ventilation does not guarantee safe moisture levels in attic spaces. Ventilation of these attic spaces seems to lead to an increase in moisture levels, and so does infiltration from the

conditioned spaces. Allowing for infiltration in combination with ventilation allows for even higher levels of moisture. From this, the results indicate that the assessed ventilation strategies under similar physical conditions does not mitigate moisture problems but may instead exacerbate moisture problems. Furthermore, exterior insulation of the attic spaces reduces the risk of condensation on the interior surface of the roofing underlay slightly. However, more data and analysis about other construction scenarios are needed for more general conclusions.

### ABSTRACT

Sealed attics with fiberglass have been in the US building codes for several codes cycles. Prior to the IRC 2018, air permeable insulation (such as fiberglass) was previously allowed to be deployed without continuous air impermeable insulation only in dry climate zones 2B and 3B in tile roofs systems. New research has revealed that asphalt shingles can also be allowed as implemented in the new IRC 2018 with a new addition to the section for sealed attics using air permeable insulations. The new building code also permits the use of air permeable insulation without air impermeable insulation in climate zones 1 to 3 (including moist climates “A”) when certain conditions are met in the design. To expand the use of the sealed attic system in moist climates (1A to 3A) field testing was needed to further understand the impacts of roof claddings and diffusion vent.

The authors identified the need for collection of field test data to validate the new sealed attic design that was being implemented in the IRC (2018 International Residential Code). Testing of sealed attics exposed to a southern climate (Charleston, SC) was launched in 2015. The goals were to determine a) if spray foam and fiberglass insulation perform differently in terms of moisture performance in sealed attics and if so, how and b) if the diffusion vent improves the moisture performance at the ridge by reducing the high humidity and moisture contents and c) if asphalt shingles could be used for unvented attics with air permeable insulations in IRC climate zones 1-3.

This paper summarizes the field testing and simulation results confirming that air permeable insulation as well as shingles can be used in humid southern climate zones. The new building code requirements regarding air permeable insulation should be required with all highly vapor-permeable insulations.

### KEYWORDS

Sealed attics, moisture performance, diffusion vent, moist climate zone

### INTRODUCTION

Sealed attics with air permeable (and vapor permeable) insulation had experienced moisture problems in the past (GBA 2010, JLC 2010, Colon 2011, Miller 2016). Some of the past problems had resulted in changes to the building codes that ultimately prevented using air permeable insulation in sealed attics. Even with these changes the problems continued occurring. In recent years further research has created better understanding of the reasons for failures and has enabled development of systems that fix the issues (Boudreaux et al. 2013, Salonvaara et al. 2013). However, field testing to prove the concepts was needed to allow for the sealed attic systems to be used in different climates and with air permeable insulation.

Conventional attic construction involves providing insulation on the floor of the attic and ventilation of the attic space (vented attic) from the outside. When an air distribution system is installed in the vented attic, any duct or air handler leakage creates an energy penalty in addition

to conduction and radiation losses. An alternative to conventional vented attics is an unvented attic which is also known as a sealed attic. Insulating the attic roof deck and blocking ventilation of the attic space to the outside moves the thermal boundary to the sheathing roof line. The air distribution system is now located within a semi-conditioned space, which increases its overall efficiency, durability, and maintainability. The sealed attic can be built as an unvented attic with insulation in direct contact with the roof deck or with a ventilated roof deck with an air tight interior layer in the attic side of the ventilation gap. The ventilated roof deck is not common in unvented attics, but is an option for a cathedral ceiling. The cathedral ceiling is over conditioned living space whereas the roof deck in the sealed attic is exposed to an attic space that is typically only indirectly conditioned.

### **Moisture problems in sealed attics and proposed solutions**

The moisture problems experienced in some sealed attics are mainly of two types (Salonvaara et al, 2013): 1) High moisture in the roof sheathing mostly at the ridge and 2) high humidity or condensation in the attic space.

The latest changes to the International Residential Building code (IRC 2018) include a requirement for conditioning the sealed attic by supplying air from the ductwork at a rate of 50 cfm per 1000 sqft of ceiling ( $0.25 \text{ L/s, m}^2$ ) and the addition of a diffusion port when air-permeable insulation is used in sealed attics. The purpose of the diffusion port and conditioning are to provide control for moisture at the ridge and the attic humidity, respectively. A diffusion port is a gap at the ridge (greater than or equal to 1:600 of the ceiling area) covered by a vapor permeable membrane (vapor permeance 20 perms or more) to create water and air tightness but allowing for vapor transport between the ridge and outdoors. Previous studies have been carried out by Kohta and Lstiburek (2013) regarding the diffusion port. Attic conditioning is a new approach that has previously not been well investigated.

### **METHODS**

Field tests were conducted at the Natural Exposure Test (NET) facility (Figure 1) located in Hollywood, SC, a suburb of Charleston. Charleston is in climate zone 3A which is described as warm-humid with cooling degree days CDD10°C ranging from 2500 to 3500 and heating degree days HDD18 °C  $\leq$  3000 and with precipitation more than 50cm annually. Personnel from Oak Ridge National Laboratory (ORNL) instrumented attic assemblies on the NET facility and collected data for two years. The instrumentation included temperature, relative humidity and moisture content sensors. The site has its own weather station recording hourly values.

Simulations with a hygrothermal simulation model (Fraunhofer IBP) were carried out to compare simulated predictions of performance to the field performance.

Studies in a Large Scale Climate Simulator at ORNL were performed in addition to the field tests to carry out side by side tests with different configurations. Data from these tests are shown in discussion of the performance of the diffusion port only.

The test period covered two years at the NET facility. Attics installed in the NET facility include three different insulation types: open cell spray foam (ocSPF, density  $0.5 \text{ kg/m}^3$ ), closed cell spray foam (ccSPF, density  $2 \text{ kg/m}^3$ ) and netted and blown fiberglass (FG,  $21 \text{ kg/m}^3$ ). The solar reflectance of the shingles is 4% and 25% for conventional and cool roof shingles, respectively. The attics are listed in Table 1 in the order they appear in the test hut.

### **RESULTS**

Installation of the roof sections occurred early 2016. Data has been collected from March 2016 till March 2018. Data are missing for October to mid-November 2016 due to storms causing unrecoverable power shortage. In the end of May 2017, computer fans were installed in the attics insulated with fiberglass to provide the venting rate 50 cfm/1000 sqft of ceiling area ( $0.25 \text{ L/s, m}^2$ ) as specified in IRC 2018 for sealed attics with air permeable insulation in southern

climate zones 1A-3A. The setup did not allow for conditioning the attics with air from the ductwork and instead the ventilation air is coming from the conditioned test hut.

Table 1. Types of attics, insulation and shingles details.

Attic #	Type	Insulation/R-value	Shingles type
2	Sealed	ocSPF, R-22/RSI-3.9	Conventional
3	Sealed	ccSPF, R-22/RSI-3.9	Conventional
4	Sealed	FG, R-38/RSI-6.7	Cool Roof
5	Vented	FG, R-38/RSI-6.7	Conventional
1	Sealed	FG, R-38/RSI-6.7	Conventional
7	Sealed, FG + Diffusion port	FG, R-38/RSI-6.7	Conventional

The roof planes (3:12 pitch) are facing South and North. Figure 1 shows the different attics as arranged in the test hut.

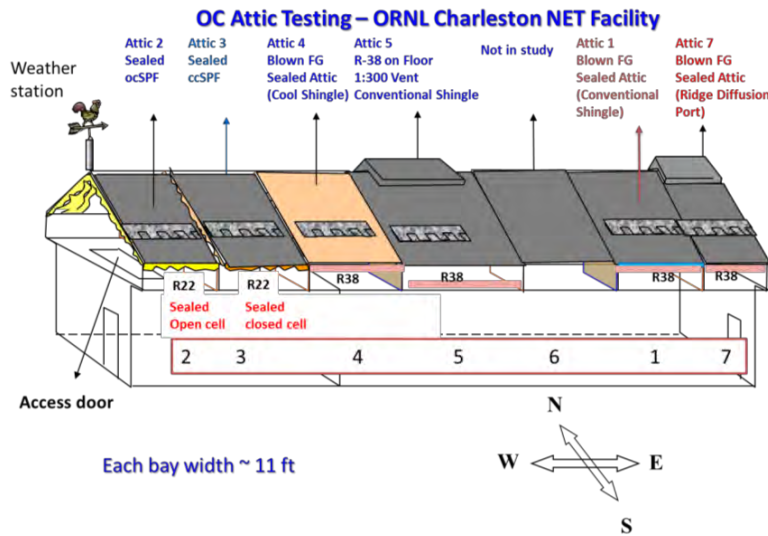

Figure 1. Schematics of the attics in NET facility. The arrangement includes 5 sealed attics and one vented attic.

### Climate conditions and attic humidity

During summer in the first year the attic humidity in the attics with vapor permeable insulation rises quite high reaching 80% relative humidity and even higher above 90%-RH in the attic with open cell spray foam (Figure 2). In the end of May in 2017 fans were installed in attics 1, 4 and 7 to ventilate the attic spaces with indoor air at the rate 50 cfm/1000 sqft of ceiling area (0.25 L/s,m<sup>2</sup>). The humidity level in the attics dropped right after the fans were installed which is clearly seen in attics 1 and 7. Attic 4 has cool roof shingles with solar reflectance 0.25. This attic does not reach as high humidity in the attic space and the overall level is lower than in the other attics with fiberglass insulation. This is due to the cooler roof deck which creates less vapor flux from the roof deck into the attic space. Similarly, the low humidity in attic 3 with closed cell spray foam is a result of low vapor flux from the roof deck which is due to the low water vapor permeance of the insulation layer.

### Roof deck moisture content

The moisture content of the roof deck (OSB=oriented strand board) never reached unacceptable levels and mostly stayed below 14% by weight (Figure 3).

Figure 2. Indoor and outdoor temperature and relative humidity (7 day moving average, left) and attic air relative humidity during the two-year test period (right).

Figure 3. Moisture content of the roof deck in the north (left) and the south (right) roof slope.

### Humidity at the ridge and the effect of diffusion port

Laboratory tests in a climate simulator for attic sections with and without a diffusion port allowed for close investigation of the effect of the diffusion port on moisture conditions at the ridge. Figure 4 shows the sensor mapping and the water vapor pressure contours in the attic in an afternoon with simulated weather data.

Figure 4. Water vapor pressure contours in a summer afternoon in the attics with shingles and fiberglass insulation with and without a diffusion port at the ridge. Results are from the Large Scale Climate Simulator tests.

The moisture removal was more isolated near the ridge area, Figure 4. Moist air is more buoyant than drier air because of the difference in molecular weight of air and water vapor. The hot roof deck during sunny hours also creates temperature differences that create buoyancy-driven flows towards the ridge. The higher the moisture content of the air the more water vapor displaces the

air, and the air-water density drops compared to air holding less water vapor. Therefore, the moist air moves toward the diffusion port which acts as a relief valve at the ridge during the hours of high humidity in the attic. Further down from the ridge the sheathing is not affected by the moist air even during periods of high humidity.

### Simulated versus measured performance

Simulation models are extensively used today to design for building envelope systems to improve thermal and moisture performance. A whole building hygrothermal simulation model was used with the weather data measured on site to evaluate whether the model simulations agree with the measured performance. Simulated and measured data were found to agree well throughout the seasons. Figure 5 shows results for the roof deck temperature and humidity during one week in the summer. The results give confidence that hygrothermal modeling is a valid approach to use for designing attic systems.

Figure 5. Measured temperature and relative humidity at the interface between the roof sheathing (OSB) and the fiberglass insulation in the north facing roof slope in attic 1.

### DISCUSSIONS

Cool roof shingles reduce the temperature swings on the roof deck, which creates less vapor drive from the roof deck into the attic during sunny days. This has both positive and negative impacts. In the summer the attic humidity stays lower and high peaks in relative humidity are less likely with cool roof shingles than with standard shingles. In the winter the lower solar absorption coefficient keeps the shingles colder thus allowing more time for the roof deck to accumulate moisture and less vapor drive to dry the roof deck inwards, which results in higher moisture contents in the roof deck with cool roof shingles than with standard shingles.

Sealed attics (unvented attics) with fiberglass have shown acceptable performance in the test hut study: moisture contents of the roof sheathing panels have stayed in acceptable levels (per moisture pin evaluations) and the analyses have not revealed any mold growth risk. Visual inspection after two years showed no signs of mold at the roof deck.

The open cell spray foam attic performed similarly to the fiberglass insulated attics in terms of moisture performance. Open cell spray foam has slightly lower water vapor permeability than the blown in fiberglass, which creates slower movement of water vapor; thus the highest daily humidity in the roof deck was typically lower than in the fiberglass attics. Closed cell spray foam has much lower water vapor permeability and the attic with closed cell spray foam showed a slower response to climatic changes even seasonally by maintaining humidity with less variations over time than the attics with vapor permeable insulation.

Diffusion port size and design is currently not optimized. Additional work is recommended on the diffusion port design and to test the performance of these sealed attics in real full-size homes in a hot and humid climate. The presented results are for a test hut. Occupant behavior in real homes may change the indoor conditions that can affect the results.

## CONCLUSIONS

The new building code requirements – diffusion port and conditioning of attic space – have proven effective in providing control of moisture in sealed attics. The diffusion port has been shown in this as well as in another study (Kohta and Lstiburek 2013) to reduce high moisture at the ridge. Conditioning of attics by introducing a small flow of conditioned air for the HVAC supply was shown to be critical for avoiding high humidity in the attic space. The attics in this study and in this climate zone (3A) had no moisture problems when the attics were conditioned. Without the conditioned air the attic space can reach high enough humidity levels that are conducive for mold growth.

## ACKNOWLEDGEMENT

Owens Corning Roofing and Insulation provided cost sharing to enable this study. The support is greatly appreciated.

### **ABSTRACT**

Ventilated pitched wooden roofs with eaves (roof overhangs) is a common building practice in the Scandinavian countries. The eaves are protecting the façade from rain, wind driven rain (WDR) and snow, and it covers the roof ventilation aperture. The eaves should be designed so that the least possible amounts of rainwater and snow enters the ventilation aperture between the roof cladding- and underlayer roofing. At the same time, adequate ventilation of the roof must be ensured to promote proper drying-out capabilities of the roof and to avoid problems of snow melt and ice formation at eaves and gutters during winter season. Small or almost non-existing eaves is a trend in modern architecture. It is a common perception that such solutions are more vulnerable to moisture damages due to possible increase of water penetration into the roof aperture.

The aim of the study is to experimentally investigate the moisture robustness of the described risk area and to find answers to how the design of eaves influence the amount of rain that is driven on to the underlayer roofing under the aperture in ventilated roofs.

It was found that the amount of collected water in the different test series to a large extent are given by the water droplet size as well as the wind velocity inside the air cavity. The results from this study simulates an example of a rain event with heavy rain intensity and strong winds (storm). The test represents an example of a storm event with a given droplet size distribution. The results indicate that an increased pressure drop decreases the water ingress. Comparative tests showed that installation of a wire mesh largely decreases the measured water collection and the dynamic pressures inside the air cavity.

### **KEYWORDS**

Roof design; eaves; robustness; precipitation, water ingress

### **INTRODUCTION**

Moisture related damages pose significant challenges to the Norwegian built environment. Indoor moisture, damp building structures and precipitation stresses the building envelope and can provoke significant damages. 75 % of all damages and defects in the Norwegian building stock are caused by moisture related problems and 2/3 of defects are related to the building envelope (Lisø 2006). In pitched wooden roofs 67 % of the defects are caused by precipitation or indoor moisture (Gullbrekken, Kvande, et al. 2016). Climate change has been proven to increase the amount and intensity of precipitation. On average, an increase of more than 20 % has been registered over the last 100 years, and an increase of an additional 20% is expected

before the year 2100 (Pachauri and Meyer 2014). Changes in temperature leads to an increase in conditions where wood materials are susceptible to degradation (Lisø and Kvande 2007). These changes lead to higher demands on the entire building and the building envelope parts, where mould and other biological growth is critical. A state-of-the-art in modelling of mould failure is thoroughly investigated by Gradeci et al. (Gradeci, Labonnote et al. 2016 ).

Ventilated pitched wooden roofs with eaves (roof overhangs) is a common building practice in the Scandinavian countries. The traditional construction technique for ventilated wooden roofs uses relatively large roof overhangs. These overhangs have two main functions related to moisture robustness; Firstly, to reduce the amount of wind-driven rain (WDR) hitting the facade and secondly to reduce the amount of wind-driven precipitation entering the ventilated air cavity between the roof underlayer and the roof cladding. WDR is one of the largest moisture sources with potential negative effects on the hygrothermal performance and durability of building envelopes. A detailed (and comprehensive) review of WDR research is given in (Blocken and Carmeliet 2004, Blocken, Abuku et al. 2011, Kubilay, Derome et al. 2014). Large deposition chambers where the air-flow velocity is reduced, have traditionally been recommended for ventilated wooden roofs (Thiis, Barfoed et al. 2007). However, new trends in architecture calls for solutions with minimal roof overhangs and slender design of the eaves. It is a common perception that such solutions are more vulnerable to moisture damages. Quantifying the amount of precipitation is important to provide a basis for future design-recommendations of moisture robust eave solutions. The design of roofs and eaves (roof overhangs) and how they influence the quantity of WDR impinging on building facades are studied in several publications (Hersels 1996, Ge and Krpan 2009, Chiu, Ge et al. 2015). However, there is a need to obtain further and more fundamental knowledge on the performance and durability of commonly used solutions, especially through experimental studies (Fasana and Nelva 2011, Boardman and Glass 2013). Some experimental studies have been carried out (Inculet and Surry 1995, Inculet 2001, Blocken and Carmeliet 2005, Kvande and Lisø 2009). To the authors' knowledge, few studies have quantified the amount of precipitation accumulation in the apertures and eaves of sloped ventilated wooden roofs caused by WDR.

The aim of the study is to experimentally investigate the moisture robustness of eaves solutions and how the design of eaves influence the amount of rain which is driven inside the ventilated air cavity of the roof aperture. Influencing factors that will be studied are; the length of the roof overhang and the ventilation aperture opening size and position.

## METHODS

Test series are described in Table 1 and 2 and Figure 1. The measurements were carried out in a *Rain and Wind apparatus* in accordance with principles in NS-EN 12865:2001 (ISO 2001) method B. Smaller quantities of rain than advised in the standard were used due to limitations in the equipment. The facility is described in (Kvande and Lisø 2009). The sample exposed to WDR had an area of 2.45 m x 2.45 m. The width of the roof surface was 1.8 m. Transparent acrylic boards were used as wind-barrier in the wall and as underlying roof and roof cladding to make visual inspection easier. The front of the roof cladding was covered with a 200 x 19 mm weatherboard, with a steel gutter in front to promote realistic air-flow vectors. An expansion chamber was used to adjust wind-speeds in the roof aperture. Ten eaves-solutions with three different overhang lengths and various closure-solutions of the eaves were tested. Table 1 and 2 shows illustrations and description of the different sample configurations. Test series B4 is identical to B3 apart from a wire mesh covering the ventilation opening in the eave. A mesh like this is used to prevent insects and birds from entering the eave in real buildings. It was chosen to add this for the series with the largest amount of water collected in the aperture (B3).

Figure 1. (left) Cross-section of the test sample. (top right) Different eaves overhang lengths (denoted  $d$  and circled in red). (bottom right) Water collection system used in the experiment.

Table 1. Test configurations. Test ID's A has 36 mm roof overhang, B has 100 mm and C has 200 mm.  $d$  = overhang length, Opening = opening size. I1 is the same as A1, but with driving rain application only. I2 is identical to I1, but w/ 300 Pa pressure difference. The Test ID numbers (1-5) aligns with weatherboard configurations presented in Table 2.

Test ID	I1	I2	A1	A2	B1	B2	B3	B4	C1	C2	C3	C4	C5

Test series	1	2	3	4	5
Configurations A-C					

Water was applied as driving-rain only, in I1 and I2. For the remaining series, both driving rain (large droplets) and a water mist (very small droplets) spray was used. This was done to cover a larger span of droplet-sizes and, thus, to represent a wider span of likely, realistic downpour conditions. No measurement of the actual droplet-size distributions was feasible to carry out. The total volume flow of water for the driving rain nozzles was measured to 660 l/h and 550 l/h after turning on the water-mist nozzles. The nozzles were positioned to create the maximum moisture load possible. Calculations were carried out to ensure the use of realistic air velocities in the aperture. A worst-case scenario of a *storm* (level 10 on the Beaufort scale) was chosen for the experiments. This corresponds to the pressure of 400 Pa used in the experiments. This gives a resulting air velocity of 26 m/s. The dynamic pressure in the aperture was measured using a pitot-tube. The pressure readings were highly irregular, indicating turbulent flow.

## RESULTS

Calibration tests were carried out to achieve the desired water-load on the sample. Several pressure differences across the sample was tested, ranging from 200 to 400 Pa. It was found that the mean droplet-size of the applied water was too large for the droplets to be transported into the aperture. This was independent of the pressure difference. Hence, water application using water-mist nozzles were used in A1-C5. Figure 2 show the amounts of water collected during the test cycles. A qualitative description of the visual observations is given in Table 3

Figure 2. Test configurations and measured retained amounts of water from roof underlay after 40 min of water application for series A1-C5

Table 3. Visual observations during the test series A1 to C5. Location of water deposition are based on visual inspections and should be treated as qualitative observations.

ID	Observations
A1	No water accumulated on the roof underlayer (RU). No water deposited on the wind barrier (WB) of the wall (e.g. on the vertical board).
A2	Rapid wetting of RU. Small droplets deposited on RU up to the first furring strip (30-40 cm). Water deposited on RU in large droplets 15-20 cm from eave. Water running down WB
B1	Rapid accumulation of water on RU (more than for A2). A lot of water running down the WB. Fewer small droplets deposited on RU, deposition length same as for A2.
B2	More and bigger droplets are transported in the airstream than for A2 and B1. Deposition on cladding, but less than for A2 and B1.
B3	Similar behaviour as B2, but with more rapid wetting of RU. Water retained in vials after 5 minutes. Water driven further along the back-side of the roof cladding than previous series.
B4	Some droplets are deposited on the roof cladding and RU but no water is collected in the vials. Water droplets are deposited in/on the wire mesh.
C1	Some deposition on roof cladding but little on RU. Some small droplets in mid-and very little in left section. Some water running down WB.
C2	Some large droplets are deposited on the RU (8-10 cm from wall/roof joint). Some small droplets are deposited up to the first furring strip.
C3	Similar behaviour as B3, but fewer droplets on RU. Some water hitting WB
C4	Very little water (small droplets) deposited on RU. Some deposition of large droplets on RU up to approximately 5-10 cm from the wall/roof connection.
C5	Similar observations as for C4.

## DISCUSSIONS

The amounts of collected water in the different test series are given by both the water droplet size as well as the air velocity inside the air cavity. The pressure difference of 400 Pa was necessary to transport water from the water-mist nozzles in through the eaves opening. Based on the strains from the applied pressure and the corresponding pressure loss through the system, the driving forces from wind can be categorized as "worst case". It is not expected that temperatures (above freezing) will affect the deposition of water on roof underlayer or wind-barrier of walls.

Water amounts collected in A2 and B3 was considerably higher than for the remaining. Close to 400 ml of water was collected in A2, which had a 36 mm long overhang and no weather-board covering the underside of the eave. The largest amount of water collected was 728 ml.

Visual observations made during the test, suggest that a possible reason was that the position and size of the opening gave a particularly disfavoured air-flow direction (vector) for this configuration. Large amounts of water were transported in the airflow and was deposited on the side of the roof cladding facing the ventilation aperture. The deposited water was then "dragged" along the surface until the water droplets became large enough for gravitational forces to force them off the cladding with a resulting deposition on the roof underlayer (RU). Furthermore, it was found that the solutions with a 100 mm roof overhang had the highest amounts of water deposition on the RU regardless of the opening size under the eave. The Norwegian building design guidelines suggests using a ventilation gap in the roof aperture with a height of 40-50 mm (SINTEF 2005).

C3 and C5 indicate that the placement of the ventilation opening in the eave toward the weather board reduce the amount of collected water. For the 18 mm cavity (C2 and C4) the comparable position gave little increase of the collected amount of water. The measured amount of water during C4 was rather low. Thiis, Barfoed et al. (2007) also found that position of the ventilation opening towards the weather board was effective to reduce snow penetration to the roof compared to a position close to the cladding. Thiis, Barfoed et al. (2007) also indicated that the snow concentration of the air entering the air channel decreased by increasing air pressure drop over the eaves construction. Hence, the measurements must be seen in connection to snow-indraft which might be a bigger practical issue to solve.

Tests B1 by B2 and C2 by C3 indicate that an increased pressure drop decreases the water ingress. This is clearly demonstrated by the introduction of the wire mesh which is representing a large pressure drop. Comparing Test B4 and B3 shows that installation of the wire mesh decreases the measured water collection and the dynamic pressures inside the air cavity.

## CONCLUSIONS

Measurements of how the design of eaves influence the amount of rain that is driven in to the ventilation aperture roofs have been carried out. The amount of water collected are given by the water droplet size and the wind velocity inside the air cavity. In practice the amount of WDR hitting the facade is dependent of wind speed, wind direction, rainfall intensity, raindrop size and the rain event duration. The results from this study simulates an example of an event with heavy rain intensity and strong winds (storm) with a given droplet size distribution. Hence, the actual amount of water collected in each of the test series are of less interest than the comparison of the amounts of water in the different series.

It can be assumed that a mesh like the one used in B4 will be effective in stopping rain with a large variation of droplet sizes and droplet size-distributions from entering the roof aperture.

There are limitations in the measurements that have been carried out. There was no feasible way of controlling the droplet size distribution other than that the use of water-mist nozzles created smaller droplets than the driving rain nozzles. Substantial amounts of water were deposited on the RU without being collected. Future measurements should take this into account. The air velocity inside the ventilation cavity was high. This was, however, necessary to induce rain penetration in the ventilation cavity. The effect of varying wind direction was not accounted for and should be included in future studies. Only rain accumulation in the ventilation aperture was studied in this paper. Future measurements should also be coupled to experiments studying challenges related to snow, which might be a bigger issue. Future studies should also include the combined effects and implications of eaves-design on WDR effects on cladding. Measurements studying real-climate performance should also be carried out.

## ACKNOWLEDGEMENT

The experiments were carried out as part of the *Tall Timber Facades* project (part of the WoodWisdom 2014-2017 program). The authors also acknowledge the Centre for Research-based Innovation "Klima 2050" for providing necessary funding.

### **ABSTRACT**

Natural ventilation provides opportunities to reduce residential cooling load in summer, but increasing the operability of a façade potentially increases infiltration, which is already a source of significant winter heat load. Solving both of these simultaneously is challenging. The test building for this study was a prototype house containing a novel ventilator detail which allows for porosity for summer ventilation and a tight, insulated seal in winter. We aimed to determine whether the prototype had low enough infiltration and thermal bridging to be worthy of further laboratory testing and subsequent deployment in more buildings. The test home was blower door tested, following the Resnet standard to determine ACH50. While the house was depressurized, diagnostic photographs were taken with a smoke wand at each ventilator to qualitatively document air exchange. The ventilator plan and section details were modeled in THERM v7.6 to look for potential thermal bridging. These tests were conducted in February 2018 on the GRoW Home, a prototype house built for the 2015 Solar Decathlon at the University at Buffalo. The home contains thirteen instances of the ventilation detail in question. ACH50 was found to be 1.16, photographs showed observable infiltration at only five of the thirteen apertures, and only when the operable interior door was open. The thermal flux magnitude analysis did not evidence major thermal bridging. Thus this ventilation approach shows promise for naturally ventilated small buildings in cold climates. Further laboratory study is warranted to characterize and further improve the construction.

### **KEYWORDS**

Natural ventilation, passive, thermal performance, residential, cold climate

### **INTRODUCTION**

Natural ventilation provides opportunities to reduce residential cooling load in summer. Residential air conditioning loads represent 6% percent of total US residential energy consumption, and are responsible for 1.5% percent of residential energy consumption in cold/very cold US climates (EIA 2009). Natural ventilation is a viable option in residential projects to reduce reliance on energy-intensive cooling strategies. Ventilation typically requires increasing the operability of the façade to allow air into occupied spaces, but doing so introduces more opportunity for infiltration in winter as well, thereby increasing heating loads in winter. Typically 6 to 22% (mean 15%) of infiltration occurs at windows and doors in residential buildings (ASHRAE 2001). Winter space conditioning is responsible for 42% percent of total US residential energy consumption, and 54% percent of energy consumption in cold climates (EIA 2009). Infiltration rates can vary by a factor of ten in north America, so the impact on energy consumption is highly variable based on construction typology (ASHRAE 2001). Single family detached homes in the US have ACH50 values from 3 to 40, with a median of about 12 ACH50 (Chan, Joh, and Sherman 2013). Buildings in cold climates with energy recovery ventilation particularly need to control infiltration so as to make best use

of the mechanical heat exchange (ASHRAE 2001). However, infiltration is responsible for a third to a half of the space conditioning load of a home (Sherman 2009). Increasing the number of operable apertures would likely further increase winter infiltration. Wall apertures present opportunities for thermal bridging in addition to infiltration because frames are typically more conductive materials spanning the insulation layer. The detail studied in this project is similar to a window or door frame in this regard.

The ventilation apertures in the test home were designed to increase summer ventilation while minimizing winter infiltration and thermal bridging. However, the thermal and air movement performance of these in either field or laboratory conditions is currently unknown. This study seeks to assess whether winter performance in the field suggests viability of this envelope detail approach, and hence whether further lab testing is warranted.

Specific requirements or standards for whole-building ventilation provide an indication of whether a building has infiltration levels within a desired range for energy efficient operations. Significant relevant examples are shown in Table 1.

Requirement	Notes	ACH 50
Energy Star (EPA and DOE 2015)	Under the prescriptive path in climate zone 5.	<4
International Energy Conservation Code (IECC) and NY State Energy Conservation Construction Code (NYSECCC) (International Code Council 2015)	NYSECCC is based on IECC	<3
LEED v4 for Homes: 1 point (US Green Building Council 2013)		<2.75
LEED v4 for Homes: 2 points		<2.0
Passive House Standard (International Passive House Association)		<0.6

Thermal bridging may be studied using finite element analysis software that maps how heat will flow through all elements of an assembly under ideal specified conditions. Analyzing the magnitude of thermal flux should identify aspects of the test apertures that allow significant heat transfer from inside to outside during winter.

We predicted that infiltration levels would be lower than the published guidelines without major thermal bridging occurring, and we tested this hypothesis with a blower door test and analysis in THERM.

## METHODS

### Ventilator / House prototype

The ventilation apertures studied were a set of thirteen  $0.121 \text{ m}^2$  operable through-wall openings, shown in Figures 1, 2. These openings cut through a 260mm SIP wall finished with 16mm gypsum board on the interior and 19mm larch rainscreen on the exterior. On the interior face, the units had an operable plywood door so the user could regulate ventilation in the summer, as shown in Figure 3. These had wing up hold open fittings to maintain ventilation when open, and magnetic touch latches to keep them closed. The exterior rainscreen was perforated with 50% openings where the ventilators occurred, as shown in Figure 4. Behind the perforated openings was an insect screen. Each ventilator had a wood-wrapped insulation plug that is inserted in winter. These plugs had an EPDM gasket and were fixed in place with a casement fastener.

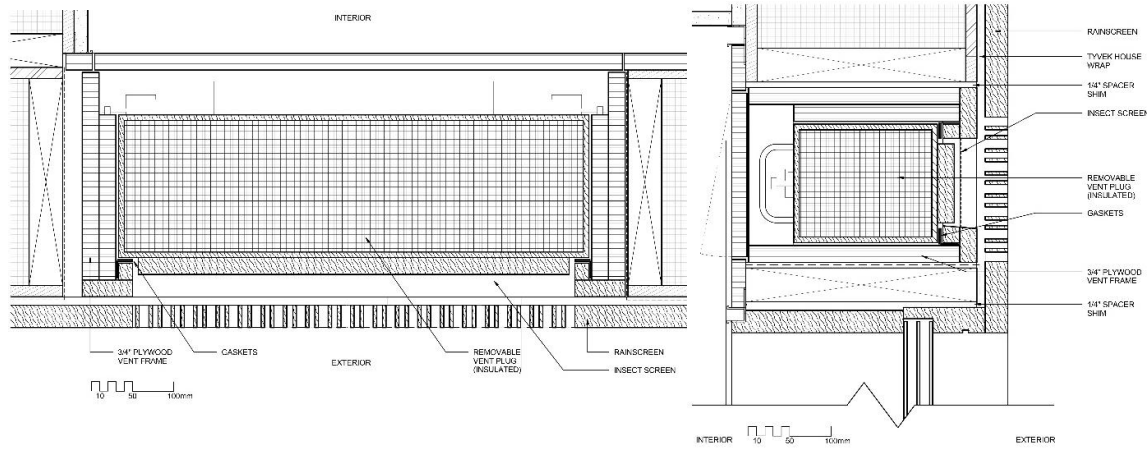

Figure 1: Ventilator construction, plan (left).

Figure 2: Ventilator construction, section (right).

The ventilators were located in a 71.5 m<sup>2</sup> prototype high-performance house located in Buffalo. Windows in the house, with the exception of an egress window in the bedroom, were fixed, triple-paned, and argon-filled. The ventilators are typically located above the windows from 2197mm to 2374mm. The house is equipped with a Greenheck Minicore-5-VG energy recovery ventilator equipped with a CO<sub>2</sub> sensor to cycle air when the house is occupied.

Figure 3: Ventilator as seen from inside test house (left).

Figure 4: Ventilator as seen from outside test house (right).

### Blower Door Test + Smoke Analysis

The ACH50 was measured by following chapter 8 of the RESNET standards, which specifies procedures for conducting a one-point building enclosure airtightness test<sup>1</sup> (RESNET 2013). We used a Minneapolis Blower door with a single fan. Tests were performed in February and March of 2018, when temperature conditions were between -1 and 4°C and conditions were not windy. While the house was depressurized to -50 Pascals relative to outside conditions, we performed a qualitative assessment of air infiltration at the ventilators. Using a smoke wand, we examined each of the thirteen ventilators with doors open and doors closed to look for evidence of infiltration, and documented each condition photographically. Ventilation plugs remained inserted for this test.

### Therm analysis

The plan and the section detail for the ventilators were examined in THERM 7.6 using a temperature difference of 20.7 °C from inside to outside (with external temperature equal to

<sup>1</sup> Chapter 8 standards were replaced with ANSI/RESNET/ICC 380-2016 and addendum A-2017 as of January 1, 2018.

0.4 °C). Table 2 shows the material properties assigned to each of the component materials of the assembly. Emissivity was set to 0.90 for each material.

		Thickness (mm)	Thermal conductivity (W/m-K)
<b>Wall assembly</b>	External larch cladding	19	0.11
	Oriented strand board	13	0.13
	Expanded polystyrene (EPS)	235	0.03
	Oriented strand board	13	0.13
	Gypsum wall board	16	0.25
<b>Insulation plug</b>	Plywood	6	0.12
	Extruded polystyrene (XPS)	190	0.034
	Plywood	6	0.12
	EPDM Gasket (D-shaped)	16	0.2

Table 2: Material properties for THERM model

## RESULTS

We have earlier postulated that the inclusion of the ventilators do not prevent the test home from meeting published air infiltration guidelines and at the same time introduce more natural ventilation possibilities. Our blower door test result (ACH50) of 1.16, indicate that the air infiltration levels of the whole house are well within the guidelines for Energy Star certification, IECC, NYECCC, LEED v4 for Homes, but do not meet the more stringent requirements for the Passive House standard, as shown in Table 1.

The smoke wand photographs taken while the house was depressurized help to identify qualitatively where infiltration is occurring in the house. Figures 6 is typical of the ventilators in the closed position, showing that there is no discernable air leakage. Figure 7 indicates some air leakage with the ventilator door is open. This occurred in five of the thirteen ventilators when the doors were open.

Figure 6: Photograph of smoke test with ventilator in closed position. No air leakage is evident in this condition at any ventilator (left).

Figure 7: Photograph of smoke test with ventilator in open position. Five of thirteen ventilators showed some discernable air leakage in this position, as shown here (right).

Smoke tests at other envelope locations in the home while it was depressurized show evidence of air infiltration at the base of the folding glass doors, the stove hood, the bathroom fan, and several of the HVAC diffusers suggesting that these are contributing measurably to the whole house air leakage.

Further, we have suggested that these apertures do not introduce substantial new thermal bridges into the building envelope. Our THERM analysis, shown in Figures 11 and 12, suggest that thermal bridging at this detail is not a primary concern but that a less conductive frame material may yield thermal improvements.

Figure 11: Results of THERM heat flux analysis, plan view (left).

Figure 12: Results of THERM heat flux analysis, section view (right).

We conclude from the results of the blower door testing and the THERM analysis that this ventilation approach is a viable one in cold climates, and may be applicable to other buildings beyond the test home. Thus further laboratory testing is warranted.

## DISCUSSION

This study performed initial analysis and in-situ research into a novel natural ventilation aperture which indicates that it is a promising detail for cold climate residential construction. That is, whole house infiltration, including that from the thirteen ventilators, is within several energy efficiency guidelines for infiltration. Further, 2D heat flow analysis suggests that thermal bridging is not problematic. Further laboratory study is warranted to quantitatively characterize heat flow and infiltration. Laboratory studies should focus on heat flux measurements through the assembly, including a hot box test.

While the house meets most of the infiltration guidelines examined, it notably does not meet the PassiveHouse standard. Given that much attention was paid to air infiltration during design and construction, this is a surprise. For example, walls, ceilings, and floors are of SIP construction, where panels are tightly connected with a spline and adhesive. All windows are fixed, with spray foam insulation around the frame; all wall and roof penetrations are caulked. However, the photographic evidence points to air leakage under the folding glass panel doors, as well as at several mechanical system connections. It is recommended that these leaky areas be addressed in order to reduce air infiltration to meet the Passive House standard.

## CONCLUSIONS

Design for high-performance residential buildings often includes novel applications of sophisticated active technologies, but may also benefit from novel applications of passive technologies. This paper reports on an investigation into the wintertime performance of novel natural ventilation apertures in a prototype high-performance single-family home in Buffalo, NY. This study assess whether the design approach of decoupling natural ventilation apertures from daylight/view windows can improve wintertime thermal performance of the home. In the test home, natural ventilation occurs through a set of thirteen  $0.121 \text{ m}^2$  wood framed, screened openings located in the upper part of the SIP-constructed walls, typically above fixed view windows. Ventilation in summer is controlled with a manual wooden door.

In winter, a gasketed plug of insulation weatherizes the opening and minimizes conductive heat transfer and infiltration.

This design approach is new for cold climates. The operable, dedicated ventilation panels found in temperate locales is modified here to include seasonal insulation. The investigation methods included analysis of whole-building infiltration using blower door testing, diagnostic photography, and modeling in THERM. Results indicate that this approach is viable in cold climates, and should be further studied for implementation to maximum effect in future projects.

### **ABSTRACT**

Radiant Floor Heating System (RFHS) has been commonly used in railway stations in cold regions of China for its advantages in thermal comfort and energy efficiency. However, the uneven distribution and extremely cold area of the heating floor, caused by cold air infiltration through door openings, are commonly found in our filed measurements. This impact is not considered in the standardized design methods, resulting in an underestimation of the design heat flux. In this paper, CFD simulations are used to quantify the impacts of natural infiltration on surface heat transfer process. Model validation was made against field measurements. 13 simulations were performed for different speeds. As a result, the mean radiant heat flux at floor surface decreased by 36.8% as the infiltration air speed increased from 0.05 m/s to 1.2 m/s, and the noneffective area increased more than 16 times. This result highlights a significant influence of natural infiltration. Regression models were finally developed as a simple method for rough estimation of this impact on radiation, which can make up the limitations of current methods and inform designers to improve their initial design of RFHS when natural infiltration is present.

### **KEYWORDS**

Radiant floor heating system (RFHS), Large space buildings, Natural infiltration, Radiation heat transfer, CFD simulations.

### **INTRODUCTION**

The proportion of radiant heat exchange in surface total heat flux counts much for the design and operation of Radiant floor heating system (hereinafter RFHS). For this system, the air temperature is allowed to be 1-2 K lower than the conventional all-air systems, due to its heat exchange mainly by radiation (Rhee K N et al, 2017). With the benefit of high energy efficiency, good thermal comfort and space saving potential, RFHS has been widely applied in most railway stations in cold regions of China and is considered as especially effective for heating this space. However, the uneven distributions and a wide low temperature region at the floor surface were commonly found in field measurements of six railway stations. This gap between the design and the reality indicates that the current design methods of RFHS are not applicable for buildings with high door opening frequency and increased ventilation heat loss. Therefore, the goals of this paper are to: 1) verify the impacts of natural infiltration on RFHS, 2) develop a simple method for rough estimation of radiation heat transfer, and 3) give reasonable advice for improving the initial design of RFHS when natural infiltration is present.

### **METHODS**

#### **Field measurement**

There are mainly 3 types of waiting hall (Fig.1), categorized by the relative position of entrance and exits. A corner type was chosen for field measurements. The test was performed from 8am to 8pm on January 8<sup>th</sup>, which was an overcast day. The measuring details are listed in Table 2. Table 1. Three types of waiting hall

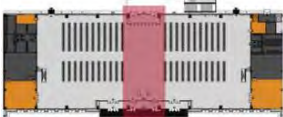

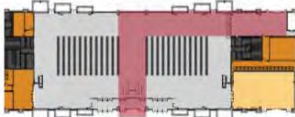

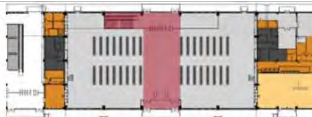

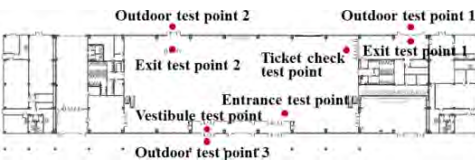

Types	Straight type	Corner type	Underground type
Examples			

Table 2. Measuring summarization

Item	Instrument name	Range	Accuracy	Measuring points	Interval	Method
Ground temp and internal surface temp	 Sentry ST677 infrared thermometer	-32~1650°C	±2°C		2h	The average value of 5 measurements
Air temp	 HOBO UX100-003	-20~70°C	±0.21°C		5min	Air Temp and Humidity Measure Method of Public Place GB/T18204.13-2000
Airflow rate	 Tesco 425 Hot wire anemometer	0~50 m/s	±0.015 m/s		15min/h	Wind Speed Measure Method of Public Place GB/T18204.15-2000

Figure 1. Measured results of waiting hall. a) Ground temp distribution, b) Air temp

The measurement interval of ground temperature was two hours. During the test period, six runs were tested, and the mean value of each point was used for interpolation. The matrix data of ground temperature was transferred into a color-filled contour image by Origin (Fig.1a). An uneven temperature distribution and a wide low-temperature region between the entrance and the main exit are observed from this image, leading to a decline of surface radiation in the combined heat transfer process. Besides, the air temperatures of point 6 and 7 are found always below average (Fig.1b), demonstrating a poor performance of convection heat transfer due to the increased ventilation heat loss.

### CFD simulation

The ANSYS's workbench platform was employed for CFD simulation. The size of the waiting hall is about 84 m (length)×33.6 m (width)×20.4 m (height). The geometry (Fig.2a) of the flow domain was modelled using ANSYS's DESIGN MODELER. The developed physical model was then meshed using 3D hybrid meshing comprised of 4, 582,417 unstructured elements and 1,611,915 nodes. The maximum mesh size was 0.2 m. Meshes near wall surface are subdivided as  $y^+ < 1$  using 10 layers inflation (Fig.2b). Separate grid independency was not tested due to the fine sizes. solar radiation, internal heat gains and heat loss of enclosures were not included, since they are often counterbalanced with one another. The associated air system was shut off

during the test periods. The flow was assumed to be 3D, steady-state, incompressible and turbulent. Buoyancy was modelled with Boussinesq approximation. Near-wall treatment was considered. The heat flux generated from the heating panel was assumed as a constant value of  $80 \text{ W/m}^2$ . Based on the assumptions above, the airflow and temperature distribution were solved by the conservation laws of mass, momentum and energy. The detailed boundary conditions are given in Table 3. The airflow rates and temperatures were set equal to their actual values. Besides, RNG  $k - \epsilon$  and Discrete Ordinate (DO) model were chosen to simulate the turbulence and radiation phenomena inside the room, respectively. The coupled-analysis model was solved as steady state using SIMPLE algorithm. Enough good convergence was obtained finally.

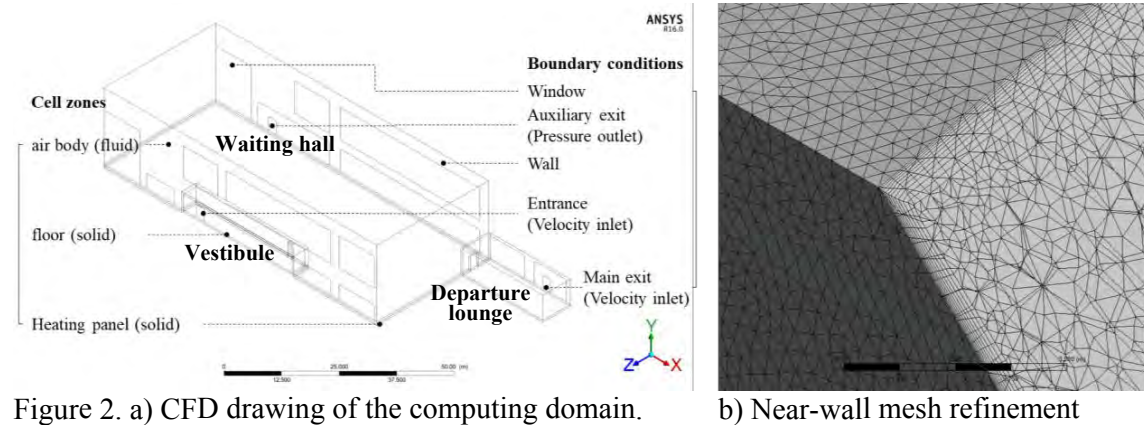

Figure 2. a) CFD drawing of the computing domain.

b) Near-wall mesh refinement

Table 3. Boundary conditions

Wall	Window	Internal wall	Floor	Heating panel
Wall temperature boundary condition ( $17^\circ\text{C}$ )	Wall temperature boundary condition ( $10.5^\circ\text{C}$ )	Adiabatic (heat flux = 0)	coupled boundary condition	Heat flux boundary condition ( $80\text{W/m}^2$ )

### Validation of the model

Figure 3. Correlations of actual measurements and simulated temperatures. a) Ground temperature of 21 measuring points ( $y=0$ ), b) Air temperature of 8 measuring points ( $y=1\text{m}$ ).

The measured floor surface temperatures at 21 points and air temperatures at eight points at 19:00 in the measured day were used for model validation. The occupancy rate was lowest. Fig.3 shows the correlation of actual measurement and simulation results. Dotted lines in the graphs represent the error range of  $\pm 1^\circ\text{C}$ , and RMSE denotes the root mean square error. Ground temperature shows general agreement with measurement (Fig 3a), considering the uncertainty

of 2°C with measurement accuracy of the infrared thermometer. In general, the overestimation of ground temperature may result from the assumption of constant heat flux and the limitations of steady state simulation, which neglect the temperature drop within the pipe and the delay effect of this system. This overestimation seems to be more prominent in the peripheral area, especially for points near entrance and exists (1, 6, 10, 13, 21 in Table 2). In contrast, the air temperature is much underestimated by CFD simulation (Fig 3b), especially for points in occupied area (3, 4, 5, 6 in Table 2). This discrepancy is due to the ignorance of internal load. Since the central area usually has more passengers than peripheral area, the bias error of point 1,2,7,8 was larger. Generally, these values verify the satisfactory performance of the CFD model, and the simplification allows a substantial decrease of the computational cost without affecting the performance of radiant heat exchange, which is the main interest to this study.

### Assessment parameters

The RFHS is defined as a system that radiant heat transfer covers more than 50% of heat exchange within a conditioned space. As the case mentioned in Chapter 6 of ASHRAE Handbook, HVAC Systems and Equipment (1992), the surface heat flux can be calculated separately for convection and radiation. Poor performance for providing stable thermal environment of convective heat transfer has been found in field measurements, which is caused by the increased ventilation heat loss at doors. Therefore, radiation is preferred. In this study, the overall level of radiant heat flux is viewed as an indicator of the system's thermal performance. To numerically demonstrate this, an index named mean radiant heat flux ratio (hereinafter **MRR**) is defined, which is a direct comparison of mean radiant heat flux and the total heat flux (80 W/m<sup>2</sup>) at the floor surface. Here, the mean radiant heat flux is calculated by the sum of radiant heat flux at the heating surface divided by the total heating area. Suffering from the decrease of ground temperature, the MRR may drop to 50%, which is a minimum value given in ASHRAE, or even lower. In such area the performance of the system is identified as noneffective. The ratio of the noneffective area to the total heating floor area is defined as the noneffective heating area ratio (hereinafter **NAR**). The two indices above were employed to quantify the impact of natural infiltration.

## RESULTS

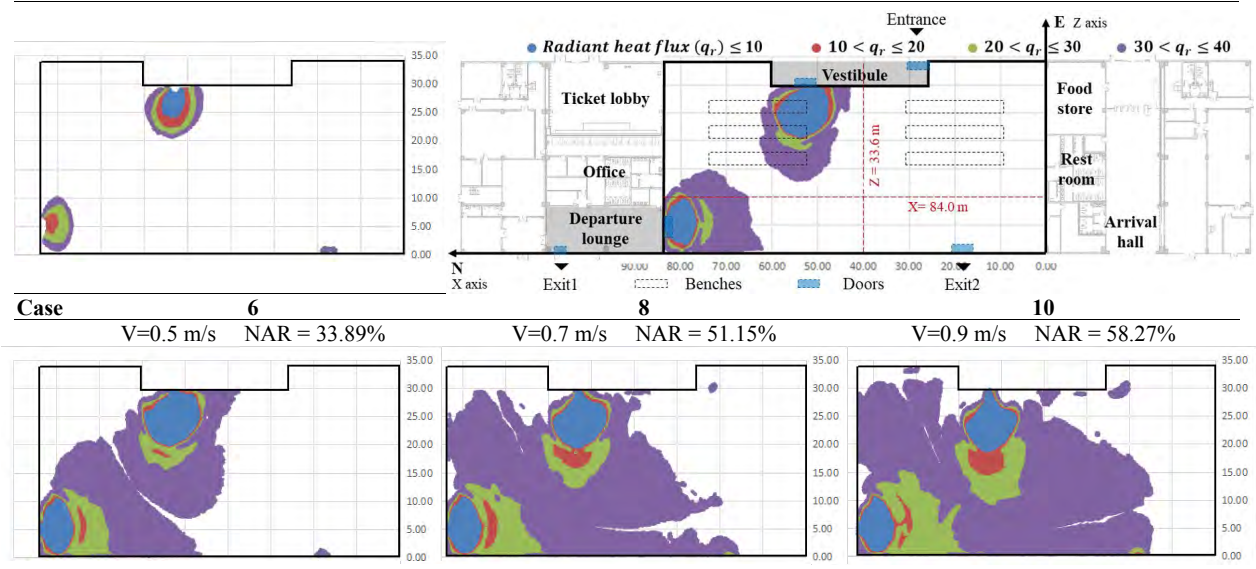

Table 4. CFD simulation results summarization

Case	1	2	3	4	5	6	7	8	9	10	11	12	13
Infiltration air speed (m/s)	0.05	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9	1	1.1	1.2
Average radiant heat flux (W/m <sup>2</sup> )	53.0	51.4	48.2	44.3	41.33	39.0	37.2	36.0	34.9	34.1	33.3	33.6	33.5
Average convective heat flux (W/m <sup>2</sup> )	27	28.6	31.8	35.7	38.67	41	42.8	44	45.1	45.9	46.7	46.4	46.5
Mean radiant heat flux ratio (MRR)	70.0%	67.4%	61.7%	56.8%	52.9%	49.9%	47.7%	46.0%	44.6%	43.5%	42.5%	42.9%	42.8%
Noneffective heating floor area (m <sup>2</sup> )	121	150	296	494	742	956	79	1185	1445	1645	1775	1902	2072
Noneffective area ratio (NAR)	4.3%	5.3%	10.5%	17.5%	26.3%	33.9	42.0%	51.2%	58.3%	62.9%	67.4%	69.9%	73.4%

According to the measured data, the wind speed at entrance and exits was initially set as 0.05m/s and then to increase from 0.1 to 1.2m/s at an increment of 0.1m/s. 13 scenarios in total were simulated. The main simulation results were tabulated in Table 4. Table 5 gives an intuitionistic exhibition of the noneffective heating area distributions under different wind speeds. In each figure, the noneffective area was categorized into four levels according to its radiant heat flux and filled with corresponding colors as the legend shows. The same coordinate system and room plan were only attached to case 4 as a reference. Part of cases are not shown due to limited space, but the gradually enlarging distribution pattern of the noneffective area is still obvious.

Table 5. Noneffective heating area distribution

Case	2	4
V=0.1m/s	NAR=5.34%	V=0.3 m/s
		NAR=17.54%

## DISCUSSIONS

Scatterplots were used to evaluate the correlation of air velocity with MRR and NAR, and the acquired regression models were described in Fig.4.  $R^2$  values over 0.9 show significant correlations between the input and output, indicating a deep impact of wind speed on radiation heat transfer. For MRR (Fig 4a), the decreasing rate is apparently higher when the air speed is increasing from 0.05 to 0.7 m/s, implying even a slight increase of wind speed could cause a significant drop. After that, the descending rate levels off, and the lowest ratio is about 43%. For NAR (Fig 4b), it is positively related to the infiltration air speed, which is considerably low at first but grows rapidly as the wind speed increases. Taking the distribution into account, the noneffective area only appears near the entrance and exits, and the MRR of occupied area is acceptable when air velocity is low, as shown in Table 5. However, the noneffective area becomes larger and gradually spreads to the occupied area with the increase of wind speed. The occupied area thus would be at great risk of discomfort. In this way, the impact of natural infiltration could be quantified at the initial design stage once the prevailing wind speeds at the entrance and exits are given. A microscopic correlation analysis was performed between near-surface-wind-speed ( $y=1\text{mm}$ ) and the corresponding surface radiant heat flux ( $y=0$ ) to further validate the findings above by using a large sample size and taking the position factor into account. To this end, 80857 sample points were investigated and 10% of them were selected with systematic sampling method for correlation analysis. These nodes were evenly distributed at the floor surface. The result is shown in Fig 5a, taking case 6 ( $V=0.5\text{ m/s}$ ) as an example. The vertical axis represents the radiant heat flux, and the horizontal axis represents the node number which is defined sequentially according to its near-surface-wind-speed. An obvious piecewise

linear change was found at the two sides of the dividing line, which corresponds to a near-surface-wind-speed of 0.3 m/s. The left part of the dividing line shows a general decreasing trend. The discrete distribution shows a common influence of the speed and position factor. The near-surface-speed limit of 0.3 m/s and a decreasing amplitude of 33% are obtained as a design reference. While for the right part, which is replotted in Fig 5b, the highly linear correlation ( $R^2=0.85$ ) highlights the dominate influence of speed factor. The decreasing rate is apparently higher than the left, and the surface radiation is extremely low. However, this part only accounts for a small portion of the entire sample size. In all cases, the near-surface-wind-speed shows 0~1.4 m/s at the occupied area regardless of the wind speed at the entrance and exits, and the results of piecewise correlations are found to be quite similar. Therefore, case 6 is representative for all other cases.

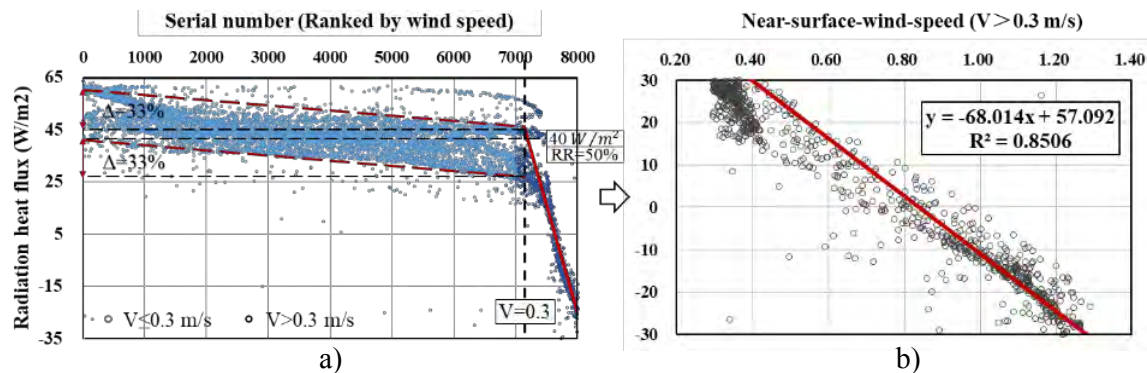

Fig.5 a) Surface radiant heat flux ( $y=0$ mm) according to the near-surface-wind-speed ( $y=1$ mm). b) the regression curve for  $V>0.3$ m/s

## CONCLUSIONS

The results of field measurements provide evidences that the existing RFHS design methods are theoretically insufficient when this system operates with significant natural infiltration. Regression models for wind speed at doors and near-surface-wind-speed were developed in this paper. For a better performance of RFHS, the near-surface-wind-speed should be controlled under 0.3 m/s. Within this limit, comprehensive estimations are recommended for surface radiation, noneffective heating area and its distributions to guide reasonable design decisions. These assessments are easily to perform with the acquired regression models. When necessary, designers should take extra measures to increase the design heat flux at affected floor area, such as adding extra heat source, reducing pipe spacing or imposing the regional control methods.

### **ABSTRACT**

Improving the energy efficiency of typical 19th century townhouses in middle Europe the focus on the wooden beam bearing's hygrothermal performance has become more and more important during the last years. There are several issues for the risk of rotting of the wooden parts of the ceiling, because the retrofitting process of the masonry totally changes the hygrothermal conditions inside the wall. Applying an interior insulation or changing the air-tightness of the building envelope as well as the introduced moisture from the retrofitting process lead to a moisture increase inside the masonry and might cause rotting of the ceilings' wooden beam ends.

This paper introduces two demonstration objects which were retrofitted during the last years. Temperature and humidity sensors have been integrated at the wooden beams' ends to show the hygrothermal conditions during and after the retrofitting process. In the first building measurements started at the beginning of the renovation in September 2013 and are still being carried out. To compare different situations the monitored beam bearings are situated in two different retrofitted wall constructions, an inside insulated and a not insulated wall. Additionally, different indoor climates in the flats above and below the measured ceiling are monitored. In the second building 16 wooden beam heads situated in two different storeys with differing masonry thicknesses were measured. In this demonstration object the influence of building construction moisture from the renovation process as well as the drying out process were evaluated.

In conclusion, the wooden beam heads' durability will be assessed based on the measurement results and possible risk of damage influenced by the retrofitting process.

### **KEYWORDS**

Wooden beam ceiling, interior insulation, in-situ measurements, hygrothermal performance

### **INTRODUCTION**

During the course of the project „Improving Durability of Wooden Beam Bearings in Inside Insulated Walls by Tempering the Beam's Heads“ in-situ-trials on existing constructions with wooden beam ceilings were carried out in two late 19th century townhouses in Vienna. For a targeted analysis of the hygrothermal performance of wooden beam heads, sensors to measure temperature and relative humidity were installed in the floor-bearing-areas during a typical retrofitting process. Thus, the conditions in temperature and moisture could be examined during the state of construction and over the ensuing years of use.

Currently, no interior insulation is installed when a late 19th century townhouse is renovated conventionally, as there is no requirement for the thermal transmittance (U-value) with renovations according to the Austrian building code. However, due to noise abatement, a suspended ceiling is always mounted, which – because of the placement of mineral wool

results in cooling of the floor bearing area during wintertime. Future, energy-efficient renovations will stipulate the installation of an interior insulation, necessitating a detailed planning of accompanying measures on the ceiling-to-wall bearing. On the one hand, the measurement results document a long-term study on the functional efficiency of current methods of renovation. On the other hand, they form the basis for further research and the set-up of a bench test in a double climate chamber. The aim is to show that with constructions using interior insulation the floor bearing area cools of severely during winter and, because of the high relative humidity, the risk of wood rotting increases.

## METHODS

Temperature and relative humidity sensors were installed in the construction of two demonstration buildings in selected apartments during the renovation works. Depending on the wooden beam's installation situation, the sensors were mounted in different positions. Figure 1 exemplarily shows, using the installation situation of building "Eckertgasse 10" that measurement points were chosen at the top, the bottom as well as in the middle of the beam head. Additionally, every wooden beam was spot-drilled, to be able to position a sensor in half of the beam's height in the air space between the wood and masonry. To measure the climatic boundary conditions, the indoor climate of the flat resp. the particular room and the outdoor climate on the façade were recorded.

Figure 1. Example of sensor positions at the beams' end for long time monitoring; façade section of "Eckertgasse 10" (above), picture in the ceiling cavity (bottom left), picture of the sensor on top of the beam (bottom right);

There are different installation situations of beam head abutments (Wegerer et al., 2017) and thus also different hygrothermal behavioural patterns which are influenced by constructional parameters. While numerous publications (e.g. Kehl et al., 2013; Guizzardi et al., 2015; Strangfeld et al., 2012) often report on the calculation resp. the simulation of beam heads, there are little findings on the actual behaviour of wooden beam bearings in practice, especially after a retrofitting process.

The fundamental aims of this research paper consist in examining a sufficiently large enough sample of wooden beam heads as well as to achieve a multi-year measurement time. Figure 2 shows the façade of demonstration object “Trubelgasse 8”. In this building, 16 beam heads were equipped with sensors. The measurements on the two demonstration buildings started at construction level and, in the beginning, show the building moisture’s drying-up-process. The continuous, multi-year gathering of data that started in July 2016 gives information about the hygrothermal behaviour during the utilisation phase.

Figure 2. Façade (left) and section (right) of demoobject “Trubelgasse 8” with 16 schematically marked monitored beam heads.

## RESULTS

### Demonstration building “Eckertgasse 10”

So far, more than 4 years of measurement data are available from this monitoring. Beam heads B1 to B3 are located in the area of an outside wall with interior insulation analogous to the construction in fig. 1. Beam heads B4 to B6 are located in the area of the original outside wall without interior insulation and serve as a reference.

The results clearly show the fluctuations between winter and summer. Furthermore, a steady drying-up-process since the beginning of the measurements is noticeable with all beam heads on the basis of the relative humidity at at least one measurement position. An increase in relative humidity is noticeable with nearly all beam heads during the cold season, which dries up again during the summer months.

To obtain a direct comparison between a construction with and a construction without interior insulation, the measurement data of the sensor positions in the middle of the respective beam head are shown in the diagrams in fig. 3. These positions were made almost identically in all 6 beam heads using drill holes. This comparison shows that in the interior insulation’s area (B1 to B3) critical moisture conditions are reached at the wooden beam heads. Sensor positions on the beam heads bearing in the original, non-insulated construction yield only marginally to barely critical measurement values after the building moisture’s drying-up (B5 and B6). Only B4 shows a higher relative humidity during the winter months.

Figure 3. Temp. graphs (left) and rel. hum. graphs (right) over 4 years after the retrofitting process. The object “Eckertgasse 10” has an inside insulation below the measured floor.

The indoor climate (figure 4, left) shows a moisture load typical for residential use and can be classified into moisture class 3 according to EN ISO 13788.

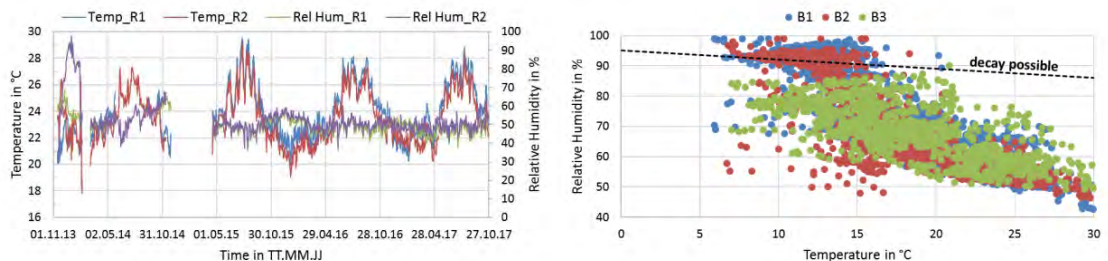

Figure 4. Left: Indoor climate; right: relation between temperature and relative humidity on the beam ends 1 to 3 (daily average values) and limiting curve according to WTA MB 6-8

The comparison of temperature and relative humidity (figure 4, right) in accordance with WTA MB 6-8 shows that only a few days during wintertime yield critical values. Most of the time there is a low risk of wood rotting because of the drying-up during summer.

**Demonstration building “Trubelgasse 8”**

In this demonstration building, 16 beam heads are examined after a conventional renovation of the façade without fitting an interior insulation. Three sensors were mounted on each beam head, one in the air cavity facing to the outside and two sensors on the abutment at the contact of wood and masonry. The outside wall has three different thicknesses (see figure 2). As a result, the hygrothermal conditions on the beam head vary highly depending on the storey. Beam heads 1 to 8 are situated in a 60cm thick wall and are covered by 45cm with masonry on the outside. Beam heads 9 to 16 are located in a 45cm thick wall and are covered by 30cm with masonry on the outside. This leads to lower temperature and higher relative humidity at the thinner outside covering. The influence of suspended ceilings is also discernible with this construction. Due to the thermal insulation in the ceiling level, increased cooling of the beam abutments occurs during the winter months. The following evaluation shows results from the 2017/18 winter period. Figures 5a and 5b display data with different wall thicknesses.

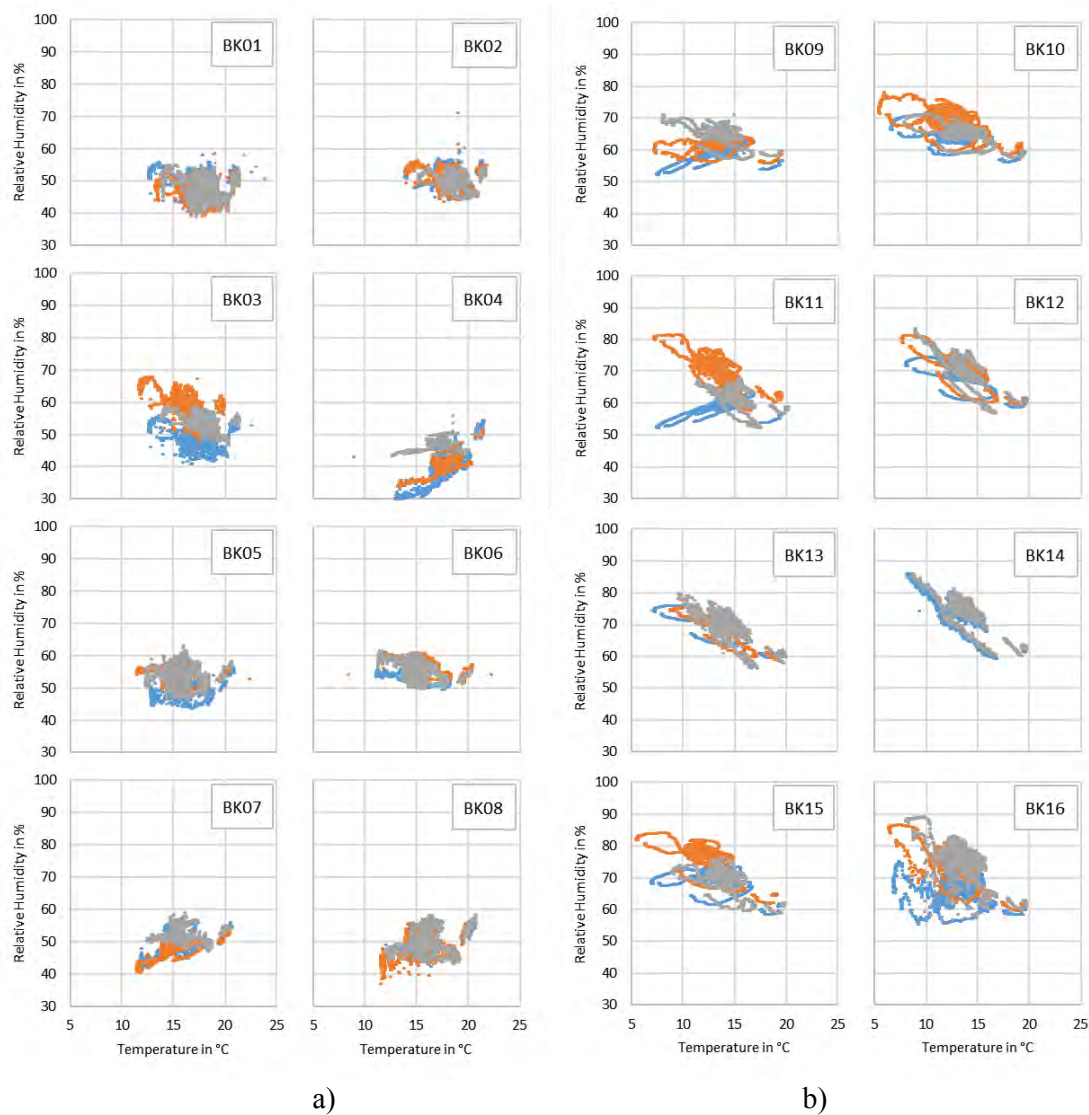

Figure 5. Measurement results at the three positions of the beam heads. a) Wall with 60cm thickness, b) wall with 45cm thickness. The object “Trubelgasse 8” has no inside insulation

on the outer wall below the measured floor. Only a suspended ceiling decreases the temperature of the beam end.

## DISCUSSIONS

The combination of long-term measurement and a greater sample size of examined beam head details provides new findings on the functional efficiency and durability of current renovation methods. Most Wilhelminian style houses are over 100 years old and virtually no cases of damage on wooden beam ceiling abutments are known. However, renovations and thermal improvements of the building envelope, especially the fitting of more airtight windows, the mounting of an interior insulation system, or the installation of a suspended ceiling filled with mineral wool change the indoor climate and the hygrothermal performance of the outside wall. The measurement results show that certain renovation measures require detailed planning to minimise the risk of damage of the improved construction. Earlier research has shown the behaviour of wooden beam heads with a retrofitted interior insulation based on concrete examples of damage or case-specific hygrothermal simulations. This research paper's results are to emphasise the importance of monitoring and sample size, especially when particular renovation methods, e.g. an interior insulations, are planned. Additionally the findings show that the renovation measures used in the demonstration objects do not put the durability of the existing construction at risk when the building moisture may dry up and the room climate corresponds to average usage.

## CONCLUSIONS

The results provide important feedback for the planner and the developer of the demonstration buildings presented. The long-term studies prove the well-tried constructions' functional efficiency and allow an apportionment on the developer's other renovation projects.

The monitoring results are important validation data for current laboratory tests, which are carried out on a true-to-life sample wall with ceiling-to-beam connection in a double climate chamber. The aim of further laboratory tests is to closer examine the beam head detail on the sample wall and to develop accompanying measures, e.g. a targeted tempering of components for constructions with interior insulation.

## ACKNOWLEDGEMENT

### **ABSTRACT**

This paper deals with hygro-thermal performance of wooden beam ends embedded in masonry walls with lime-cement plaster applied on the external side. Three different insulation systems are attached on the internal side of masonry. The real scale experiment has been monitored for three consecutive years. Microclimatic conditions in joist pockets were assessed by VTT mold growth index. The paper shows the influence of two changes of boundary conditions on the microclimate in joist pockets. First, moisture load on the internal side of building enclosure was increased (24 °C, 60 % in winter 2016/2017 instead 20 °C, 50 % in winter 2015/2016). Then, the artificial short-time rain event brought liquid water onto the external surface of building enclosure in July 2017. The rain intensity was chosen so as to mimic the intensive summer thunderstorm. The increase of water vapor concentration in the air on the internal side led to suitable conditions for mold growth in unsealed joist pockets of a vapor open insulation system. On contrary, microclimate in sealed joist pockets in both vapor open and vapor closed insulation systems stayed in acceptable levels with no mold growth. The artificial rain event significantly changed the hygro-thermal performance of joist pockets. Drying season was shortened and the relative humidity in joist pockets overtook the time profile of external relative humidity.

### **KEYWORDS**

internal insulation, wooden beam end, monitoring, moisture safety, mould growth

### **INTRODUCTION**

Uninsulated brick buildings suffer from high energy consumption, poor thermal comfort and mould growth on the coldest spots of the internal side of the building enclosure. Such buildings were erected before the Second World War in many European cities and often form entire neighborhoods. Floors are often supported by wooden beams placed in pockets embedded in brick walls. The external insulation is usually excluded from refurbishment measures, either because of the fixed building line or because of the decorative façade with cultural value. The internal insulation is therefore the only possible technical solution in these cases. However, the internal insulation significantly changes hygro-thermal performance of the masonry wall.

As the wooden beam protrudes out thermal insulation it is also located in the cold part of the building enclosure. The lower temperature in this position inevitably leads to higher relative humidity of the air in the joist pocket. Moisture content of wood in contact with the air in the pocket is therefore higher (as follows from the sorption isotherm) than it would be if wood was placed on the warm side of the building enclosure. If moisture content of wooden beam end is high enough for sufficient period of time, mold growth or even biodegradation can occur.

This paper deals with hygro-thermal conditions in the air cavity behind wooden beam ends placed in masonry pockets. To study this phenomena long-time full-scale experiments were built in University Center for Energy Efficient Buildings (UCEEB) of Czech Technical University in Prague. Boundary conditions, temperatures, relative humidity, moisture content in wood, and heat fluxes, have been continually recorded for three years. It is assessed whether microclimate of the joist pockets was suitable for mold growth on the wooden beam ends.

### EXPERIMENTAL SETUP

Two “test windows” on the south west façade, with the dimension 3.0 m x 3.2 m each, are occupied by brick masonry walls (30 cm) with lime cement plaster (2 cm) on the external side. A climatic room with controlled internal environment is located on the internal side of test walls. Three different internal insulation systems are attached on the internal side of masonry: S1 - wood fiber insulation (8 cm, 14 cm) with thin plaster applied on the internal side (5 mm), S2 - soft mineral wool (9 cm) placed between aluminum studs with smart water vapor retarder and gypsum boards, S3 - vacuum insulation plates (2 cm) covered by EPS (2 × 1 cm) with thin internal plaster (5 mm). Joist pockets were treated by different means, see Fig. 1. For more details on the experimental setup see (Kopecký et al., 2016).

Figure 1. The view on the test fields (from exterior) with position of wooden beam ends.

The following sensors were used to monitor hygro-thermal conditions at the wooden beam end: 1) temperature sensors, 2) temperature + relative humidity sensors, 3) moisture content pins. Positions of the sensors are shown in Fig. 2. Thermostat and hygostat set points during the whole experiment are introduced in Fig. 3. The air handling unit is not equipped by dehumidifier. Therefore, the unit do not keep steady humidity during warm season.

Figure 2. Position of measurement sensors in masonry pocket with wooden beam end.

Figure 3. Thermostat and hygostat setpoints during experiment.

The artificial rain experiment was realized on 19.7.2017 by means of nine nozzles mounted on a supporting frame (see Fig. 4). Time duration of showering was 40 minutes. The artificial rain imitated a summer thunderstorm with exceptional but still realistic rain intensity in the climatic locality. The experiment was intentionally performed during morning time (i.e. without direct solar irradiation on the south west facade) so evaporation was relatively low. Since sprinklers were positioned more in the central part of the test fields, the narrow stripe near the perimeter of test fields stayed dry (see. Fig. 4). The total inflow of water into the sprinkler device was 1,7 litres/m<sup>2</sup>/min (68 litres/m<sup>2</sup>/40min). The value is much higher than the strongest wind driven rain observed on site during monitoring campaign. The total volume of water sucked by the test field was 13,4 litres/m<sup>2</sup>/40 min (related to wet area, outflowing and bypassed water was taken into account). Due to the limited size of the sprinkler device joist pockets located on both vertical sides of test walls were not loaded as much as joist pockets located in the central part of test walls. Based on the porosity of the plaster and bricks and the total amount of water absorbed, it can be estimated that the saturated zone was approximately located up to a depth of 5 cm when the artificial rain was finished.

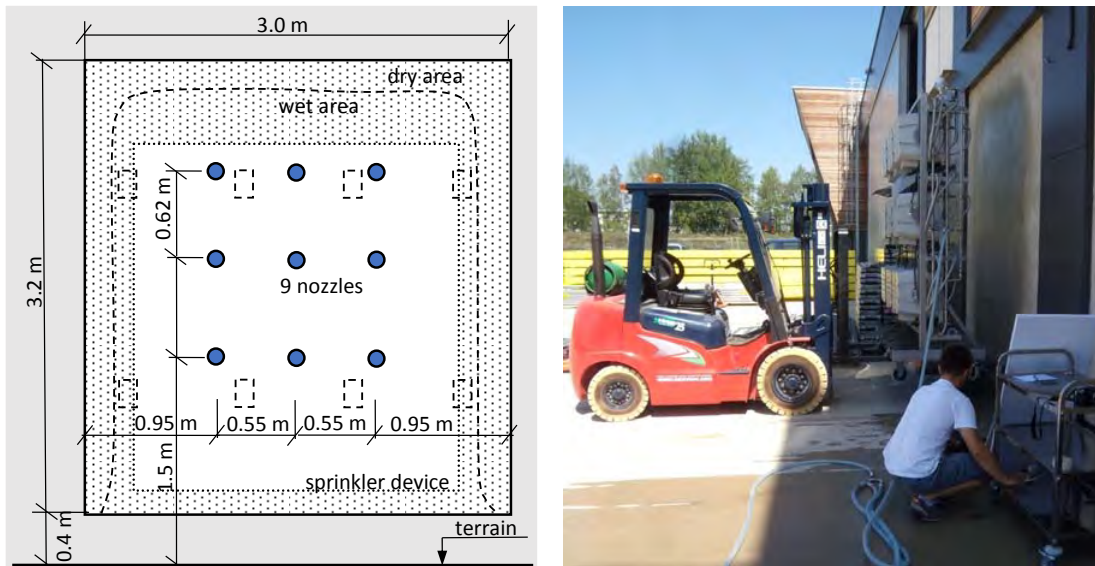

Figure 4. Left – the front view on the test field with position of sprinklers and wooden beam ends. Right – the sprinkler device positioned in the front of the test field.

## RESULTS

Long-term measured data are summarized in Fig. 5.

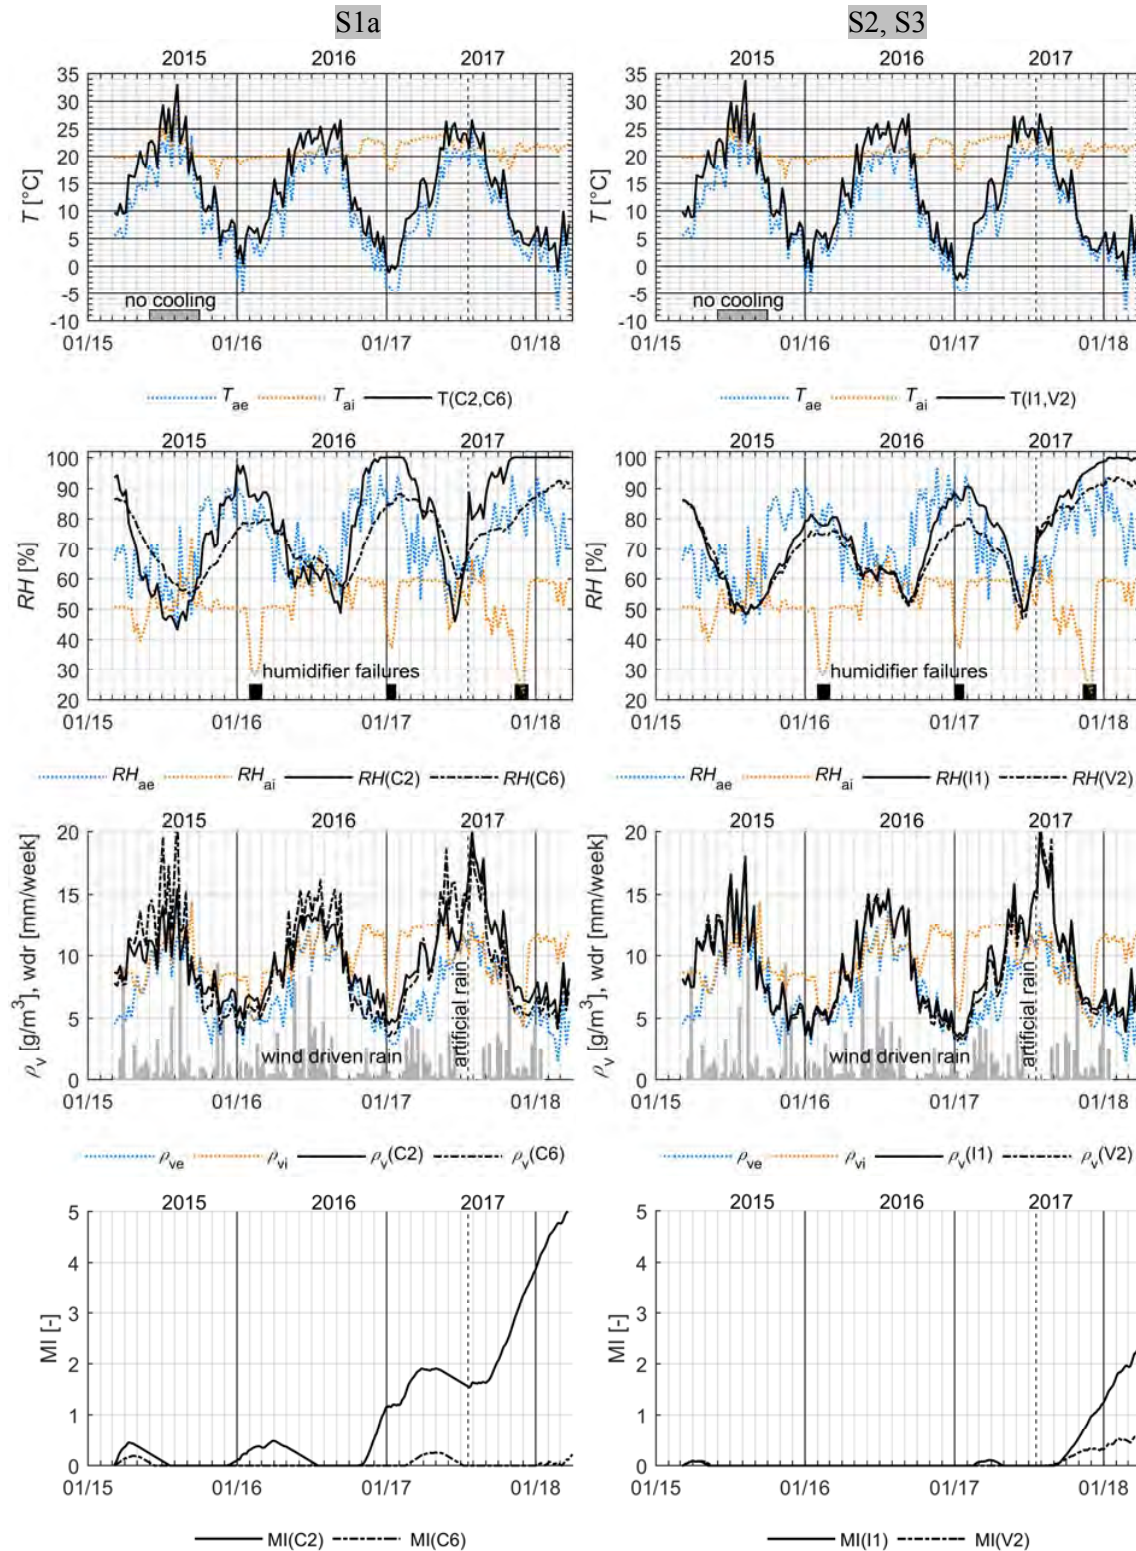

Figure 5. Measured data - temperature, relative humidity, water vapor concentration (weekly averages) and calculated mould growth index (hourly values) for selected joist pockets. Left column – system S1. Right column – systems S2 and S3. Temperature and relative humidity were measured in the bottom part of joist pockets (see Fig. 2).

Data depicted in Fig. 5 comprises weekly average values of temperature, relative humidity and water vapor concentration. Wind driven rain load was calculated by a simplified method of (Straube, 1998) for the spot near the ground in front of the test walls. Mould growth index was calculated by the improved version of VTT mold growth model (Viitanen and Ojanen 2007). The input parameters are material (spruce wood), wood surface quality (resawn) and hourly values of temperature and relative humidity measured in joist pocket.

Relative humidity in joist pockets exceeded 80 % during the experiment. Relative humidity in unsealed joist pocket (C2) of water vapor open system S1 reached 100 % in December 2016 resp. in November 2017. Relative humidity in sealed joist pocket (C6) of vapor open system S1 overshoot 90 % in February 2018. Relative humidity in the sealed pocket (I1) of vapor closed system S2 reached 100 % in January 2018. Relative humidity in the sealed pocket (V2) of vapor closed system S3 exceeded 90 %.

## DISCUSSION

Similar patterns in time profiles of relative humidity in joist pockets were observed in the first two cold seasons of the experiment. There is obvious negative correlation of relative humidity in joist pocket with external air temperature. Moreover, relative humidity signals were delayed and dampened (with exception of amplitude amplification in the unsealed pocket C2) if compared with relative humidity of external air. Time lag and amplitude are related with the treatment of pockets and the type of insulation system. Relative humidity profiles during the last year of experiment differed from the patterns observed in the first two cold seasons. Relative humidity and water vapor concentration in joist pockets was increased after the rain experiment. Increase of relative humidity occurred even though mean external air temperature stayed near 20 °C for one and half month after the rain experiment. Relative humidity in joist pockets overtook relative humidity of the external air in time. Consequently, drying season was shortened. Surprisingly, only the sealed joist pocket C2 in vapor open system S1 did not show overtaking trend after the artificial rain experiment.

Water vapor concentration in joist pockets was systematically higher than water vapor concentration in the internal and external air during summer months. Both internal and external water vapor concentration were in equilibrium in summer months (no dehumidification incorporated in the air handling unit). Therefore, some other moisture sources than both ambient environments has to be responsible for that offset. Since the external surface temperature is on average higher than external air temperature during summer time and wind driven rain load tends to be higher in summer, it can be deduced that increased water vapor concentration in joist pockets is due to moisture flow from external side towards joist pockets. In addition, desorption of adsorbed moisture from wooden beam end also takes place.

Relative humidity in joist pockets was kept safe only during the first cold season of the experiment. Initial built-in moisture dried (as a consequence of very warm summer 2015). Even sealed joist pockets tended to overshoot the critical relative humidity 80 % in cold season under higher internal moisture load. Mould growth index indicated problems in unsealed joist pocket C2 in vapor open system S1 whereas mould growth was not predicted in joist pockets of vapor closed insulation systems S2 and S3 under higher internal moisture load. Even joist pockets in vapor closed systems suffered from possible mould growth after the artificial rain event (at the end of cold season 2018). It should be noted that probability of a rain event with similar intensity is low in the locality. Moreover, mould growth index is no

proof. Therefore, material samples will be taken from wooden beam ends at the end of the experiment (spring 2018). Samples will be tested in a laboratory for presence of molds. In addition, mutual comparisons of measured data in joist pockets with measured data from 1D section of insulation systems could introduce useful information.

Some unexpected results were registered after the artificial rain experiment:

- Sealed joist pocket C6 experienced slower increase of relative humidity than unsealed joist pocket C2. Due to the effect of tape on the outflow of vapor from joist pocket towards interior one would expect faster increase of vapor concentration than in unsealed joist pocket C2. Such performance might be caused by non-uniform rain load introduced by sprinkler device (i.e. joist pocket C6 did not receive the same amount of water as pocket C2).
- Sealed joist pocket V2 experienced slower increase of relative humidity than sealed joist pocket I1. This is suspect since diffusion resistance of internal layers should theoretically be much higher in case of insulation system S3. Such performance cannot be attributed with non-uniform rain load since both joist pockets are located next to each other at the same height. In this case, the slower increase of relative humidity might be related with joints between insulation plates of vacuum insulation panels (effective diffusion resistance of insulation system S3 is reduced).

The experiment will be modified in spring 2018. Some missing variants will be built (e.g. an unsealed joist pocket in uninsulated masonry either with or without metal anchor, joist pocket with non-hygroscopic beam, etc.). Moreover, sensor instrumentation so far is not sufficient to deduce directions of moisture flows. With this respect, combined temperature and relative humidity sensor should be placed at the external and internal side of test walls (close to the surfaces). Moreover, combined temperature and relative humidity sensor should be mounted at the interface of cold side of insulation layer and wooden beam.

## CONCLUSIONS

The presented three-year long experimental results documented microclimatic conditions of wooden beam ends placed in joist pockets in three internal insulation systems attached to masonry walls located in semi-continental climate. The scope and nature of the data collected does not allow to state generally applicable recommendations. However, fundamental tendencies in performance and their relative significance can be evaluated. The more careful analysis of measured data and further real scale experiments are needed in future.

### **ABSTRACT**

The present study looks into the hygrothermal behaviour of timber frame walls with brick veneer cladding in a moderate sea climate. It specifically focuses on the contradictory criterion for the wind barrier when it comes to the risk of interstitial condensation for summer and winter conditions: a vapour open wind barrier is advantageous during an outward vapour flow (i.e. in typical winter conditions for European climates), while during an inward vapour flow (i.e. in summer conditions) a more vapour tight wind barrier is appropriate. Therefore, a field study is conducted on two typical timber frame walls with brick veneer cladding and wind barriers with different vapour diffusion resistance: the  $s_d$ -value of the vapour open wind barrier and the more vapour tight wind barrier is 0.15 m and 1 m respectively at 70% relative humidity. The experimental results show little influence of the vapour tightness of the wind barrier: in general, relative humidity levels are similar in both walls. Outcomes of numerical HAM simulations indicate that this may be caused by the moisture buffer capacity of the different materials, which seems to play an important role to regulate the moisture levels inside the timber frame walls. Further research is needed, however, to draw general conclusions about the appropriate design of timber frame walls with brick veneer cladding.

### **KEYWORDS**

Timber frame walls, brick veneer cladding, vapour diffusion resistance, moisture storage capacity, summer condensation

### **INTRODUCTION**

The increasing environmental awareness has a substantial impact on the building sector. Past research made clear that timber as building material can help to reduce the carbon emission and the total energy requirement of buildings (Australian Government FWPRDC, 2004; Milne and Reardon, 2013). Therefore, the market share of timber frame constructions is increasing, even in countries with a tradition of masonry buildings. However, since wood is a moisture sensitive material, susceptible to mould growth and wood decay, it is essential to keep the moisture levels in the walls to an acceptable level, necessitating specific care when designing such walls. Today, it is common practice in Europe to provide a vapour barrier/retarder at the inside of the wall, while the layers to the outside have an increasing level of vapour permeability. In this way, the risk of interstitial condensation in the outer layers of the wall due to an outward vapour flow is limited. A rule of thumb suggests the layers at the warm side of the insulation to be at least 6 and preferable 15 times more vapour tight than the layers at the cold side of the insulation (WTCB, 2013). However, as already stated by different

researchers (Derome and Saneinejad, 2010; TenWolde and Mei, 1965), this design principle is based on cold climates where the ‘warm side of the insulation’ corresponds to the indoor environment. It does not consider possible inward vapour flow. In a country like Belgium with a masonry tradition, timber frame walls are often finished with a brick veneer cladding, which has a high buffer capacity for wind driven rain but low cavity ventilation rates (Langmans et al. 2016). Consequently, high moisture levels in the cavity behind the brick veneer cladding, resulting in an inward vapour flow, might occur. Different solutions influencing inward vapour flow do exist: hydrophobation of the brick veneer cladding, increasing the cavity ventilation rate or using a wind barrier with a higher vapour diffusion resistance (Sandin, 1993). The last solution is maybe the most simple solution, however increasing the risk of interstitial condensation in case of an outward vapour flow. Using the Glaser method (EN ISO 13788), one can get an idea of the potential problem. The relative humidity at the interface between the insulation (in casu mineral wool) and both the interior and exterior sheathing for a common timber frame inner wall has been calculated in function of the ratio of the vapour diffusion resistance of the interior and exterior sheathing (in terms of equivalent air layer thickness  $s_d$ :  $s_{din}/s_{dout}$ ). The indoor conditions are 20°C and 50%. The cavity conditions are 3°C and 90% RH to simulate normal winter conditions and 35°C and 60% RH to simulate normal summer conditions. This simple calculation shows that only in a small range of  $s_{din}/s_{dout}$  the relative humidity at the interface between insulation and both sheathings will not reach 100% RH for the assumed winter as well as summer boundary conditions (Figure 1). In case the interior sheathing is 6 to 15 times more vapour tight than the exterior sheathing, the design will certainly lead to interstitial condensation in the assumed summer conditions according to this simple calculation.

**Figure 1: According to an elementary calculation, relative humidity conditions will be high at least at one side of the insulation layer, no matter the ratio  $s_{din}/s_{dout}$ .**

The previous example suggests that summer condensation cannot be avoided with the common type of timber frame walls. Note, though, that the Glaser method does not take into account hygric buffering, nor liquid moisture transport. Therefore, the present paper studies, in detail, the overall hygrothermal performance of brick veneer cladded timber frame walls in a moderate sea climate and its risk of interstitial condensation, with focus on the role of the vapour permeability of the exterior sheathing. Field measurements have been conducted at KU Leuven, Belgium, on timber frame walls with different types of wind barrier. The experimental results are compared with the outcomes of numerical simulations, which allow for extrapolation of the different parameters.

## EXPERIMENTAL SET-UP AND SIMULATION MODEL

### Experimental set-up

In the VLIET test building of KU Leuven (Belgium), a long-term in-situ measuring campaign is conducted on two typical timber frame walls with brick veneer cladding. The measurements started in October 2015. The walls are 2.7m by 0.8-0.9m and consist of a brick veneer

cladding (9cm), a ventilated cavity (4cm), a wind barrier (1.8cm), mineral wool insulation between wooden studs (18cm) and an OSB board as interior finishing layer (2.2cm), as shown in Figure 2. The brick has an absorption coefficient of  $0.2584 \text{ kg/m}^2\text{s}^{0.5}$  and its capillary moisture content is  $256.13 \text{ kg/m}^3$ . The wooden studs are made of Scots pine sapwood. Furthermore, the cavity is ventilated by one open head joint ( $3.5 \times 1.5 \text{ cm}^2$ ) at the bottom and top of the wall. The walls are South-West oriented, which is in Belgium the direction of prevailing winds and solar radiation. The temperature, relative humidity and moisture content of the materials is measured at different positions inside the wall. A weather station at the top of the building registers the outdoor climatic conditions.

**Figure 2:** During field tests, the hygrothermal conditions inside real-scale timber frame walls with a brick veneer cladding are measured.

In one set-up (referred to as ‘open’) a vapour open bituminous impregnated wood fibre board (Celit<sup>1</sup>) is used as wind barrier, whereas in the other set-up (referred to as ‘tight’) a more vapour tight wood fibre cement board (Duripanel<sup>2</sup>) is used. The vapour tightness of the interior finishing layer in both walls, in-casu OSB board, is in general still the highest however. Apart from a higher vapour diffusion resistance, the wood fibre cement board also has a higher moisture buffer capacity in the hygroscopic region compared to the wood fibre board (Figure 3).

**Figure 3:** Vapour diffusion resistance (left) and moisture buffer capacity (right) of the building materials

### Numerical simulation model

The same timber frame wall configuration is modelled in the numerical HAM-simulation program DELPHIN 5.9 (Grunewald, 1997; Nicolai, 2007). Only a simplified 1D model without wooden studs is considered. Since air change rates behind brick veneer cladding ranges from 1-10 air changes per hour (ACH) (Langmans, 2016), a constant cavity ventilation

<sup>1</sup> Isoproc Solutions. Celit 3D. <https://www.isoproc.be/nl/solutions/producten/detail/celit-3d/355>

<sup>2</sup> Siniat. Duripanel S3(B1). <https://www.siniat.be/nl-be/producten-en-systemen/producten/platen/vezelcementplaat-duripanel>

rate of 5 ACH is assumed. The real indoor and outdoor conditions as in-situ measured are imposed as boundary conditions.

## RESULTS

### In-situ measurements

By comparing the indoor vapour pressure (red line) with the cavity vapour pressure for the open and tight set-up (dark and light blue line respectively) on daily averaged basis, it is clear that in 2016 inward as well as outward vapour flow occurs (Figure 4). Outward vapour flow mainly occurs in winter periods, whereas inward vapour flow mainly occurs in spring and summer periods. In 2016, based on 10-minute in-situ measured data, 40% of the time the vapour pressure inside the cavity was higher than the indoor vapour pressure (Table 1). The vapour pressure difference in case of inward vapour flow is on average twice as high compared to outward vapour flow, the standard deviation approximately three times higher. These figures show that inward vapour flow in case of brick veneer clad timber frame walls cannot be neglected.

**Figure 4:** Daily averaged indoor (red line) and cavity (dark and light blue for open resp. tight set-up) vapour pressures indicate in- as well as outward vapour flow throughout the year.

**Table 1:** The occurrence of inward vapour flow and the vapour pressure difference between indoor climate and cavity (average and standard deviation) clearly show that inward vapour flows must be taken into account in case of brick veneer clad timber frame walls.

	open		tight	
	In	Out	In	Out
Occurrence (%)	40	60	40	60
$\Delta P_{v,average}$ (Pa)	430	240	410	250
$\Delta P_{v,std}$ (Pa)	460	150	450	175

Next, the hygrothermal conditions at the potential condensation layers, the interface between mineral wool and interior and exterior sheathing, are analysed (Figure 5). At the interface between mineral wool and OSB board, a higher relative humidity is observed in summer conditions compared to winter conditions. However, the relative humidity rarely reaches values higher than 80% RH during the entire measurement period. Furthermore, little difference is observed between both set-ups. Only during springtime, when the cavity vapour pressure reaches high values while the indoor vapour pressure is still relatively low, the benefit of a more vapour tight wind barrier can be observed. At the interface between mineral wool and wind barrier, on the other hand, the relative humidity is higher in winter conditions than in summer conditions. Again, little difference is observed between both set-ups: the set-up with the more vapour tight wind barrier does not result in a higher condensation risk than the other set-up. A possible explanation for the fact that only small differences are noted between both set-ups is the moisture buffer capacity of the different materials inside the timber frame wall. To get more insight in the role of the moisture buffer capacity and vapour diffusion resistance, numerical simulations have been performed.

### Numerical HAM-simulations

The trends in relative humidity at the interface between mineral wool and interior and exterior sheathing are quite well predicted by the numerical model (Figure 5). Only the relative humidity at the wind barrier in the tight set-up is underestimated in winter conditions. Although the wooden studs are not included in the numerical model, the simulations do not predict a higher condensation risk. This might indicate that the buffer capacity of the other materials inside the walls is already sufficient to lower the relative humidity peaks.

**Figure 5: The in-situ measured relative humidity at both sides of the insulation layer shows only little differences between both set-ups. The numerical simulations are in line with the in-situ measured data.**

To study the impact of the buffer capacity of the exterior sheathing on the potential condensation risk in winter conditions, the hygrothermal behaviour of the wall is simulated with a wind barrier as vapour tight as the wood fibre cement board, but with the same low moisture storage capacity of the wood fibre board. The results are compared with the original numerical outcomes (Figure 6). A lower moisture buffer capacity indeed leads to a higher relative humidity. In contrast, increasing the vapour diffusion resistance does not generally result in higher relative humidity. It must be stated, however, that the difference in vapour tightness of both wind barriers is less in the range of 80-90% RH compared to lower RH regions.

**Figure 6: According to the simulations, the moisture buffer capacity of the wind barrier is more important than the vapour diffusion resistance.**

A second simulation focuses on the buffer capacity of the OSB board. Figure 7 shows the change in relative humidity at the mineral wool – OSB interface with a theoretical OSB board without moisture buffer capacity. It is clear that in this case solar driven moisture transport leads to a condensation risk. Even the use of a more vapour tight wood fibre cement board as wind barrier does not eliminate this risk: the tight set-up is below 97% RH for only 6% of the time during which the open set-up is above this level. The different simulation assumptions, amongst them the exclusion of the wooden studs, may affect the hygrothermal conditions inside the wall. Nevertheless, the simulation outcomes emphasize the importance of the moisture buffer capacity of the different materials in the wall.

## CONCLUSIONS

The present study investigated the contradictory criterion for the wind barrier in timber frame walls with brick veneer cladding when it comes to interstitial condensation for summer and winter conditions. Therefore, a field study on two typical timber frame walls with brick veneer cladding was conducted. One set-up had a vapour open wood fibre board as wind barrier, advantageous for outward vapour flows, the other set-up had a more vapour tight wood fibre cement board, which has potentially a higher resistance against solar driven

**Figure 7:** According to the simulations, the moisture buffer capacity of the OSB board is more important in avoiding summer condensation than the vapour diffusion resistance of the wind barrier.

moisture ingress. In contrast to an elementary calculation using the Glaser method, the experimental results showed only little differences in the hygrothermal behaviour of both walls. Numerical simulations indicate that this is probably caused by the moisture buffer capacity of the different materials in the wall, which is at least as important as the vapour diffusion resistance to lower the moisture levels inside the wall. However, to draw general conclusions about the design of timber frame walls, more numerical simulations should be performed. A 2D numerical model can point out the influence of the wooden studs on the hygrothermal behaviour. Also the climatic conditions should be treated as a varying parameter apart from the vapour diffusion resistance and moisture buffer capacity.

#### ACKNOWLEDGEMENT

The research presented in this paper is part of research project 3E140592 funded by the Fonds voor Wetenschappelijk Onderzoek – Vlaanderen (FWO): ‘A stochastic and dynamic risk assessment methodology for mould growth and wood rot on timber frame constructions.’

## Performance evaluation of a highly insulated wall to withstand mould

Klodian Gradeci<sup>1\*</sup> and Umberto Berardi<sup>2</sup>

<sup>1</sup>SINTEF Building and Infrastructure, Norway

<sup>2</sup>Ryerson University, Canada

### ABSTRACT

In this paper, the performance to withstand mould growth of a highly insulated wall is evaluated by applying a probabilistic-based methodology that accounts for the involved uncertainties and investigates their significance. A sensitivity analysis according to the Morris method is conducted to understand the influence of each parameter and simplify the system representation. Deficiencies in terms of moisture and air leakages are accounted for. The mould growth outcome is evaluated by integrating different mould models and assessment criteria. The study demonstrates that a probabilistic-based methodology enables a more systematic approach to evaluate wall constructions since it accounts for the involved uncertainties, provides a clear association of the microbial growth to its likelihood, and enables the identification and significance of the dominant parameters; hence, it delivers a more comprehensive assessment of a building envelope.

### KEYWORDS

Uncertainty; Sensitivity analysis; Probability; Mould; Building envelope.

### INTRODUCTION

Highly insulated walls, which are walls with a considerable insulation thickness, have found increasing acceptance over the last few years to reduce the heat flow across the construction by increasing its thermal resistance. However, by increasing the thickness of the insulation the likelihood of moisture-related damages may increase significantly on the layers on the colder side of the insulation (Gullbrekken et al., 2015; Lepage et al., 2013). Especially when wood-based materials are used, biodeterioration presents a serious concern due to the lower requirements for microbial growth (Gradeci et al., 2017).

The design of wall constructions is replete with uncertainties. These are related to the outdoor and indoor climate, physical parameters of the materials properties and geometries, and the transfer of physical phenomena into numerical equations and models. Probabilistic-based methodologies can account for these uncertainties, and thus have found increasing acceptance over the last few years in the field of building performance simulation. Similarly, sensitivity analysis techniques have found increasing application since they can facilitate a better understanding of the system representation and the relationship between inputs and outputs (Gradeci et al., 2018b). The objective of this study is to evaluate the performance to withstand mould growth of a highly insulated wall by applying a probabilistic-based methodology. A sensitivity analysis is performed to simplify the system representation and to identify the most influential parameters. Finally, potential deficiencies from moisture or air leakages are accounted for.

## METHODS

### Building envelope

The building envelope investigated in this study is a stacked wood outside wall (Waltjen et al., 2008) using an MDF-board as the wind barrier and a membrane as the vapour barrier (see Figure 1 and Table 1). A construction with a wood-based material is selected due to the higher susceptibility to biodeterioration. A ventilated construction is chosen since the simulated rain data in current software may need further improvement, and these constructions are the least affected by rain.

Figure 1. Configuration of the building envelope analysed in this paper.

Table 1. Mean values of material properties of the wall construction analysed in this paper.

Material	Thermal conductivity [W/mK]	Water vapour diffusion factor [-]	Density [kg/m <sup>3</sup> ]	Heat capacity [J/kgK]	Porosity [m <sup>3</sup> /m <sup>3</sup> ]
Spruce Cladding	0.09	130	455	1500	0.73
MDF-board	0.12	15	508	1700	0.667
Insulation	0.033	1.3	91	840	0.95
Membrane			$s_d=20$ m		
CLT	0.13	156	462	1400	0.627

### Probabilistic-based methodology

The probabilistic-based methodology (Figure 2) as presented in (Gradeci et al., 2018a) has been further advanced by considering potential deficiencies, as described in the subsequent sections. The Monte Carlo Latin Hypercube Sampling is used to propagate, in a stratified way, the input variables by the simulation model to output variables. A total of 80 simulations are performed with this technique and a Beta distribution is fitted to the results.

The Morris method (Saltelli et al., 2008) varies one parameter at a time and screens important parameters by calculating two sensitivity measures: a) the mean  $\mu$ , indicating the overall effect of the parameter; and b) the standard deviation  $\sigma$ , indicating either interaction or non-linear behaviour. A total of 24 parameters are considered for this study (see following sections); thus,  $(24+1) \times 4 = 100$  simulations are performed. Three case scenarios are considered: the standard case without any deficiency, the second case when an amount of wind-driven rain (WDR) is assumed to penetrate, and the last case when an air leakage is accounted for.

### Hygrothermal simulations and deficiencies

The hygrothermal simulations are performed by WUFI® 6.1. WUFI does not entirely model the air layer; therefore, a simplification that the temperature and relative humidity in the air are similar to exterior conditions can be assumed (Tietze et al., 2017). The effect of the wind-driven rain ( $WDR = 0.2 \times \text{rain} \times \text{wind speed}$ ) is considered by applying moisture sources, while short-wave radiation absorptivity is set to 0.4 for untreated wood cladding (Tietze et al., 2017).

The initial conditions are set at RH = 80 % and T = 20 °C. The interface (wind barrier and insulation layer) is investigated due to the most favourable conditions for mould growth.

Figure 2. Schematic workflow of the probabilistic evaluation procedure.

In real life conditions, wall constructions are subject to moisture loads from a number of sources including wind-driven rain, bulk water (introduced by leakage), built-in moisture, water vapour (introduced by vapour diffusion or air leakage), and capillary transport through materials in contact with water or in contact with the ground (Lepage et al., 2013). Many of the latter may originate from human errors. They are difficult to identify and to represent quantitatively their distribution. Due to length requirements, this study considers only two scenarios, except for the base case, in a parametric way; 1 % moisture source representing moisture leaks from wind-driven rain according to ASHRAE recommendations and an interior air leak according to (Lepage et al., 2013). The moisture source is mounted between the MDF and insulation, while the air leak with airtightness class B is modelled according to recommendation in WUFI® (2017).

### Representation of climate exposure and material parameters

The performance of the building envelope is evaluated when exposed to Oslo climate, which is a humid continental climate (ranked Dfb) with hot summers and very cold winters. The hourly-based historical data, from 01.01.1997 to 31.12.2016, are used to represent the outdoor climate. Each year among the 20-year long measurements is randomly distributed for each simulation as applied in (Hagentoft et al., 2015). In the current study, the initiation date of the simulation is also randomly sampled since it is another stochastic variable. Especially when the simulation period is one year long, the results of mould growth are very sensitive to the initiation (Gradeci et al., 2018a). The indoor climate is represented by a stochastic model based on a random distribution of the moisture categories and model uncertainties, as developed in previous study (Gradeci et al., 2018a).

A stochastic representation of the thermal conductivity of insulation material by conducting experiments is presented in (Gradeci et al., 2018b) and used in this study. Ideally, all parameters involved in the performance evaluation should be represented by their probabilistic models. However, due to limitations of the necessary data that are retrieved from experimental analyses, simplified assumptions are considered. A normal distribution (Salonvaara et al., 2001) is assumed for the parameters presented in Table 1, while the rest of the parameters were assumed as deterministic. The coefficient of variation is assumed 15 % for the vapour diffusion resistance, 8 % for the thermal conductivity of material other than insulation, 5 % for the density, 10 % for the heat capacity and 10 % for the porosity. The initial conditions for the relative humidity and temperature are also randomly distributed with mean values as presented in previous section and a coefficient of variation equal to 10%.

### Representation of the failure event and performance evaluation

Different models have been developed to represent the mould growth and are characterised by specific strengths and limitations (Gradeci et al., 2017). Consequently, in the current study, the mould growth is calculated according to the integration of three most established mould models: VTT model (Viitanen et al., 2007), MRD model (Thelandersson et al., 2013) and IBP-biohygrothermal model (Sedlbauer, 2002), as previously presented in (Gradeci et al., 2018a). The *substrate class 1* is used for the biohygrothermal model, the standard case (*spruce, planed*) for the MRD, and the *very sensitive class* for the VTT model. Due to the lack of established design criteria related to building envelopes and biodeterioration, results are expressed as a density function associating potential levels of microbial growth to their respective likelihood.

### RESULTS AND DISCUSSION

The sensitivity analysis results are presented in Figure 3 and Figure 4. The screening between influential and non-influential parameters, among the variables set up previously, is performed according to Morris method criteria (Saltelli et al., 2008). Only the influential parameters are depicted in the figures. They differ based on which mould model is applied. Similarly, the parameters' importance in the sensitivity analysis, as presented by the mean value, and its non-linearity or interaction, as presented by the standard deviation, differ based on which mould model is selected. The Mixture model and MRD model conclude that more parameters are important. The outdoor weather is screened as the most important parameter with non-linearity or interaction with other parameters. The indoor temperature is screened as important only from MRD model and the Mixture model. This parameter is judged as important considering engineering experience. The initial relative humidity is screened as an important parameter, which makes sense considering the short time of simulations. For the standard case and when an air leakage is accounted for, only the outdoor temperature and initial relative humidity are screened as important parameters. The reason might be the fact that this construction provides satisfactory performance, with low mould growth and/or due to one-dimensional simulations. The important screened parameters are increased when the wind-driven rain penetration is accounted for. The calculated mould growth is highly increased for this case.

Figure 3. Sensitivity analysis results for the case when the wind-driven rain is accounted for. Difference between mould models. (In: indoor climate, Out: outdoor climate, RH-In: initial relative humidity, MDF-VP: water vapour diffusion factors of MDF, INS-ThC: thermal conductivity of insulation material.)

The results from sensitivity analysis enables a simplification of the system representation by reducing the number of variables, and thus the number of simulations. For the following calculation, only the influential parameters are accounted for as uncertain. The mould growth

results are shown in Figure 5 as the cumulative density function assessed against different available criteria. In addition, the results from applying the deterministic approach are shown as vertical lines when applying the MDRY (Moisture Design Reference Year), which is a conventional engineering approach, and the maximum mould growth during one year for the past 20 historical years in Oslo. The likelihood of obtaining the mould growth based on the historical data is high, while for MDRY is relatively lower implying that the probabilistic approach prevails the conventional one when representing the past twenty years.

Figure 4. Sensitivity analysis results. The effect of deficiencies.

Figure 5 Cumulative density function of the mould growth according to three case scenarios assessed against different available criteria.

Moreover, a clear association can be retrieved between the different mould growth levels and their likelihoods. The performance of the investigated wall is satisfactory unless wind-driven rain penetration is simulated. However, it should be noted that there are no available criteria in codes/standards following simulations results with a duration of one year. Therefore, different assessment criteria can be considered, as shown in Figure 5, providing the flexibility to adapt the requirements and criterion based on the case study at hand. Otherwise, it is advised a longer time for the simulations to resemble the expected service life of the construction.

## CONCLUSIONS

The probabilistic-based methodology enables a more systematic approach to performance evaluation of highly insulated walls since it accounts for uncertainties and delivers a clearer association of the mould growth to its likelihood. Furthermore, the application of sensitivity analysis is very beneficial in the design of wall constructions since it identifies and ranks the most dominant parameters influencing the outcome. The application of this methodology could be extended to different wall constructions, failure modes, climate exposures, and other deficiencies.

## **Renovation with Internal Insulation and Heat Recovery in Real Life – Energy Savings and Risk of Mold Growth**

Martin Morelli<sup>1,\*</sup> and Eva B. Møller<sup>1</sup>

<sup>1</sup>Aalborg University, Danish Building Research Institute, Denmark

*\*Corresponding email: mmo@sbi.aau.dk*

### **ABSTRACT**

This paper presents a pilot project for renovation of a large residential area; focus is on energy consumption and risk of mold growth. The renovation included internal insulation of walls with capillary active insulation material, balanced mechanical ventilation with heat recovery and insulation of floor towards basement. These types of measures are not completely new and have been used in other buildings as well, however the measures may be either risky regarding mold growth or the effect is uncertain with the specific external wall composition. A pilot project including six apartments was performed to test the measures in these specific buildings. Furthermore, six reference apartments were monitored simultaneously.

For two years, energy use for heating was measured as well as temperature and relative humidity in the internal insulation, indoors and outside. The insulation was dismantled in two apartments after two years, to test for mold growth at the original wall surface.

In extreme cases, the relative humidity in the walls behind the insulation system was up to 90 % RH shortly after installation, and mold growth models predicted growth of mold. However, the relative humidity decreased, typically to 70 % RH in the second winter. The inspection and measurements after the removal of the insulation material did not show signs of mold growth. Apparently, the used insulation material can be used in this specific case without risk of mold growth. Energy savings for heating was measured and calculated to around 25 %. However, the electricity use for ventilation was almost equal to savings from heat recovery.

### **KEYWORDS**

Internal insulation; capillary active material; measurements; moisture; heat

### **INTRODUCTION**

To save energy a large residential area from the 1950s is considered for renovation. The intent of the project is to demonstrate that energy savings are possible and moisture-safe using internal insulation with capillary active insulation materials combined with insulation towards a basement and mechanical ventilation with heat recovery. The case is Folehaven; a large urban area in Copenhagen, Denmark consisting of three-story apartment houses with approx. 74,200 m<sup>2</sup> heated floor area, rented out by a housing association. The brick masonry expression of the area is deemed worthy of preservation because of its architectural value. Internal insulation is therefore the only option for energy improving the walls. The Danish National Building Fund subsidizes energy-saving measures in social housing projects; however, the fund only subsidizes known and low risk measures. Traditional internal insulation with mineral wool and vapor barrier is not considered among these, due to high risk of mold growth, which has been experienced in other dwellings. Capillary active insulation materials have a specific pore size and pore distribution, allowing moisture to be transported by capillary suction from an area with capillary condensation to a more dry area, i.e. from the intersection wall/insulation material to the inside. Capillary active materials have been investigated by several researchers (e.g. Häupl et al, 2003; Pavlík and Černý, 2009; Vereecken

and Roels, 2015). However, well-documented projects with more than two years' experience are rare. Therefore, the objective of this pilot study is to provide documentation of the hygrothermal effects – including energy savings – of internal insulation with capillary active materials in these specific buildings. This would comply with The Danish National Building Fund requesting measurements conducted over a longer period e.g. five years in Denmark.

## METHODS

### The test site

The settlement Folehaven consists of 55 three-story apartment houses with 932 apartments. The buildings were built 1952-1962, and the materials may vary from building to building; generally, the walls are 360 mm thick made of bricks outside (110 mm) and lightweight concrete (240 mm) and plaster on the inside. The horizontal divisions are made of concrete. Attic and basement are unheated. Six apartments in the same staircase were chosen for the pilot project, see Figure 1. All apartments had a size of approx. 75m<sup>2</sup>. Energy saving measures were installed in the summer of 2015. As a reference, six apartments were chosen, these were not renovated, however; layout, location and orientation were similar to the test apartments.

Figure 1. a) Layout of two apartments. Red designation is an internal apartment and blue designation is an apartment with a gable. In the grey area, a suspended ceiling is used to hide ventilation ducts. b) Cross section of the three apartments, basement and attic.

Several possibilities to reduce the energy consumption of the settlement Folehaven were considered but abandoned: External insulation was excluded for architectural reasons; internal mineral wool insulation with vapor barrier was deselected due to moisture risk from leaky vapor barriers; vacuum panels were rejected due to the high price and not being adjustable on site. New more energy efficient windows were considered, however, windows were renewed within the last 15 year and the building owner wanted to take advantage of the remaining service life. The attic floor was recently insulated. Conclusively, few options were left:

- Mechanical ventilation with heat recovery to replace the old system with natural ventilation through opening of windows and the stack effect of a ventilation shaft leading from the bathroom to the rooftop.
- Internal insulation with materials that need no vapor barrier (capillary active materials), and insulation of the floor division towards the basement.

The insulation material was chosen based on several criteria; i.e. thermal conductivity, price, robustness and flexibility. It was decided to test PUR foam with thin calcium silicate channels every 40 x 40 mm ( $\lambda$ -value of 0,031 W/m·K). The gable was insulated with 80 mm and the facades with 50 mm due to large windows and limited space behind installations.

### **Energy-saving potential**

The energy savings were theoretically calculated and measured on site. The theoretical energy consumption for heating and ventilation was calculated using the software program Be10 (DBRI, 2015). U-values and  $\Psi$ -values were calculated through detailed 2D thermal calculations of assemblies before and after renovation and used in the Be10 model.

Energy consumption for room heating was measured with energy meter on the main heating pipes in the basement. Energy meters were installed on the mixing pipes before the after-heating surface of the ventilation system. Furthermore, the ventilation unit's electricity consumption was measured. The measurements covered the period April 2016 to March 2017 as a comparison between the test apartments and the reference apartments. The set point for the ventilation unit was 21 °C; however, at outdoor temperature above 18 °C, the after-heating surface was bypassed.

### **Onsite measurements of temperature and moisture**

Temperature and relative humidity were measured and logged:

- Hourly in three rooms inside the six test apartments and six reference apartments with data logger Lascar EL-USB 2+ (Lascar Electronics) before and after the renovation. Data collection time: September 2014 to August 2015 and again March 2016 to June 2017.
- Hourly outside with similar data loggers and collection time as used inside. Alternatively, equivalent measurements were obtained from the Danish Meteorological Institute, as some loggers were stolen during the test period.
- Hourly inside the wall, at the intersection between original wall and the new interior insulation material. In each apartment, eight to ten sensors (Tramex Hygro-i connected to Transmitter IP65) were installed. The signals from the transmitters were collected by Profort mini data collector and were accessible via Internet. All instruments from BMT instruments (BMT Instruments). Data collection time: From December 2015 and ongoing.

### **Dismantling of insulation**

Two years after installation, the interior insulation material was dismantled in two test apartments to inspect the area behind the insulation for mold growth; a check whether reality corresponds with mold growth models using actual hygrothermal measurements. One apartment was chosen because the installation of the insulation material was not in accordance with the guidelines of the manufacturer. The other apartment was chosen because the moisture load was high in this apartment before the renovation and measurements inside the wall showed high relative humidity the first winter after the installation of the insulation material. After dismantling the insulation material, the walls were visually inspected and Mycometer tests (Reeslev and Miller, 2000) were performed in critical areas. In the apartment with high moisture level behind the insulation material, additional mold tests were made with pressure plates and tape strips that were investigated in a microscope.

## **RESULTS**

### **Energy consumption**

The energy consumption for heating in the six renovated apartments during the heating season 2016/2017 was measured to 31.2 MWh at an average indoor temperature of 22.2 °C. The reference apartments with similar indoor temperature had a consumption of 41.1 MWh. This corresponds to a 24 % reduction in the energy consumption for heating or 9.9 MWh/year. Table 1 shows the theoretical calculation of the savings for the six apartments. The total energy savings for heating are 10.4 MWh/year. The specific fan power for the ventilation was 800 J/m<sup>3</sup>, which for an air change of 516 m<sup>3</sup>/h in constant run corresponds to 1.0 MWh/year.

Table 1. Theoretical calculation of U-value, air changes and energy saving for heating.

Measure	U-value <sup>A</sup> [W/m <sup>2</sup> K]		Air change [m <sup>3</sup> /h]		Heating energy saving	
	Before	After	Before	After	MWh/year	%
Internal insulation of walls	1.05	0.65			7.3	70
Insulation of floor	0.70	0.40			2.2	22
Balanced ventilation <sup>B</sup>			344 <sup>C</sup>	516 <sup>C</sup>	0.9	8

<sup>A</sup> U-values includes the linear thermal transmittance. <sup>B</sup> Heat recovery of 80%. <sup>C</sup> Air change before is 2/3 of the air change after which correspond to 0.5 h<sup>-1</sup>.

### Measurements of temperature and relative humidity

From October until March the average indoor temperature was 22.3 °C and 22.2 °C in the winter 2014/15 in the test apartments and the reference apartments, respectively. In the winter 2016/17 the average indoor temperature was 21.9 °C and 22.5 °C, respectively. The average outdoor temperature was 6.1 °C in the winter 2014/15 and 4.9 °C in the winter 2016/17.

Indoor relative humidity depends on moisture content in outdoor air, moisture supply depending on ventilation rate and use of the apartment, and the indoor temperature. To eliminate the influence of temperature of the indoor air, the results of the measurements in one room in a test apartment is presented in Figure 2 as moisture supply.

Figure 2. Moisture supply in a bedroom in one of the test apartments before and after the renovation. Compared to other apartments, the moisture supply was high before the apartment was renovated. The straight line in the middle covers the period without measurements.

Figure 3 shows a typical example of the temperature and relative humidity measured at the intersection of the interior insulation material and the existing wall. The most extreme case, and therefore, the one with the highest risk of mold growth, had a relative humidity of approx. 95 % RH in the winter 2015/16 at a temperature of 5-10 °C. The following winter the relative humidity had decreased to approx. 85 % RH at a temperature of 5-10 °C. The interior insulation was dismantled in that apartment.

The visual inspection of the walls after dismantling the interior insulation material did not show any signs of mold growth. This corroborates with the Mycometer tests, where only one test was higher than level A (background level). The highest Mycometer number was 34 i.e. very low number at level B (typical for e.g. dust), that goes from 25-450 (Reeslev and Miller, 2000). In the same point, the pressure plate test showed more than 50 colony forming units. All tape tests showed few spores but no mycelium on the wall.

Figure 3. An example of typical conditions measured in the intersection between interior insulation material and existing wall.

## DISCUSSIONS

### Energy

The settlement Folehaven had from 2013-2016 an energy consumption for heating of 143-147 kWh/m<sup>2</sup>, compared to key figures for the council housing sector, this is about 30 kWh/m<sup>2</sup> or 20 % higher than average. The findings from this study showed that the heating energy consumption could be reduced by 24 % when insulating the floor above the basement, installing internal insulation and balanced mechanical ventilation with heat recovery. If the savings found in the six apartments can be applied to the entire settlement, the heating energy consumption could be reduced to 109 kWh/m<sup>2</sup>. These savings are obtained in six apartments where three have gables and three are internally located. As 1/3 of the staircases only have internally located apartments, the total savings might be lower. The indoor temperature was at a similar level before and after renovation, thus the rebound effect was minimal. In this pilot project, the energy use for running the ventilation corresponded to the heat savings obtained from the heat recovery. Furthermore, the ventilation rate was increased after renovation.

### Temperature and relative humidity

The indoor climate varied in the different apartments but were within what was to be expected in apartments according to ISO 13788 (ISO, 2012). However, the moisture supply in Figure 2 was high before the renovation. After the renovation, the moisture supply decreased to normal level, probably due to the installation of a mechanical ventilation system. In apartments where the moisture supply was low before the renovation, no change could be detected.

When the measurements from behind the insulation material were used in mold growth models like Viitanen et al. (2011), mold index > 1 was to be expected in a few points, however, the inspection did not show mold in these areas. That may be because the walls were completely cleaned before the insulation material was installed, therefore, there was no organic material in the area, and theoretically dirt could not enter, i.e. no nutrients for the mold. In one point, the Mycometer level was B and there was mold growth on the pressure plate. However, the tape test combined with the Mycometer test indicated, that there was no active growth in the area. In areas where the relative humidity was high in the beginning, it decreased in the next winter; probably some build in moisture from the application with wet glue mortar had to dry out. Consequently, it is still necessary to follow the relative humidity and temperature in the wall to see how the system will perform over time. Especially because the two winters were mild compared to winter in the Danish reference year.

## CONCLUSIONS

Renovation of buildings with special architectural appearance often ends in discussions of the possibility of applying external or internal insulation to save energy or improve the indoor environment. Therefore, it is important to decide what is most essential; obtaining energy savings, improving indoor environment, architectural value, etc. It is the author's opinion that moisture safety is crucial. When this is ensured, the heating energy savings in renovation projects can be calculated relatively easy. In this case, 24 % savings were documented.

When buildings are internally insulated, the indoor moisture supply becomes critical. Some users may not be aware of this; therefore, combining internal insulation with mechanical ventilation is a good idea, as the study confirms that mechanical ventilation reduces the moisture supply in apartments where the moisture supply was high.

Although the investigation of mold growth did not reveal any danger, it is still too soon to conclude that the investigated type of internal insulation is moisture safe in these apartments. Partly because mold models indicate, that mold growth may occur, partly because the two winters have been mild. Furthermore, it is important to notice, that the investigation only apply to these specific buildings. There is still a need to investigate how the internal insulation materials perform in other buildings; this applies to energy savings as well as moisture risk.

## ACKNOWLEDGEMENT

The authors would like to thank Copenhagen municipality for financing the project, the building owner 3B housing association, Rambøll consulting engineers for performing the energy calculations and BMT Instruments for assisting with the measurement equipment.

### **ABSTRACT**

There are many historic brick buildings in downtown areas of the U.S. that are awaiting appropriate strategies for their adaptive reuse and preservation. The adaptive reuse method enables the adaptation of existing, obsolete historic buildings into new, mixed-use developments that will play an essential role in enhancing urban environments. However, many of these buildings have poor energy performance. This paper explores sustainable methods to balance between historic preservation and reduction of peak energy loads, through analyzing design strategies and conducting energy simulations for a building in downtown, Austin, TX. Energy retrofits related to windows, high performance of the facades with added insulation, and passive (spatial) interventions are covered in depth. Four retrofit scenarios were applied and simulated using the energy analysis tool in Revit, a popular BIM program. Analyzing the energy consumption data, we compare an existing building's facade condition to the retrofit scenarios' energy performances and record the energy performance data. This research proposes energy efficient preservation options for historic buildings and ultimately emphasizes potential values such as balancing the integrity of the original design with energy goals. We explore novel solutions for making historic buildings more sustainable through combining the adaptive reuse method with energy retrofit strategies that play up the historic buildings' unique passive potentials. The various solutions are found to be highly dependent on the climate.

### **KEYWORDS**

Energy retrofit, adaptive reuse, historic preservation, facade, peak energy demand reduction

### **INTRODUCTION**

Our research questions start from the growing trend of repurposing historic buildings. Because their original functions have been abandoned or new uses are emerging for them, architects and planners need to consider dealing with historic buildings economically, environmentally, and socially (Orbasli 2008). The act of extending the life of a building through adaptive reuse helps to lower material, transport and energy consumption; significantly contributing to sustainability goals and providing multiple benefits (Bullen and Love 2009).

Restored masonry buildings create vast opportunities for revitalizing communities and promoting cultural value. Instead of destroying the old brick materials and wooden structures, facade retrofits can create spaces that offer new experiences. Such reuse of buildings gives specific opportunities for the public to perceive the value of historic buildings and to make them attractive to neighborhoods and visitors. However, commonly, historic brick buildings are recognized for their poor energy performance with installed single pane glass windows. Therefore, they require a new approach to be adapted with appropriate uses and energy retrofits.

The method of dealing with existing facades comprises a large proportion of the adaptive reuse of old buildings. Because people tend to recognize buildings by the materials and patterns of their facade, facade retrofits can help preserve the historical significance of facades and meet modern energy standards. There are many articles dealing with the advantages of adaptive reuse or retrofits of old buildings, and the improvement of the building envelope, such as insulated roof and window replacements, could significantly reduce heating energy demand, for example, by 52% (Gourlis and Kovacic 2016).

This research addresses four retrofit scenarios for historic brick buildings in downtown Austin, TX. The study presents qualitative and quantitative comparisons of those scenarios, to help architects and planners to understand and apply the appropriate strategies for facade retrofits of old brick buildings in similar areas. The findings demonstrate which strategies are suitable for facade energy retrofits, while balancing energy goals and preserving the cultural value of old brick buildings.

## METHODS

Facade retrofit scenarios are analyzed through Revit 2017, using the Energy Analysis for Autodesk Revit Engine. The 3D models represent a building that is 45 feet by 125 feet in plan and 35 feet high, typical for a historic building in downtown Austin. They comprise a ground floor and second floor with a stair opening. Southern and northern facades have four glass doors (7 feet wide by 12 feet high) on the first floor with wood framing and four windows (6 feet wide by 10 feet tall) on the second floor. We set up the input data as retail (building type), Austin (location), and occupancy rate (default of retail facility occupancy: 107.64 SF per person). The 3D models include brick facades and wooden structural systems. We obtain the energy data based on the information and change the specifications of windows and the glass front entry. This paper proposes four types of energy retrofit strategies for historical brick buildings and evaluates them by using the energy consumption data that we obtain from simulation in Revit (see Table 1).

Table 1. Retrofit typologies.

	Retrofit Option	Description	U-value (Btu/(h·ft <sup>2</sup> ·°F))	R-value ((h·ft <sup>2</sup> ·°F) Btu)
Existing	Single pane glass	8-inch masonry	1.18	0.85
		1/4-inch single pane glass with 3/8-inch cavity	0.50	1.98
Alt-1	Double glazed low-e	8-inch masonry	1.18	0.85
		1/4-inch double glazed glass (clear, low-e (e=0.05))	0.35	2.86
Alt-2	Wall insulation	3-inch thermal/Air layer + metal stud + gypsum wall board on interior of exterior wall	0.02	50
		1/4-inch double glazed glass (clear, low-e (e=0.05))	0.35	2.86
Alt-3	Secondary glazed windows	Alt-2	0.35	2.86
Alt-4	Double skin (glass)	Secondary windows system	0.35	2.86
		Alt-2	0.35	2.86
		Glass covered facade (system panel; 1/4-inch double glazed glass (blue-green, low-e (e=0.05))	0.35	2.86

Through conducting the energy analysis in Revit, we obtained the data including annual energy consumption, monthly peak demands, and monthly cooling/heating load. This paper selects 'peak demands' representing peak cooling/heating load for comparing an existing building to

four facade retrofit scenarios. A growing number of retrofit interventions have started to take place around the world. All of them represent unique characteristics and respond to specific budgets, contexts, and functions. We re-classify those interventions into four categories of facade retrofit based on Martinez's table (Martinez 2013) (e.g. single pane glass, double glazed low-e, wall insulation applied to the interior of the exterior facade wall, secondary glazed windows, and double skin). Based on the proposed typologies, we create 3D models in Revit and run energy analyses in order to better understand how those strategies deal with energy improvements.

It should be noted that the simulated data would be different with measured results in an actual building because of orientation, climate condition, surroundings, and accuracy of simulation models. However, through modeling, this paper addresses facade retrofit typologies based quantitative and qualitative analysis of the simulation data, ultimately including the cultural value of the brick material, the design, and aesthetics. Thomas describes that successful sustainability should be evaluated by qualitative and quantifiable criteria simultaneously (Thomas 2004), which is why we chose to also value the aesthetic impact of retrofit measures - keeping our interventions as visually subtle as possible.

## RESULTS

Five 3D models were designed in Revit for energy analysis based on the narrow rectangular type commercial building in downtown Austin. We gathered energy data to compare sustainable solutions for the adaptive reuse of historic brick buildings. Nagy explains that window replacement alone is able to reduce heating energy consumption by 12%, according to measured and simulated data for a building in Zurich, Switzerland (Nagy et al. 2014). Considering the total peak energy demands of an existing brick building in Austin, TX, which has a different climate and occupancy, the replacement of single pane glass with double low-e glass (low emissivity) enables the reduction of the peak energy demand by 0.70% (see Table 2).

Table 2. Comparison of energy simulation data. (1Btu=0.293Wh)

Retrofit Option	Floor Area (ft <sup>2</sup> )	Peak Cooling total load (Btu/h)	Peak Heating total load (Btu/h)	Total Load (Btu/h)	WRT Single Pane Glass
Single pane glass	11,035	531,657.30	326,727.40	858,384.70	100.00%
Double glazed low-e	11,035	526,012.30	326,283.70	852,296.00	99.29%
Wall insulation	10,454	154,253.40	24,268.00	178,521.40	20.80%
Secondary glazed windows	10,194	130,663.10	14,465.70	145,128.80	16.91%
Double skin (glass)	11,084	188,675.40	32,413.10	221,088.50	25.76%

Table 2 illustrates peak energy demands of five typologies. 'Improvement of the wall insulation' resulted in approximately 80% total peak energy demands reduction as compared to the existing brick model, 'Single pane glass'. The 'secondary glazed windows' option allows for a reduction of 19% peak energy demand compared to 'improvement of insulation'.

According to Figure 1, the 'double skin scenario' reduces the peak energy demand less than the improvement of wall insulation. Rather, total peak energy demands are increased as compared to insulation improvement.

Figure 1. Peak energy demand comparison. (1-Single pane glass, 2-Double glazed low-e, 3-Wall insulation, 4-Secondary glazed windows, 5-Double skin (glass))

Table 3 shows the energy analysis models, plans, and section drawings. The double skin type has an additional seven feet wide corridor at the southern facade. Comparing facade visualization of five scenarios, the double skin option is only changed by layering the old brick material with glass (see Table 4). However, all the typologies enable the preservation of the brick material and its facade elements.

## **DISCUSSIONS**

The building type analyzed is typical as part of downtown Austin's grid, planned by Edwin Waller in 1839. In general, most of the narrow rectangular type buildings face north and south, and are surrounded on the sides with adjacent buildings. Window to wall ratios are already low in such historic buildings, so replacement of the glass will not have as much of an impact as it would in buildings with larger windows. As seen in the second scenario, replacement of windows by low-e, the peak demand reduction is smaller than we expected, when looking at similar retrofit studies elsewhere. Moreover, as the occupancy is retail/commercial, and a narrow rectangular building facing south, it will not benefit as much from window replacement because there are more internal heat loads from the greater number of occupants, while the west and east facades are insulated by attached buildings.

The energy consumption significantly depends on building types or internal thermal loads, such as human activities. Replacing old single pane glass in this case helps to reduce peak cooling total loads more than peak heating loads. Improving specifications of facade wall type have positive effects on peak energy demand reduction. Upgrading old windows and doors to meet modern standards should be adopted into old buildings in Austin, with improving energy performance of the wall. These interventions are also visually unobtrusive to the original design.

Keeping old facades and preserving historic districts can produce social benefits to visitors and neighborhoods. The adaptive reuse and retrofit strategies for old buildings are produced by various decision makers. However, social aspects and the aesthetic value of historic brick buildings should also be considered as a positive solution for urban sustainability, and are not found to be in conflict with energy saving measures, according to our study. Moreover, a double skin type might be possible solution for harmony with modern goals while also preserving the historic brick material, but would most visually alter the facade and would also perform better in a climate less prone to overheating.

## **CONCLUSIONS**

Austin, Texas has a humid subtropical climate, which requires a consideration to reduce cooling load from May to September. This study focuses on peak energy demand reduction for historic brick buildings, with retrofit alternatives evaluated and predicted with energy consumption data in balance with aesthetic impacts important for historic preservation. The best solution that balances the energy performance and aesthetic of the historic building is the option of adding an additional layer of glass on the interior side of the historic single pane windows (secondary glazed windows) in addition to better insulation. This totally preserves the character of the building from the outside, including the original window appearance, while greatly improving the energy performance with only a slight reduction of interior space.

This paper deals with balancing energy retrofit strategies and social-cultural value. Symbiotic strategies need to be considered in the early design phase of energy retrofit projects (Eliopoulou and Mantziou 2017). Unless the simulated data might be different with measured data in actual buildings, this paper proposes potential methods for the development of energy retrofits for historic buildings. Historic buildings are often limited in their energy retrofit options because of preservation requirements (Zagorskas et al. 2013). Therefore, this study does not cover shading options that would greatly alter the external appearance of the facade. However, it has been argued that the interaction between building regeneration, economic development and social renewal enables planners to make cities creative places (Sepe 2013). For this reason, balancing between historic preservation and energy retrofit strategies proves a significant step for architects and planners to make cities more sustainable.

## **Experimental investigation of latent heat thermal energy storage for highly glazed apartments in a continental climate.**

Shahrzad Soudian<sup>1</sup>, Umberto Berardi<sup>1,\*</sup>

<sup>1</sup>Ryerson University, Toronto, Ontario, Canada

*\*Corresponding email: uberardi@ryerson.ca*

### **ABSTRACT**

The high solar heat gains in highly glazed buildings are a major thermal discomfort factor leading to higher energy consumption for space cooling. Higher window to wall ratios (WWR) also entail large temperature fluctuations due to heat loss and temperature extremes in buildings. Passive latent heat thermal energy storage (LHTES) is a potential solution to regulate the indoor thermal environment in buildings through mitigating the indoor surface temperatures. In this study, the effectiveness of phase change materials (PCMs) in the context of a highly glazed apartment unit with 80% WWR is investigated for internal wall and ceiling applications. To provide thermal energy storage across the year, a composite PCM system with two melting temperatures is proposed, comprised of two PCM products, one with a melting temperature of 21.7 °C and the other with a melting temperature of 25 °C. To test the performance of this PCM, experimental tests were performed using test cells placed under climate conditions of Toronto to monitor changes in the phase change cycles of the PCMs and their impact on indoor air and surface temperatures. The results indicate improved thermal performance of the test cell containing the PCM system compared to a baseline cell in lowering peak indoor air and surface temperatures up to 6 °C. A relation was observed between the peak solar gain periods and the PCM behavior during the melting and solidification processes. This paper shows the potential of using PCMs as retrofit applications in highly glazed buildings by targeting specifically annual LHTES with two melting temperatures in one zone in a continental climate.

### **KEYWORDS**

Thermal energy storage, phase change materials, thermal comfort, test cell, building retrofit.

### **INTRODUCTION**

The thermal discomfort in buildings implies higher reliance on mechanical systems to provide a comfortable thermal environment. This is a critical issue considering the highest share of energy use in buildings is for space conditioning (Berardi, 2017). This effect is specifically important in buildings with high window to wall ratios (WWR) as they experience overheating in the cooling season and extreme heat loss in the heating one. Meanwhile, newer high-rise apartments in Canada often adopt transparent facades that are faced with high energy consumption and thermal discomfort levels (Touchie et al., 2014; Bennet and O'Brien, 2017).

To improve the thermal environment of highly glazed apartments, passive latent heat thermal energy storage (LHTES) has been considered through the incorporation of phase change materials (PCMs) as a retrofit measure for interior surfaces of apartment units. PCMs stabilize surface and indoor temperatures by undergoing a phase change at specific melting temperatures. It is argued by Heim (2010) and Navarro et al. (2016) that the isothermal behavior of PCMs allows for better surface temperature stabilization compared to traditionally high mass building structures with sensible storage. The high thermal storage capacity of PCMs in small volumes represents a main advantage of LHTES systems (Saffari et al., 2017).

Thermophysical properties of PCMs such as melting temperature, latent heat, and specific heat direct how PCMs affect the surface and indoor air temperatures. In particular, the melting temperature of PCMs is the most influential parameter of a PCM, and must be compatible with the environment and the climatic conditions the PCM is applied to (Cabeza et al., 2011, Kosny et al., 2012). The integration of PCMs in the Canadian climate has been investigated by Chen et al. (2014), Delcroix et al. (2017), Guarino et al. (2017) and Berardi and Soudian (2018) showing good potential in both heating and cooling seasons. Nevertheless, optimizing PCMs to operate for an entire year is difficult as PCMs with a melting point close to summer boundary conditions do not operate in other seasons. Consequently, recent studies have suggested optimizing PCMs for annual performance by using two or more melting temperatures in a hybrid PCM system (Hoes and Hensen, 2015, Kheradmand et al., 2016).

The aim of this paper is to evaluate the benefits of integrating thin layers of PCMs as unobtrusive retrofit measures to regulate indoor temperature swings. Considering the case specific design and performance of PCMs in relation to climate, this research focuses on the Canadian climate and looks at the annual thermal energy storage using a PCM system with two melting points to address both heating and cooling seasons with different boundary conditions.

## METHODS

The composite PCM system investigated in this study is comprised of two commercially available PCM products with different melting temperatures as shown in Figure 1. The first layer in the composite PCM system has a melting temperature of 25 °C and the second layer in the system has a melting temperature of 21.7 °C, closer to winter boundary conditions. As shown in Fig. 1, the high latent heat storage capacity of this composite PCM system in a small thickness suggests a good potential for temperature stabilization in buildings. Both PCM products used in the composite PCM system are individual boards attached to each other.

Figure 1. The composite PCM system (left) and temperature-enthalpy curves for the PCM boards (right).

Quantifying the performance of PCMs is more accurate using experimental test methods considering the simplifications of simulation modeling in calculating PCM behavior on a material scale (Cabeza et al., 2015). Therefore, in this study, two small scale test cells were constructed, one reference cell as a baseline and one cell with PCM-enhanced walls and ceiling. Test cells were constructed to represent typical highly glazed apartment units on a scale of 1:10 with one glazed wall covering 80% of one wall with an overhang shading (Fig. 2). The construction characteristics of the test cells are shown in Fig. 3.

The performance of the composite PCM system was assessed on a surface and room level through a comparative analysis between the reference test cell and the PCM integrated test cell. The main parameters of analysis were the rate of change in surfaces and room temperatures of

the composite PCM test cell compared to the reference cell in relation to ambient weather and solar gain variations. The experimental tests were conducted in Toronto under free floating conditions from July to October (2016) to assess the effects of different weather variations on the composite PCM's performance.

Figure 2. Experimental test cells: the test cell on the right contains the investigated PCM system.

Figure 3. Construction characteristics of the experimental test cells.

## RESULTS

### Influence of solar gain on PCM performance

Figure 4a shows the indoor cell temperature variations in three days in July when the cells were facing south. The temperature changes are attenuated in the composite PCM test cell and overall, the air temperature swings are reduced by 6.8 °C. In particular, the effectiveness of the composite system at night is significant in maintaining indoor temperatures. An apparent peak temperature shifting of one hour happens in the composite PCM test cell. The maximum air temperature is shifted to later afternoon due to thermal lag in the composite PCM test cell. By rotating the test cells towards west, significant changes are observed as demonstrated in Fig. 4b. Unlike the south facing orientation, the highest temperatures in the test cells occur close to the sunset period from 5 to 7 pm when the benefits of PCM system also become more evident.

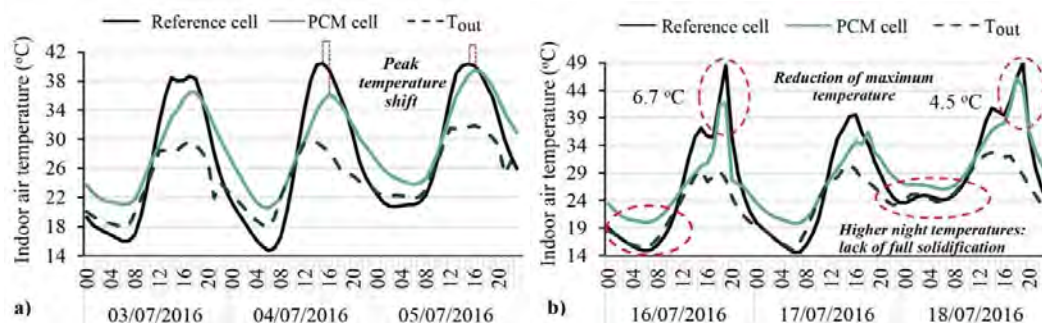

Figure 4. Hourly indoor room temperatures; a) South orientation – b) West orientation.

To further assess the influence of solar gain on the PCM performance, the shading part of the cells were removed to allow more solar radiation to get into the cells for one week in October. The reference test cell showed high dependence on outdoor weather conditions ultimately leading to average colder indoor air temperatures. Whereas, in the composite PCM test cell, indoor air temperatures were constantly above the outdoor temperatures. Removing the shading negatively affected PCMs performance in reducing excessive heat gain in the spaces. Figure 5 shows that by removing the shading, indoor air temperatures in the composite PCM test cell increased by 11 °C in the peak solar period in the south facing orientation. This sharp increase in the indoor air of the test cell is due to the sensible heat gain after the PCMs are melted.

Figure 5. Hourly indoor room temperature variations from October 8th -10<sup>th</sup>.

### Performance of PCM integrated surfaces

One side wall and the ceiling in the two test cells were simultaneously monitored. The primary parameter of analysis was the difference between the wall and ceiling surface temperature changes in relation to the room temperature. The hourly surface temperatures in the composite PCM wall show a faster response to ambient and indoor room temperature variations compared to the ceiling surface temperature changes. During the day, the wall heats up more rapidly, and at night, it loses heat faster as temperatures decrease compared to the composite PCM ceiling.

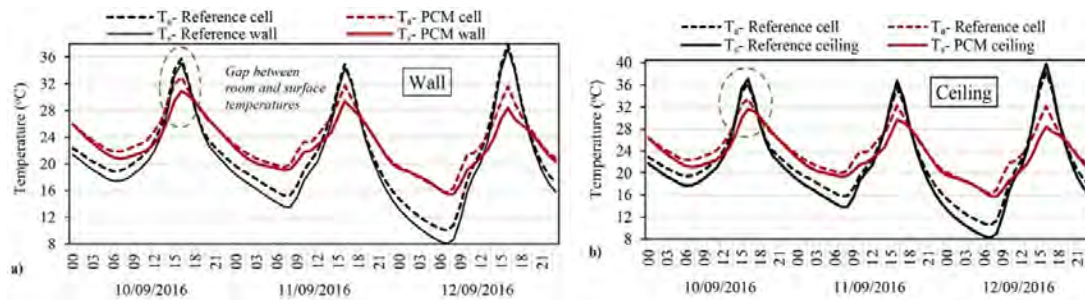

Figure 6. Hourly indoor air and surface temperature variations on wall (a) and ceiling (b)

Figure 6 shows hourly room ( $T_a$ ) and surface temperature ( $T_s$ ) variations in three consecutive days in September. Without PCMs, the indoor room temperatures of the reference cell show a close proximity to the reference wall and the ceiling's surface temperatures particularly in maximum peak periods in the day. Conversely, a gap is observed between the indoor air in the composite PCM cell and the composite PCM surface temperatures.

## DISCUSSION

The focus in this study was to assess the impact of solar gain and ambient weather variations on PCM performance. The experimental results demonstrated that the impact of ambient weather is more significant as temperature variations control the entire transition of the composite PCM system during the day. Nevertheless, the exposure to solar radiation enhance the melting process periodically, specifically at times of highest solar intensity.

To better explain the impact of ambient weather on PCM performance, average data in the testing period are compared in Table 4. The trend of outdoor temperature variations and PCM activation points to the highest percentage of PCM being activated in July. Correspondingly in July, the composite PCM system reduced the indoor temperature swings and high peak temperatures significantly compared to other months. The benefit of a hybrid PCM system is evident as during the summer the Energain PCM is mostly in liquid form where in contrast, the BioPCM is often in the solid state during the fall.

Table 1. Summary of the impact of the composite PCM on indoor air temperatures.

	Average ambient conditions (°C)	Decrease of $T_{\max}$ (%)	Increase of $T_{\min}$ (%)	Decrease in temperature swings (%)	Frequency of PCM activation			
					PCM Layer	Solid	Phase change	Liquid
July	19.2 - 31.1	6%	18%	46%	BioPCM	29%	28%	43%
					Energain	6%	30%	64%
August	19.9 - 35.7	4%	16%	37%	BioPCM	7%	18%	74%
					Energain	0%	9%	91%
September	15.2 - 31.1	6%	19%	35%	BioPCM	57%	18%	25%
					Energain	41%	21%	38%
October	11.2 - 25.6	1%	24%	18%	BioPCM	86%	7%	6%

The relation of solar gain to PCM performance on surfaces and their influence on indoor air temperatures showed that in addition to peak temperature reductions, peak temperature shifting is another benefit of applying PCMs to highly glazed rooms. Similar observations were made by Kosny et al. (2012), showing that low peak temperatures were shifted to early morning and high peak temperatures in some instances were shifted to later evenings. However, in this study, it was discussed that the latter observations are relative to the orientation. Further testing on the factor of shading showed that due to lower temperatures, the availability of solar radiation was more important in the fall to ensure the activation of the PCMs, whereas in summer, the shading would be beneficial.

## CONCLUSIONS

The performance of a composite PCM system proposed for annual thermal energy storage for retrofit applications in high-rise residential buildings in the climate of Toronto was investigated using experimental test cells for four months. The capability of the composite PCM system was clearly displayed as each PCM targeted the fall and summer months as expected. In conclusion, PCM systems constituted by two or more PCM products with different melting points offered potential in becoming a more prominent approach for PCM application in buildings, particularly in continental climates such as Toronto which undergo different weather patterns during the year. This research has shown that with an addition of layer only 2 cm thick of PCMs to interior surfaces, the temperature extremes could be significantly reduced.

### **ABSTRACT**

The societal demands on a more energy efficient building stock in Sweden creates challenges to find suitable retrofitting measures. One of the measures currently discussed is to use interior insulation. This measure leads to a reduced temperature in the wall, which increases the risk for elevated moisture levels in the wall. When the thickness of the insulation layer is limited, super insulation materials (SIM) may be used. SIM can be divided into advanced porous materials, such as aerogel blankets (AB), and vacuum insulation panels (VIP). Often moisture from the outside is the major moisture source why a solution may be to apply a water repellent substance on the surface. A previous study showed that it is difficult to predict all the uncertainties in the laboratory using hygrothermal numerical simulations. This paper presents the design of a field investigation of a homogenous brick wall where AB and VIP are installed as interior insulation.

### **KEYWORDS**

Listed building, brick wall, interior insulation, super insulation material, moisture

### **INTRODUCTION**

The demands on a more energy efficient building stock in Sweden creates challenges to find suitable retrofitting measures. Around 25% of the energy use in buildings in Sweden is used in buildings from before 1941. Out of these buildings many are built in brick masonry and have not been renovated before, which means they are practically non-insulated. The energy use in these buildings can be reduced by adding insulation to the walls. The conventional thermal insulation materials, such as fiber glass and EPS, often demand a thick layer of insulation to reach the energy targets. Super insulation materials (SIM) are thermal insulation components with a 2-10 times higher thermal resistance than the conventional insulation materials. The thermal transmittance (U-value) of the building envelope can thereby be substantially reduced using a limited additional insulation thickness.

Additional insulation can be added either to the interior or exterior side of a wall. Exterior insulation is preferred since the hygrothermal performance of the wall is in many cases improved compared to interior insulation. Interior insulation leads to a reduced temperature in the wall which increases the risk for elevated moisture levels in the wall (Künzel, 1998). Also, internal connections, such as intermediate floor beams, make it difficult to reach a continuous layer of insulation, thus resulting in large thermal bridges. Earlier research has shown that interior insulation decreases the drying-out capacity of the wall and thereby increases the risk for freeze-thaw damages in brick walls. In older brick constructions there is risk for frost damage when they are exposed to driving rain and fluctuating temperatures. Internal insulation can increase the risk of structural damages even more (Mensinga et al., 2010).

Often moisture from the outside is the major moisture source. Consequently, one solution may be to apply a water repellent substance on the surface. This measure leads to less moisture into

the construction (Sandin, 2003). There are several different impregnations available which can be applied to the surface of the façade. However, for brick masonry it is important to make sure that the surface is free from cracks and other defects. Otherwise, the impregnation can have adverse effect on the performance of the façade, since the drying out capacity is decreased while water can still enter the cracks. Slapø et al. (2017) tested four different impregnations on a brick wall with fresh mortar. They recommend great care when using the substances on brick walls in areas with much driving rain and frequent freeze-thaw cycles.

This paper presents results from a laboratory study of a brick wall and the first results from a field investigation of a homogenous brick wall insulated on the interior. Hygrothermal simulations in WUFI 2D were used to predict the hygrothermal performance for different designs. Previous studies have shown that it is difficult to predict the real performance of full-scale wall assemblies in the laboratory. For instance it is not possible to replicate old brick masonry walls in the laboratory and the climate is difficult to simulate (Johansson et al., 2014a). This calls for investigations in the field. Here, an old industrial brick building located in a cold and moist climate was selected where aerogel blankets (AB) and vacuum insulation panels (VIP) were installed as interior insulation. There were challenges to implement the internal insulation in the building. One of these was the ground water rising in the brick masonry which had to be taken into account.

### INTERNAL INSULATION WITH SUPER INSULATION MATERIALS

When the thickness of the insulation layer is limited, SIM may be used. Two examples of SIM are AB and VIP, see Figure 1. VIP are rigid panels which cannot be cut on site and are sensitive to puncturing. Therefore, attention has to be paid in the design of details and envelope components. AB are more similar to conventional fiber-based insulation materials. They can be cut at the construction site and adapted to the specific measurements. VIP were first tested in buildings in the early 1990s which were later followed by several case studies both in laboratory and in the field. AB have been installed in various building assemblies since the early 2000s (Adl-Zarrabi & Johansson, 2018).

Figure 1. Super insulation materials; a) aerogel blanket (AB), b) vacuum insulation panel (VIP).

Among the important material properties for building materials are thermal conductivity, heat capacity and vapor diffusion resistance. The hygrothermal properties for AB and VIP differ substantially. The thermal conductivity of AB is 0.015-0.020 W/(m·K) and 0.002-0.008 W/(m·K) for VIP (Heinemann, 2018). The vapor diffusion resistance of AB is around  $\mu=5$  which is a factor five higher than mineral wool. The blankets are coated with a water repellent substance which reduce the liquid water transfer. The VIP on the other hand, are

wrapped in an air and moisture tight metallized multi-layered polymer laminate which gives a vapor and liquid water transfer only at the edges between the VIP (Johansson et al., 2014b).

### NUMERICAL SIMULATION AND LABORATORY STUDY RESULTS

Up until the early 1900s, hydraulic lime mortars were used in brick masonry buildings in Sweden. These have large tolerances to movements caused by temperature and moisture fluctuations, while one of the disadvantages is the longer curing time compared to mixtures of lime and cement mortar. In a previous numerical study to design a laboratory study (Johansson et al., 2014a), a mortar with a short curing and adhesion time, but with similar hygrothermal properties as the hydraulic lime mortar, was desired. To resemble the properties of an old brick wall it was also important to use a brick and mortar similar to what was used in Sweden during this time period. It was shown that the moisture content in the wall was highly influenced by the properties of the brick and mortar. The time before the walls were saturated differed with a factor of 6 between the least and most permeable bricks while the type of mortar influenced the drying of the wall. The mortar giving the lowest drying rate was the pure cement mortar while the mixture of lime and cement gave a lower drying rate than pure lime mortar.

In the numerical study, a historical brick was investigated with a thickness of 250 mm and a 10 mm thick layer of fine lime cement mortar between the bricks (Johansson et al., 2014a). On the interior of the bricks, 4 cases were simulated:

- 1) reference wall without insulation ( $h = 8 \text{ W}/(\text{m}^2 \cdot \text{K})$ ,  $s_d = 0.2 \text{ m}$ ),
- 2) vapor barrier (high performing) on the interior ( $h = 8 \text{ W}/(\text{m}^2 \cdot \text{K})$ ,  $s_d = 1.500 \text{ m}$ ),
- 3) 60 mm AB ( $h = 0.242 \text{ W}/(\text{m}^2 \cdot \text{K})$ ,  $s_d = 0.2 \text{ m}$ ),
- 4) 20 mm VIP (moisture resistance as vapor barrier) ( $h = 0.242 \text{ W}/(\text{m}^2 \cdot \text{K})$ ,  $s_d = 1.500 \text{ m}$ ).

The initial conditions of the materials were 20°C and 50% RH and the interior climate was 20°C and 40% RH. The exterior climate was based on the HAMSTAD benchmark with an exterior surface heat transfer coefficient of 25 W/(m<sup>2</sup>·K) and a wind dependent vapor surface transfer coefficient. The walls were well protected with a rain water absorption factor of 0.1, i.e. a small amount of rain was available for capillary absorption assuming that the remaining water runs down the façade or splashes off at impact. The results from the one-dimensional numerical simulations of the four cases are shown in Figure 2.

Figure 2. a) Numerically simulated RH 60 mm from the interior of the brick. b) Numerically simulated moisture content in a 250 mm thick wall (adapted from (Johansson et al., 2014a)).

Adding a vapor barrier to the interior of the brick wall does not change the total moisture content in the wall compared to the case without the vapor barrier. However, at the location 60 mm from the interior surface of the brick, the RH is higher than without the vapor barrier. This is caused by the restricted drying from the interior surface of the wall. In the two walls with a layer of interior insulation, both the RH and the moisture content increases compared to the case without interior insulation. The wall with the vapor open insulation has a slightly lower RH and moisture content than the wall with VIP. The main part of the vapor and water flow in the wall is caused by the rain on the exterior surface. Thus, the indoor moisture load is of minor importance for the conditions studied here.

Based on the results above, a brick wall was built in the laboratory of NTNU and SINTEF Building and Infrastructure in Trondheim, Norway. The wall was tested in a large-scale building envelope climate simulator where it was exposed to a temperature gradient and cycling climate with driving rain. The wall was first tested with 20 mm VIP on the interior and then without any layer on the interior side. The wall was divided in two parts (upper and lower) by a horizontal ledge made by a rubber strip to stop liquid water from being transported along the wall. Even though the temperature in the wall was lower in the case with interior VIP, the RH in the upper part of the wall increased more in the wall without VIP. For the lower part of the wall, the RH increased slower on the interior surface of the brick during the first few days, but was then equal to in the middle of the wall. The time before all sensors reached 100% was 180 h for the wall with interior VIP and 170 h for the wall without VIP.

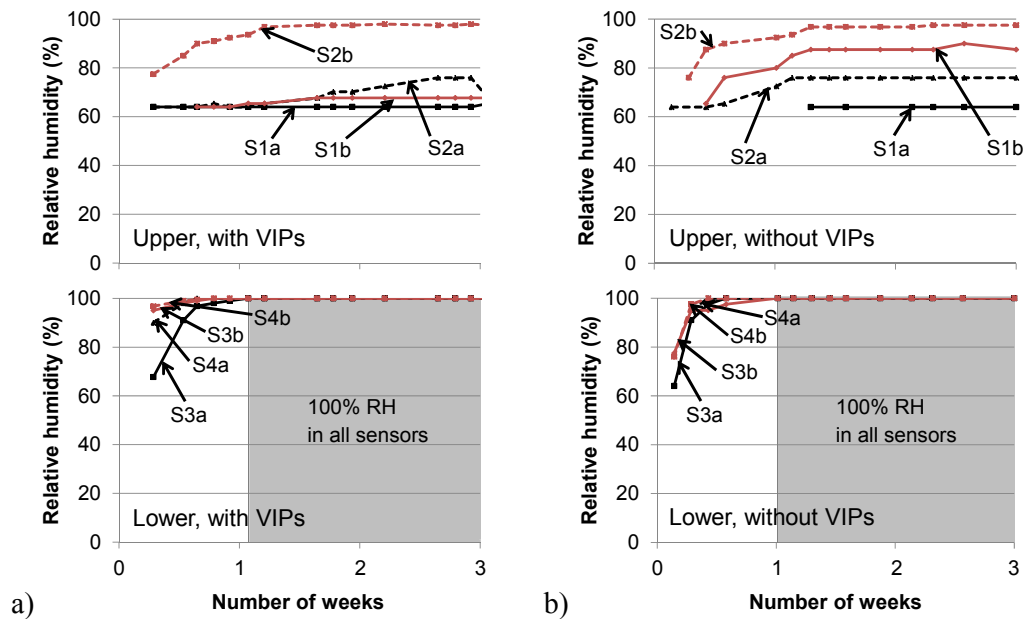

Figure 3. Measured moisture content: a) with VIP in the upper and lower parts of the wall. b) without VIP in the upper and lower parts of the wall. The sensors were located in the mortar in the middle of the wall (S1b-S4b) and in the mortar on the interior surface of the brick (S1a-S4a) (adapted from (Johansson et al., 2014a)).

### CASE STUDY BUILDING

An old industrial brick building south of Gothenburg on the Swedish west-coast is under initial testing for evaluation of AB and VIP on the interior of the wall. The building was constructed in 1896 and has been reconstructed several times since then. The case study building was used for paper production which was in operation until the paper mill was closed in 2005. Left

deserted, the building was vandalized and degraded rapidly due to the cold and humid climate. The remaining heritage values and character defining elements of the building have been evaluated and one of the features that are considered important is the brick façade. Therefore, interior insulation is thought to be an interesting solution to reach sufficient energy performance. A small room was constructed inside the building with insulated (170 mm mineral wool) floor, walls and roof and the exposed brick wall, see Figure 4.

Figure 4. a) Industrial building from 1896 in south of Gothenburg, b) Sensors (marked with arrows) in the brick in the plastered brick wall, c) The test room with installed VIP and AB (removable for inspection of the wall).

Prior to the installation of the internal insulation, the existing plaster was removed from the interior brick surface. There was substantial capillary suction from the ground. The initial measurements showed that the rate of water flow in the bricks is approximately three times higher than that in modern bricks. The room on the inside of the brick wall was heated to around 22°C and ventilated by natural ventilation through two openings. The air in the room was circulated by a fan to create homogenous temperature and moisture conditions in the entire room. The temperature and relative humidity of the air is measured by three sensors. The measurement accuracy is  $\pm 2.5\%$  for relative humidity in the range of 10 to 90% and  $\pm 0.5^\circ\text{C}$  for temperature at 25°C. The temperature can be measured between -40 to 85°C (GE Sensing, 2007). A weather station monitors the outdoor temperature, relative humidity, wind speed and rain intensity on a free field, nearby the façade.

The brick wall is divided into three parts (500 x 1,200 mm) where AB and VIP is tested and compared to a non-insulated reference. The wall is equipped with 10 hygrothermal sensors that every hour register the temperature and relative humidity. The sensors are wireless Sahlén sensors (wood moisture sensors) which measure the weight percentage moisture in a piece of birch around the sensor. The measurement range corresponds to 60% to 100% RH. The size of the sensors is 40 mm x 13 mm (height x diameter), inserted in a 15 mm wide hole in the wall.

In the field study building, the temperature and relative humidity were measured during 20 December, 2017, to 29 January, 2018. The temperature was on average 4.1°C and varied between 0.9°C and 9.5°C. The relative humidity was on average 92.8% and varied between 66.7% and 100%. This can be compared to the outdoor temperature and relative humidity in a nearby weather station which was on average 3.0°C and 87% relative humidity. The outdoor temperature varied between -7.9°C and 10.0°C and the relative humidity varied between 48.0% and 100%. This gives a moisture excess of 0.8 g/m<sup>3</sup> in the building. The moist and cold climate

give several challenges for the application of internal insulation in the field study building. Consequently, the installation of the AB and the VIP was delayed until mid-June, 2018.

## CONCLUSIONS

A brick wall was insulated on the interior with AB and VIP to evaluate the hygrothermal performance before and after this measure. In a previous study, hygrothermal numerical simulations and laboratory measurements showed that it is important to investigate the amount of moisture from driving rain. The properties of the interior insulation material showed to have a lesser influence on the moisture accumulation rate. The rain load was the dominating factor determining the vapor and water transport in the wall. Having the possibility of inward drying lowered the moisture accumulation rate slightly. However, during dry periods with less rain, the VIP reduce the drying capacity of the moisture in the brick. In the end it was difficult to predict all the uncertainties in the laboratory measurements using the hygrothermal numerical simulations. This calls for field investigations.

## ACKNOWLEDGEMENTS

## Lighting characterization of a new coating for window retrofit

Umberto Berardi<sup>1,\*</sup>

<sup>1</sup> Ryerson University, Toronto, Ontario, Canada

*\*Corresponding email: uberardi@ryerson.ca*

### ABSTRACT

The present paper describes a new high-performance coating used for the retrofit of existing glazing systems. The easy application of this new coating on the internal side of the glazing makes possible to reduce quickly the solar heat gain coefficient of an existing window. A full laboratory characterization both from the thermal and light transmissibility point of views is presented. Moreover, the paper reports the results of long-term studies aiming at assessing the risks of aging and related performance reductions for the investigate coating.

### KEYWORDS

Glazing coating; light transmissibility; window retrofit; high-performance window.

### INTRODUCTION

The heat flow across a window assembly results by a combination of different heat transfer modes. In particular, two distinct types of radiation heat transfer take place: long-wave radiation heat transfer in the range from 3 to 50 microns (3000-50.000 nm), and short-wave radiation heat transfer in the range from 0.3 to 2.5 micron (300-2500 nm). The short-wave range includes the ultraviolet, visible (from 380 nm to 780 nm), and solar-infrared radiation. Common glass is transparent to solar-infrared radiation and it is opaque to long-wave infrared radiation. Strategic utilization of this behavior may allow to realize high-performance glazing. In fact, even though the physical process of heat radiation transfer is the same, there is no overlap in the heat transfer at long-wave radiation and short-wave radiation, and so the glass properties may be modified, adding coatings or through glass treatments.

The properties of glazing that affect the radiant energy transfer are the transmittance, reflectance, and emittance. These properties are generally expressed using three coefficients:

- Light Transmittance, which refers to the percentage of radiation that can pass through a glazing. In particular, the Visible Transmittance (VT) indicates the amount of visible light transmitted through the glass, i.e. the transmittance in the range from 380 nm to 780 nm;
- Solar Heat Gain Coefficient (SHGC), ruling the ability to control the heat gain by direct or indirect solar radiation, and hence a significant factor in determining the cooling and heating load of a building;
- U-factor (U-value), assessing the heat lost or gained by the combined effects of conduction, convection, and radiation.

Figure 1 helps to understand how ideally a glazing system should behave in different climates or for different building loads. Building envelope specialists typically target high transmittance in the visible range and aim to control the rest of the spectrum in different ways:

- If low solar heat gains are preferred, the glazing should have a treatment (typically a low-E coating) designed to transmit the visible light and reflect the solar-infrared radiation;
- If high solar heat gains are preferred, the idealized transmittance of a glazing should be such that the visible light and solar-infrared radiation are both transmitted.

Figure 1. Ideal spectral transmittance: 1 for low-solar heat gains and 2 for high-solar heat gains.

With the recent advances in glazing technology, manufacturers can control how a glazing behaves in the different portions of the spectrum. For example, a window optimized for daylighting and for reducing overall solar heat gains should transmit light in the visible portion of the spectrum, while excluding heat gains from the near-infrared part of it.

Coatings may control the passage of long-wave solar radiation, through transmission and/or reflection. In the past, windows that reduced the solar gain (with tints or coatings) also reduced the visible transmittance. However, new high-performance tinted glass and low-solar-gain low-E coatings have made possible to reduce the solar heat gain with little reduction in the visible transmittance. This paper aims to present several tests done on single glazing and IGUs which were coated with a new product designed to be used for retrofit applications.

### GLAZING COATING TRENDS

With conventional clear glazing, a significant amount of solar radiation passes through the windows; then, the heat radiated from internal surfaces within a space is radiated back towards the glass and from this to the outside. A glazing design for maximizing energy efficiency during the heating period should allow the solar spectrum to pass through, and should block the re-radiation of heat from the inside of the space (Rezaei et al., 2017).

Spectrally selective coatings, which act in specific portions of the spectrum, transmit the desirable wavelengths and reflect the rest. A coated glazing material can hence be designed to control (and optimize) the solar heating gain, daylighting, and cooling demand. Originally, the first low-E coatings, intended mainly for residential applications, were designed to have a high solar heat gain coefficient and a high visible transmittance to allow the maximum amount of sunlight into the interior. A glazing designed to minimize the (summer) heat gains, but to maximize the Visible Transmittance for daylighting purposes, would allow most visible light through, but would block all other portions of the solar spectrum, including the ultraviolet and near-infrared radiation, as well as the long-wave heat radiated from outside objects. These new low-E coatings which still allow to obtain a low U-factor, are designed to reflect the solar near-infrared radiation, thus reduce the total SHGC, while provide high Visible Transmittance (Fig.2).

Figure 2. Sunlight transmitted by a clear glass with different coatings.

## METHODOLOGY

A new coating (SNG) intended for window retrofit was investigated in this paper. This coating is composed of n-Butyl-acetate, Ethylene glycol monobutyl acetate, and 1-Methoxy-2-propanol acetate. For this study, the following samples were prepared: single glasses with a thickness of 3, 6, and 8 mm both clear and treated with the new SNG coating; insulating glass units (IGUs) clear, treated with a low-e coating, treated with the new coating, and treated with both a low-E coating and the new coating. The IGUs which had both a low-E coating and the SNG coating were realized with the coatings on the same glass (in positions #3 and #4 respectively) and on different glasses (in positions #2 and #4 respectively). The coating was applied with a special custom 6" high density foam rollers. The applied product was in the range of 25 grams of products per square meter. The thickness of the cured product was 8-10 microns. The product hardened in 2-4 hours (depending on the curing environment).

The intent of the study was to investigate the following properties: solar transmittance; visible transmittance (VT); UV transmittance; solar heat gains coefficient (SHGC); U-factor; and aging effects for exposure to extreme temperature and UV.

In order to determine the light transmittance, a spectrophotometer VARIAN CARY 5000 was used. This equipment makes possible to record the light passing through a glass between 190 nm and 3300 nm. The measurements were done at 5 nm intervals. Below the results will be shown only from 300 nm to 2500 nm, where the accuracy of the equipment is higher.

In order to predict the long-term performance, a series of accelerated aging tests was performed. Like any building material, which needs constant performance while being subject to weathering events, the thermal conductivity and light transmissibility of the glazing were tested after exposing the samples to various environmental loads designed to make sure the coating still performed as expected. Accelerated tests were performed at elevated temperature, extreme temperature fluctuations (freeze-thaw cycles), and combining UV exposure with high temperatures and relative humidity levels, following the methodology presented in previous studies (Berardi and Nosrati, 2018).

The samples were placed in several types of accelerated aging equipment and their long-term behaviour was assessed after an age acceleration equivalent to 10 years in natural outdoor conditions. The aging conditions included both thermal cycling aging (freeze-thaw cycles) and UV exposure aging. To investigate the durability of the different glazing against weathering caused by temperature, moisture, and UV light exposure, the effects of these factors were studied in the QUV accelerated weathering tester by Q-LAB Corp using the

cycle based on ASTM G154 standard (2016). Each cycle consisted of 8 hours of UV radiation at 60 °C black panel temperature, and 4 hours of condensation at 50 °C (Fig.3).

Figure 3. QUV accelerated weathering tester for studying the effects of temperature, moisture, and UV light exposure.

## RESULTS

Figure 4 shows the light transmittance through a 6 mm clear glass and through the same 6 mm glass treated with the SNG coating. As it can be seen, the clear glass has a light transmittance in the range between 75% and 90% from 350 nm to 2500 nm. The 6 mm glass treated with SNG resulted in a lower light transmittance in the visible range, especially below 400 nm and above 600 nm (only reaching values above 70% from 400 nm to 600 nm), and had a transmittance below 20% in the range from 900 nm to 1750 nm. Similar results were obtained for the tests done for clear and treated 3 mm and 8 mm glass panes, which showed a shift of the results towards higher and lower absolute values of the light transmittance respectively.

Figure 4 - Light Transmittance of 6 mm in the range from 300 nm to 2500 nm.

Figure 5 shows the light transmittance results for IGUs with clear non-treated (3mm /15mm space air filled/ 3mm), low-E non-treated, clear treated on one side on #4 and low-E treated glasses. The following resulted emerged:

- the clear non-treated IGU has a light transmittance consistently between 70% and 80% across the range from 300 nm to 2500 nm, with higher values in the visible range;
- the low-E non-treated IGU results in some lower transmittance in the wavelength range up to 400 nm, no significant difference in the rest of the visible range, and a significant lower

transmittance above 800 nm, with values linearly reducing down to a 10% transmittance above 2000 nm. However, the results in the range from 400 nm to 800 nm show minimal reduction compared to the clear non-treated IGU;

- the clear treated with SNG IGU results in lower transmittance in the wavelength range up to 430 nm compared to the low-E non-treated IGU. Light transmittance values between 10% and 20% were recorded in the range from 850 nm and 1800 nm, while the transmittance values increased above this wavelength. The light transmittance values increased linearly from 1400 nm to 2500 nm from 10% up to 40% respectively;
- the low-E treated IGU (basically the IGU with two coatings) results in lower transmittance in the wavelength range up to 430 nm, significant reduction above this wavelength, with values always below 10% above 900 nm.

Treating one glass in the IGU with a low-E coating resulted in a reduction of the transmittance mainly below 460 nm and again an appreciable reduction above 600 nm. The IGU with both a low-E and a SNG coating showed a transmittance substantially overlapping the IGU with the SNG coating, as the low-E showed a generally limited effect in the higher wavelengths in the visible range.

Figure 5 - Light Transmittance of the IGUs in the range from 300 nm to 2500 nm.

Table 1 reports a summary of the light transmissibility tests. The table reports the UV transmission factor, the VT Light transmission factor, the direct transmission of solar energy, and the color rendering index. The VT index for a clear glass decreases from 89% to 76% for a treated SNG glass, a reduction of 13%. Assessing the IGUs, it emerges that the VT was 82% for the clear non-treated glass, 80% for the low-E non-treated glass, which means that the low-E resulted in a particularly small reduction of the VT, and 70% and 69% for the clear treated with SNG and low-E treated with SNG IGUs respectively. This means that treating the IGU with a coating of SNG resulted in a reduction of 12% on average of the VT factor. The UV transmission factor which was 60% for a clear glass and 54% for a clear non-treated IGU, reduced significantly with a low-E coating and became zero once a SNG coating is applied.

The color rendering index (CRI) showed that the clear glass, the IGU clear non-treated and the IGU with a low-E only had a CRI close to a perfect perception of the color, whereas treating the glass with the new coating (SNG) resulted in a difference of the CRI of 4 to 5, and

in a final CRI value for clear treated SNG of 94 to 95. This may be considered a good result, since the coating does not alter the perception of the color in a substantial way.

Finally, the direct transmission of solar energy (%) shows a significant reduction from values as high as 81% for a clear glass and 75% for a clear non-treated IGU, to the value of 60% for a IGU with a low-E coating and 43% for a IGU with a face covered with a SNG coating. Applying the SNG coating to an IGU with a low-E coating resulted in a direct transmission of solar energy of 39%.

Table 1 – Indices resulting from the light transmissibility tests.

	UV transmission factor (%)	VT light transmission factor (%)	Direct transmission of solar energy (%)	Color rendering index
Clear 6 mm glass	60.16	89.30	80.98	99
Treated (SNG) 6 mm glass	0.91	75.98	46.59	94
IGU 3/15/3 clear non treated	54.39	81.89	74.61	99
IGU 3/15/3 low-E non treated	22.50	79.79	60.51	99
IGU 3/15/3 clear treated SNG	0.92	69.87	42.70	94
IGU 3/15/3 low-E treated SNG	0.61	68.70	39.46	95

The results of the aging tests performed on the different glazing systems proved no risks of the coatings over an equivalent life of 10 years. In particular, the light transmissibility tests showed results perfectly overlapping to the related sample in pristine, non-aged, conditions. This shows that the coating is strong and does not suffer thermal cycling or UV radiation at a rate equivalent to a life-span exposure.

Interesting tests regarded the UV exposure of the samples TOO. Based on the experiences of over four weeks of testing in the QUV machine which were calculated as a period equivalent to 10 years in typical application in a moderate climate following the methodology presented in Berardi and Nosrati (2018), no visible effect was perceived on the single panes and IGU systems, confirming the robust behavior of the SNG coating, and it was impossible to distinguish the sample that underwent the UV exposure to the one that did not.

## CONCLUSIONS

Based on the measured results, it can be concluded that the application of the new coating on a glazing unit (IGU) allows to block 99% of the ultraviolet (UV), allows to block over 80% of the infrared (IR), with indices as high as 85% if assessed in the IR range where most of the sun radiation falls, allows to have a SHGC in the range between 0.30 and 0.33, and allows to obtain a visible transmittance in the range of 70%. This means that the performance of the coating overcomes that of a low-E coating with the only exception being the capability to limit transmittance above 2000 nm, which showed to be better for the low-E coating, and the reduced color rendering index which resulted in a slightly blue color of the glass.

### ABSTRACT

As part of a larger project to develop prefabricated technologies for retrofitting building envelopes of Canadian homes, a small building was retrofitted and instrumented. This prefabricated retrofit method is intended to be applied directly over existing cladding. Two prototype retrofit wall systems were installed on the building; a nailbase panel, and a wood frame panel. The existing wall had an RSI value of  $1.80 \text{ m}^2\text{K/W}$  (including film coefficients) and the resulting retrofitted walls reached values of  $6.40 \text{ m}^2\text{K/W}$  and  $5.72 \text{ m}^2\text{K/W}$ . With the addition of a new air barrier, blower door tests have shown a large reduction in infiltration from 7.62 ACH to 0.82 ACH at 50 Pa. This paper discusses the approach taken, the construction of the prefabricated panels, preliminary in-situ RSI measurements, and modelling of thermal bridging and energy savings for the pilot project.

### KEYWORDS

Exterior wall retrofit, building energy simulation, prefabricated retrofit.

### INTRODUCTION

Canada's housing stock consists of more than 11 million low-rise detached, semi and row-attached dwellings (Natural Resources Canada, 2018). More than two-thirds of these dwellings were built before the existence of residential energy efficiency standards. Although close to one million homes took advantage of retrofit program incentives to date, exterior wall insulation improvements have been uncommon, despite exterior walls often accounting for 25 to 35 percent of heat loss in residential buildings. Anecdotal barriers to exterior wall retrofits include: unpredictable costs; occupant and neighbour disruption; long completion times; and, perceived and real risk related to moisture issues.

This paper discusses Natural Resources Canada's Prefabricated Exterior Energy Retrofit (PEER) project (Natural Resources Canada, 2017a). This project seeks to develop technologies and processes for applying prefabricated components to retrofit existing homes and buildings from the exterior. Guided by a working group to provide technical guidance and market intelligence, the project team is collaborating with industry partners to develop technology specifications and build and test prefabricated panels. There are three main components: field dimensioning using 3D imaging and scanning; development of panel prototypes; and evaluation of their performance through field trial installations.

The PEER project team recently completed a proof-of-concept, pilot-scale field installation in Ottawa, Canada. The project involved surveying the existing building (using hand measurements, 3D laser scanning, and tacheometry), and fabricating and installing two prototype wall assemblies.

Many European projects have been addressing deep energy retrofits of the housing stock. (Ochs et al., 2016; Garay Martinez et al., 2017; Sandberg et al., 2016). The Energiesprong initiative

that started in the Netherlands has retrofit thousands of social housing units to achieve net-zero performance and is now being adopted in other countries. These projects often focus on prefabricated approaches to envelope retrofit to minimize on-site work. Prefabrication has a longer history and higher prevalence in Europe than in North America.

In Canada, off-site fabrication for low-rise residential construction is uncommon, and virtually non-existent for retrofit. However, prefabrication promises a host of benefits, including: minimized demolition and time on site; reduced waste and landfilling; improved quality control; and cost-savings if achieved at scale. The PEER project seeks to explore whether prefabrication may help realize these benefits and overcome technical barriers to traditional, piecemeal approaches - ultimately to enable a leap to industrialized deep retrofit.

Other North American organizations are actively working to overcome barriers to deep and net-zero energy retrofits and to adopt or adapt Energiesprong-type programs in their regions (PEMBINA Institute, 2018; Clean Foundation, 2018; Sustainable Buildings Canada, 2018; Rocky Mountain Institute, 2018; NYSERDA, 2018).

### **EXISTING WALL ASSEMBLY AND RETROFIT PANELS**

The pilot field installation was performed on a construction trailer used for storage of material on the CanmetENERGY campus in Ottawa, Canada. The exterior wall assembly of this building is representative of typical Canadian home construction from 1961-1983. A pitched truss roof was assembled on top of the existing roof with a raised heel to achieve the target ceiling R-value. The existing wall assembly consists of the following layers from interior to exterior:

- 3 mm fibreboard interior finish surface
- 0.2 mm polyethylene
- 38 x 89 mm studs @ 405 mm O.C. (on-center) c/w RSI 2.29 (estimated) fibreglass batts
- 8 mm OSB (Oriented Strand Board) sheathing
- Building paper, lapped not taped
- Prefinished profiled galvanized sheet steel cladding

Based on the isothermal planes method, this provides a total RSI value of 1.80 m<sup>2</sup>K/W if a 23% framing fraction is assumed (Natural Resources Canada, 2016).

A narrow strip of the existing cladding was removed at the top and bottom of the existing walls, in order to tie-in the new air-barrier to the existing top plate and floor sheathing. Two different retrofit wall panels were installed directly over the remaining cladding. New windows and doors were preinstalled in the panels.

### **PEER Prototype 1: Nailbase**

The nailbase panel consists of a high-density Expanded Polystyrene (EPS) core bonded to structural sheathing on the exterior and low-density batt adhered to the interior (“squishy layer”). The squishy layer is compliant and helps to plumb the panel and absorb surface irregularities. It also provides dimensional tolerance at panel corners and is vapour-open. This may aid upward drying by diffusion. The EPS core is factory cut to receive continuous structural members at the top and bottom of the panel. These members serve to connect several sub-panels together and provide strength and stiffness for transportation and hoisting. New windows and doors are installed in the EPS layer and supported by a wood perimeter buck. Vertical strapping is installed over a self-adhered, vapour permeable air and weather resistive barrier membrane to support cladding that is installed in the shop. A thicker EPS core layer could be specified to

achieve higher R-values. The nailbase panel is described from interior layer to exterior layer in Table 1.

Table 1. Retrofit panel descriptions

	<b>Nailbase</b>	<b>Woodframe</b>
<b>Layer 1</b>	50 mm low-density (24 kg/m <sup>3</sup> ) fiberglass or mineral wool batt	90mm continuous cellulose insulation (56 kg/m <sup>3</sup> )
<b>Layer 2</b>	150 mm Type-II expanded polystyrene (EPS) core with continuous let-in structure	38 mm x 89 mm studs @ 405mm O.C. c/w cellulose insulation (56 kg/m <sup>3</sup> )
<b>Layer 3</b>	11 mm OSB sheathing	11 mm (OSB) sheathing
<b>Layer 4</b>	Self-adhered vapour permeable air and weather resistive barrier	Self-adhered vapour permeable air and weather resistive barrier
<b>Layer 5</b>	19x89 mm strapping @ 405 mm O.C.	19 x 89 mm strapping @ 405 mm O.C.
<b>Layer 6</b>	Prefinished engineered wood siding	Prefinished engineered wood siding

### PEER Prototype 2: Woodframe

The woodframe panel consists of a 38 x 89 mm stud wall, sheathed with OSB with a self-adhered vapour permeable air and water resistive barrier membrane, strapping and cladding installed prior to arrival to site. The prefabricated stud wall is stood-off from the existing cladding and supported on brackets anchored into the foundation. The stand-off gap is specified to achieve the target thermal resistance. Dense pack fibrous insulation is blown-in on-site through designated access zones at the top and bottom of the panel. In the case of the pilot, a 90 mm stand-off gap was selected. The woodframe panel is described from interior layer to exterior layer in Table 1.

### Support

Steel brackets were anchored to the existing rim joist. Both panel systems sit on a continuous bearing plate placed atop the brackets. The wall panels were attached at the top with steel straps fastened to the existing and new top plates.

### Air barrier details

Both prototypes utilize an exterior air barrier consisting of self-adhering vapour permeable air/weather resistive barrier applied outboard of the sheathing. This membrane wraps the top and bottom of both panels and connects to the existing building with transition membranes.

Fig. 1 shows the construction trailer before, during, and after the retrofit. The installation of all the wall panels was done in less than a day.

### MONITORING RESULTS

In order to verify the thermal performance of the retrofitted walls, measurements of clear wall RSI values were taken in-situ. This was accomplished with Hukseflux HFP01 heat flux sensors on the existing sheathing, and 100 kΩ NTC thermistors on the indoor wall surface and in the ventilated cavity, in line with the heat flux sensors. A total of 7 days was used for the initial measurement, but the RSI value converged in approximately one day. The results for both panels, and a comparison with a calculated value can be seen in the first two rows of Table 2. In addition to increased wall RSI, blower door tests have shown a large increase in airtightness from approximately 7.62 to 0.82 air changes per hour at 50 Pa pressure difference.

Figure 1. Construction trailer before (a), during (b), and after (c) retrofit.

### EFFECTIVE RSI-VALUE AND SIMULATION

The effective RSI-value, considering the effect of thermal bridging through framing at the top and bottom of the panel was assessed using THERM (Lawrence Berkeley National Laboratory, 2018). THERM is a 2D steady-state finite element heat transfer software. A vertical section of each panel was modelled with the existing wall construction, roof and floor. To account for additional bridging in the layers with insulation in the stud cavities, an effective conductivity was imposed on those layers. A framing fraction of 23% was assumed for stud cavities, but the top and bottom plate were removed from this fraction as they are explicitly modelled in the 2D vertical section. The overall effective thermal resistance was then determined for two scenarios:

- The as-built case of the construction trailer without a foundation; and
- A more typical scenario with an insulated foundation. The two panels are depicted on a foundation in Fig. 2.

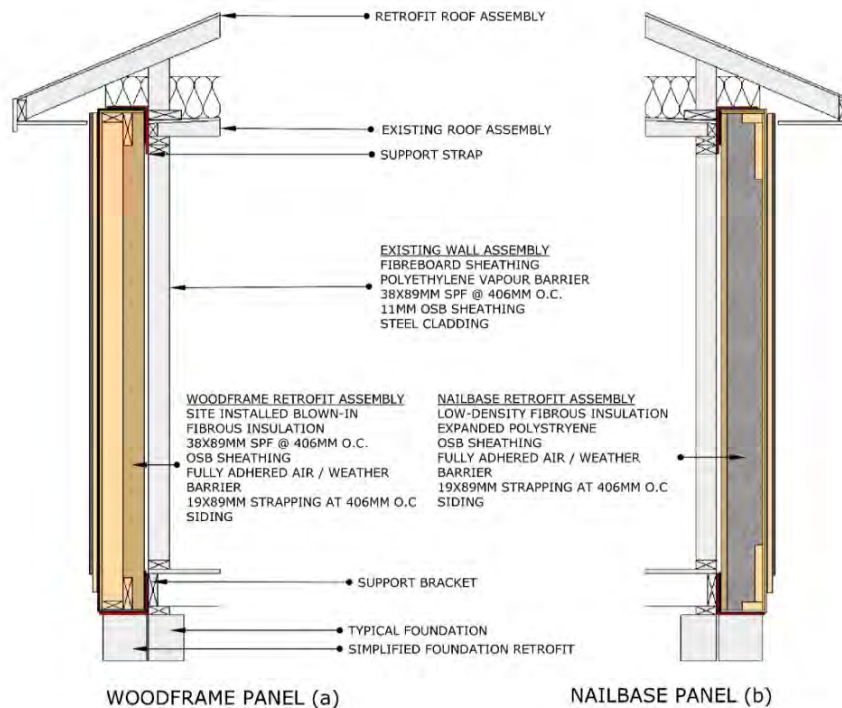

Figure 2. Section of Woodframe (a) and Nailbase (b) panels on existing hypothetical building.

The last three rows of Table 2 show the simulation results. The last row shows the results at the mid-point of the wall, where thermal bridging effects from the top and bottom of the wall are insignificant. There is a significant difference between the RSI values and the mid-point RSI

values for both panels. This is due to thermal bridging through the wood portions at the top and bottom of the assembly, as seen in Fig. 3 for the nailbase panel on insulated foundation. Additionally, the woodframe panel performs worse than the nailbase panel because of additional thermal bridging caused by studs.

Table 2. RSI values for retrofit assembly, including existing wall

	RSI (m <sup>2</sup> K/W) Nailbase	RSI (m <sup>2</sup> K/W) Woodframe	Notes
<b>Measured Clear Wall</b>	7.80	7.80	a
<b>Calculated Clear Wall</b>	7.69	7.64	
<b>Simulated Effective (insulated foundation)</b>	6.77	6.03	
<b>Simulated Effective (as-built)</b>	6.40	5.72

a Uncertainty:  $\pm 0.47$  m<sup>2</sup>K/W, method by Moffat (1988)

Figure 3. Plot of heat flux at top (a) and bottom (b) of Nailbase assembly.

## WHOLE BUILDING ENERGY IMPACTS

The effective thermal resistance values of the retrofit building envelope components and the measured air leakage rates were used to estimate the annual energy use of the existing building and the improvements. In addition to the two prototype wall panels, other retrofit measures included blown-in insulation in the attic, floor batts replaced with spray applied polyurethane, windows replaced with triple glazed units and doors replaced with urethane insulated units. Simulation was performed using HOT2000 v 11.3 (Natural Resources Canada, 2017b). The results in Table 2 show significant improvements in many performance metrics, including a 71.9% improvement in the Thermal Energy Demand Intensity.

Table 2. Whole Building Energy Impacts

Performance Metric	Unit	Pre Retrofit	Post Retrofit	% improvement
Air leakage at 50Pa	ACH	7.6	0.82	89.2%
Annual Gross Heat Loss	MJ	39627.0	14290.0	63.9%
Annual Heat Loss via Walls	MJ	15242.8	4695.8	69.2%
Annual Heat Loss via Air Leakage	MJ	3677.2	393.7	89.3%
Design Heat Loss	W	5760.0	2540.0	55.9%
Design Cooling Load	W	2902.0	2324.0	19.9%
Thermal Energy Demand Intensity	kWh/m2	230.3	64.7	71.9%

## CONCLUSIONS

This paper presented preliminary results of a pilot project for prefabricated deep energy retrofit of building envelope for low-rise residential buildings. It was shown that thermal bridging can be an important source of heat loss, and that the bottom and top of the panels must be carefully designed while considering the existing building to minimize bridging. Additionally, annual simulations have shown significant improvements in thermal energy performance metrics. Field monitoring is continuing, and future work will include assessment of the hygrothermal performance of the envelope over an extended period.

### **ABSTRACT**

The energy retrofit of existing buildings and more in general building rehabilitation represents an important challenge in EU countries since a large part of their building stock is old, poorly insulated and affected by pathologies, i.e. mould growth, with relevant implications on users health other than aesthetical drawbacks. Unfortunately, the energy retrofit of existing buildings and particularly when dealing with historic buildings presents several issues, i.e. the compatibility between the identified solutions and the heritage value or the reduction of the internal space if internal solutions have to be adopted.

An emerging solution to address the target of the energy efficiency, according to the abovementioned issues, is the application of advanced materials characterized by high thermal performance and thus allowing to keep low layer thickness.

In the framework of an on-going Wall-ACE Horizon 2020 project, a set of aerogel-based novel super insulating plasters, particularly suitable for internal and external application on existing walls is under development. As far as the interior layer is concerned, so far two different aerogel-based products have been developed: an interior plaster and a thermal coating were developed respectively aimed at reducing the heating energy needs and mitigating thermal bridges mould issues.

The paper reports the first results of the laboratory tests carried out on the thermal coating. Moreover, a monitoring activity in a 1920s building in Torino (Italy, Lat.45°N, Long 7.65°E) was carried out to characterize the actual thermal performance of the insulating layer and to assess the technical and the hygrothermal compatibility of the intervention.

The monitoring results highlight that the application of a thin thermal coating finishing layer can lead to a significant increment of the indoor surface temperature of ~1.5°C with a decrease of the wall heat losses of ~30%. Moreover, a mitigation of the effect of the thermal bridge was also observed with an increment of the node surface temperature (wall-window frame) of up to 2°C.

Aerogel, coating, finish rendering, plaster, thermal performance

### **INTRODUCTION**

The building sector is responsible for nearly 40% of the total energy consumption in Europe (Directive 2010/31/EU). About 50% of the European stock was built before the first thermal regulations in 1970s (EU Buildings Factsheets). Italy is a clear example, in fact, more than 60% of residential buildings were built before 1976, the year the first law on energy savings, and the 30% of buildings (12.5 million buildings) is dated before 1945 (ISTAT 2011), therefore, characterized by traditional construction systems. About 1.8% of this Italian

building stock can be classified as cultural heritage, according to the definition of the Legislative Decree no. 42 of 22/01/2004 pertaining to the Cultural Heritage and Landscape Code, that means subject to protection by the competent Ministerial Authorities.

In the last decade, the importance of energy efficiency and thermal comfort in historical buildings has increased immensely and, the most recent research shows a shift in viewpoints. While energy retrofits were previously seen as a potential threat to the character and fabric of historic and traditional buildings, they are now seen largely as an opportunity to protect these buildings and respond to global environmental concerns (Webb A.L - 2017))

There is a growing body of research facing the challenge of merging energy efficiency measures and internal thermal comfort with the requisite of maintaining the cultural and historic significance of buildings (De Bouw M. et al. - 2016). Among the technical solutions to reduce thermal losses, technologies for the indoor insulation are the most suitable for this purpose (Walker R. and Pavia S. - 2018). Innovative materials and products like aerogel-based plasters and renders shall be explored because of their reduced thickness of installation and their high insulation potential.

In the framework of an on-going Wall-ACE Horizon 2020 project a novel aerogel-based thermal coating has been developed, with the main aim of mitigating thermal bridges and mould growth issues.

In this paper first results coming from laboratory tests and in-field monitoring are presented.

## **METHODS**

A novel aerogel-based thermal coating, here called R4, was developed adopting both mineral and organic binders, with Kwark® granular aerogel (produced by Enersens), perlite, glass and ceramic spheres used, in various percentage, as lightweight aggregates (LWA).

A first series of preliminary tests, aimed at determining its thermal and mechanical properties were carried out in the laboratory to check its conformity to the market and its potentials in mitigating thermal bridges and avoiding mould growth. A monitoring campaign was then set-up and carried out on a case study building, in order to test its behaviour under actual operating conditions.

### **Laboratory test**

The laboratory tests were aimed at determining the dry bulk density, the mechanical resistance and the thermal conductivity of the material.

The density was measured by weighing a specimen with a known volume of 0.4 x 0.4 x 0.05 m, previously dried in a climatic chamber (ACS DM 340, figure 1c) until any weight variation of more than 0.2%, occurs. Flexural and compression strength tests were carried out adopting prismatic samples according to UNI EN 1015-11:2007 (figure 1b). The dried specimen was also adopted for the thermal conductivity measurements carried out according to UNI EN 12667:2002, through a heat flux meter apparatus (Lasercomp FOX 600, figure 2d).

Figure 1: a) Coating sample surface aspect; b) Flexural strength measurement; c) Climatic chamber (ACS DM 340); d) Heat flux meter (Lasercomp FOX 600).

### Application phase and in-field monitoring

In addition to laboratory measurements, an assessment of the behaviour under actual operating condition was performed aimed at investigating aspects related to the technical feasibility as well as energy effectiveness. A monitoring campaign on a 1920s building located in Turin (Italy, Lat. 45°N, Long. 7.65°E) was thus set-up and carried out. From the energy point of view, the aim of the in-situ measurements was to evaluate the capacity of the R4 coating, on one hand, to reduce heat losses through the solid masonry wall and on the other hand to mitigate thermal bridging effect due to the increasing of the wall indoor surface temperatures. An east-oriented room was chosen and two identical walls, named TW and RW, respectively the wall with the thermal coating (figure 3a) and the reference one (figure 3b) were continuously monitored.

Figure 3: a) Coated wall (TW); b) Reference wall (RW); c) Schematic sensors position

Figure 4: a) Primer application; b) Mixing; c) Coating application; d) Final thickness;

The coating was prepared and applied on TW and the related thermal bridge. To improve the adhesion of the thermal coating on the existent wall, a mono-component primer in thin layer

was firstly applied (figure 4a). The thermal coating, mechanically mixed with ~1:1 water ratio, was manually applied to reach a thickness of 12-15 mm (figure 4b, c, d).

For the monitoring campaign, carried out according to UNI ISO 9869-1:2015, temperature and heat flux sensors were placed both on TW and RW and on the relative thermal bridges. As reported in figure 3c, two heat flux sensors were applied in the centre of walls. T-type thermocouples were placed for measuring air and surface temperatures both on the walls and in the thermal bridges zones<sup>1</sup>, in addition, thermocouples were also placed at the interface between the thermal coating and the wall (TW) (figure 3c).

In order to measure the incident solar radiation, a pyranometer sensor was adopted. To force the temperature difference between indoor and outdoor, reaching at least 10 °C, the indoor setpoint temperature maintained at  $23 \pm 1^\circ\text{C}$ .

## RESULTS AND DISCUSSION

### Physical properties

Laboratory test showed generally good properties (table 1). The density of dried specimen is ~50% lower than the value obtained from thermal insulating coat without aerogel grains (R0 table 1). As far as mechanical properties are concerned, flexural strength assumed the value of 0.8 MPa. Thermal conductivity was 0.051 W/mK for the dried specimen, that is ~65% lower than the  $\lambda$ -value assumed by mineral-based thermal insulation coating (R0 table 1).

Table 1: Results of laboratory measurements carried out on R4 sample

Sample	Density [kg/m <sup>3</sup> ]	Flexural strength [MPa]	$\lambda$		
			T <sub>avg</sub> 10°C	T <sub>avg</sub> 25°C	T <sub>avg</sub> 40°C
R4	326	0.8	0.051	0.052	0.053
R0	617	1.1	0.138	0.143	0.151

### Monitoring results

The temperature and heat flux analyses were focused on the last week of the entire monitored period; these days (from 26<sup>th</sup> February to 05<sup>th</sup> March) were considered the most representative due to the low solar radiation value and low external air temperature (figure 5).

Figure 5: Boundary conditions

In figure 6a the boxplot analysis of the surface temperatures of the TW and RW in the centre of the walls and along the thermal bridge is reported. The graph shows an increase on W1 temperature surface due to the presence of the thermal coating. Particularly, near to the

<sup>1</sup> It is worth to be mentioned that the measurement set-up does not allow to quantify the linear thermal transmittance. For this sake, the measured wall-edge temperatures can be used to validate heat transfer models able to quantitatively assess the incidence of the thermal bridges.

window frame (●), the surface temperature increases of  $\sim 2^{\circ}\text{C}$  compared to the uncoated surface. The thermographic analyses highlight the temperature increase on the TW thermal bridge due to the presence of the thermal coating (figure 7b, 7c). Looking at the TW external surface the temperature is, as expected, lower than that of RW, reaching a value below zero, which can determine freezing problems in rain-exposed façade (figure 6b, 7c). As well as the increasing of the internal surface temperature, a noticeable reduction of about 30% of the heat flux on the thermal coated wall, when compared to the RW wall (figure 7c), can be observed.

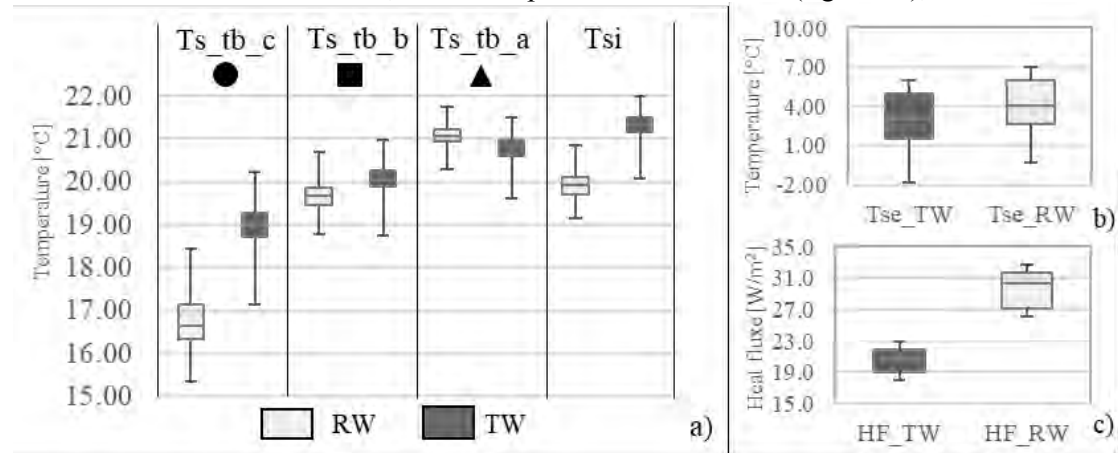

Figure 6: a) Thermal bridges and walls surface temperature monitored; b) external surface temperature monitored; c) Heat flux measured on TW and RW.

Figure 7: a) Thermocouples on thermal bridges; b) Infrared image of TW thermal bridge; c) Infrared image of RW thermal bridge; d) External infrared image.

## CONCLUSIONS

In the framework of a Horizon-2020 project ‘Wall ACE’ a novel aerogel-based thermal coating finishing for interior insulation was developed.

As a first research step, the main physical properties of the developed material were assessed through laboratory analyses. The thermal results of the selected product show a low thermal conductivity value of  $\sim 0.05 \text{ W/mK}$ . Furthermore, the material was applied to a 1920’ demonstration building in Turin. The thermal behaviour of the retrofitted wall was monitored for an entire winter season after the application and was compared with an uncoated reference wall. The monitoring results highlight that the application of a thin thermal coating finishing

layer can lead to a significant increment of the indoor surface temperature of  $\sim 1.5^{\circ}\text{C}$  with a decrease of the wall heat losses of  $\sim 30\%$ . Moreover, a mitigation of the effect of the thermal bridge was also observed with an increment of the node surface temperature (wall-window frame) of up to  $2^{\circ}\text{C}$ . The obtained results reveal that the developed thermal coating finishing present a non-negligible reduction of the heat losses as well as significant mitigation of the condensation risks in thermal bridges demonstrating the suitability of the developed product for the application in all the buildings in which usual thick internal insulating solutions cannot be addressed for space, historical and technical constraints.

## ACKNOWLEDGEMENT

The research project Wall-ACE has received funding from the EU Horizon 2020 research and innovation programme under the Grant Agreement No. 723574. The authors wish to thanks the project partner ATC (Agenzia Territoriale per la Casa del Piemonte Centrale) and CASE which make available the demonstration building and ENERSSENS that provided the Kwark® aerogel for the development of the insulating coating finish.

## Comparing Exterior Wall Finishes Using Life-Cycle Assessment

Brandi Dodge<sup>1</sup>, Rui Liu<sup>1,\*</sup>

### ABSTRACT

Selecting products that are environmentally friendly can help reduce the negative environmental impacts associated with the built environment. However, the process can be difficult. Life-cycle assessment (LCA) is an approach used to measure the environmental performance of a product or service by considering all stages of a product's life-cycle from extraction of raw materials to its end of life. Many products that claim to be environmentally friendly are based on a single life-cycle stage or environmental impact. These claims are often misleading as they do not consider other life-cycle stages or other environmental impacts associated with the products. This study examines alternative exterior wall finishes for a traditional single-family home in the State of Ohio from an LCA approach to determine which finishes are friendlier on the natural and built environment. Advantages and disadvantages of exterior wall finishes including aluminum siding, brick, wood siding, fiber cement siding, stucco, and vinyl siding have been investigated, as well as the impact each finish has on each of the life-cycle stages. Their life-cycle environmental impacts during various life-cycle stages are compared using the BEES (Building for Environmental and Economic Sustainability) software developed by the National Institute of Standards and Technology. Each of the exterior wall finishes were compared in the following categories: overall life-cycle environmental impacts, global warming potential, recyclability, service life, and the cost of material and labor. Not one of the materials scores the best in every category. While vinyl siding does not have much potential for recycling or a long service life, it performs well in other categories and appears to be a better option from an environmental and cost perspective overall.

### KEYWORDS

Exterior Wall Finishes; Life-cycle Assessment

### INTRODUCTION

The construction industry consumes about 50% of the natural resources extracted from the earth. The process of extracting raw materials leads to resource depletion, creates pollution and landfill waste, and contributes to biological diversity losses. Also, transporting raw materials to manufacturing plants, and turning those materials into products, generates additional pollution and requires energy consumption resulting in higher greenhouse gas emissions. Products typically generate wastes during installation or have short service lives that result in disposal and the manufacture of replacement products. Energy consumption by the built environment is responsible for 40% of greenhouse gas emissions worldwide, so selecting building products that are environmentally friendly is one way to help reduce the negative environmental impacts associated with the built environment (Lippiatt, 2007). When considering products, people will typically look at the cost, lifespan, and product maintenance. However, people tend to only consider the end product and are not aware of the negative impacts that these products have on the environment from a life-cycle perspective (Robertson, 2008). By implementing life-cycle assessment (LCA), it is possible to optimize aspects of a product from the extraction of raw materials to the end of life. LCA helps to look

at the ways in which to improve environmental processes, ways in which to prevent adverse environmental impacts, how to enhance the quality of life, and ways to allow people to live in a healthy environment. In comparison between the findings of this study and existing studies, a lack of comparable research was discovered. Existing residential LCA studies on exterior walls tend to study entire wall assemblies rather than just the exterior wall finishes. The purpose of this study is to consider only the exterior wall finishes for a traditional single-family home in the northeast Ohio, United States. These finishes are compared to help aid in the selection of finishes that are environmentally friendlier from an LCA approach. The cost of the materials and installation are compared as well.

## METHODS

The project is a 2-story residential house, located in a subdivision in the northeast Ohio. The house contains 4 bedrooms, 2.5 baths, and a 2-car attached garage. The house is constructed of 2x4 wood framing with batt insulation. The current materials on the envelope of the house include vinyl siding and asphalt shingles, shown in Figure 1. The finishes in this study include aluminium siding, brick, wood siding, fiber cement siding, stucco, and vinyl siding.

Figure 1. House used for the study (SketchUp Warehouse model by Paulwall)

The Building for Environmental and Economic Sustainability (BEES) software, developed by the U.S. National Institute of Standards and Technology, was used to compare the overall environmental performance of the exterior wall finishes according to their life-cycle stages.

BEES generates environmental performance scores for building products sold in the United States. The scores generated help with selecting products that are environmentally preferred. Manufacturing of a product involves several unit processes with inventory flows. The basis for the unit of comparison is the functional unit, which for this study will be 1 ft<sup>2</sup> of product lifetime for a 50-year period. Inventory analysis involves quantifying the inventory flows for a product. Data categories are used to group the inventory flows. For generic products, as used primarily in this study, assumptions concerning the associated unit processes were verified through industry experts.

The impact assessment quantifies the potential contribution of a product's inventory flows to a variety of environmental impacts. Twelve impacts include global warming, acidification, eutrophication, fossil fuel depletion, habitat alteration, criteria air pollutants, indoor air quality, human health, smog, ozone depletion, ecological toxicity, and water intake are addressed. Inventory flows contributing to each impact have been quantified and characterized in terms of U.S. flows per year per capita. Adding all characterized flows for each impact results in impact category performance measures. These measures represent a baseline against which to compare the environmental impacts of a product.

During interpretation, the normalized impact assessment results are analyzed. To compare the overall environmental performance of the alternative products, the performance scores for all the impact categories are synthesized. This is achieved by weighting each of the impact categories by its relative importance to the overall environmental performance, and then computing the weighted average impact score. The weighting used for this study is based on the EPA Science Advisory Board study (USEPA, 2000). Highest-risk problems include global warming and habitat alteration. High-risk problems include indoor air quality, ecological toxicity, and human health. Medium-risk problems include ozone depletion, smog, acidification, eutrophication, and criteria air pollutants. Fossil fuel depletion and water intake were not explicitly considered as impacts (Levin, 1996). These classifications are then converted into numerical importance weights using a method known as the analytic hierarchy process (ASTM International, 2002). Finally, the materials and installation costs are compared for these alternative exterior wall finishes using 2016 construction cost data (RS Means, 2016).

## RESULTS AND DISCUSSIONS

The first step in the BEES assessment is to specify the analysis parameters. For this part of the study, other environment performance of the exterior wall finishes is being considered, so the environmental performance is set at 100% while the economic performance is set at 0%. In the building element for comparison section, shell is the major group element, exterior enclosure is the group element, and exterior wall finishes is the individual element. The product alternatives represent the six exterior wall finishes to be compared. The transportation distance represents the number of miles from the manufacturer to the site. Manufacturer locations and site locations vary for each analysis, so a default mileage, which represents an average, was used.

After selecting all the products for LCA comparison, the analysis was completed. The analysis looked at the overall environmental performance, the overall global warming potential, and the effect that each finish has on environmental impacts. Refer to Figures 2-4 for the results of the comparisons. The results are based on a performance score and do not represent absolute performance. Instead, these scores represent proportional differences in performance among the alternatives. The lower the number of the performance score, the more environmentally friendly the product is (Lippiatt, 2007).

Figure 2. Environmental performance

Figure 3. BEES global warming results

Figure 4. BEES results of each finishes' effect on environmental impacts

The results of the exterior wall finishes analyzed for comparison shows that of the five life-cycle stages, the extraction of raw materials has the greatest negative impact on the environment of each material except for brick. Wood siding has the least harmful impact on the environment, with a total performance score of 0.0006. Brick has the most harmful impact on the environment with a total impact performance of 0.0053. Viewing the global warming potential from these life-cycle stages, the results show that the extraction of raw materials is the greatest contributor to the negative impact on global warming of each material except for brick and wood siding. Wood siding has the least harmful impact on global warming with a total performance score of 126. Brick has the most harmful impact on global warming with a total performance score of 4513. The life-cycle stages of the finishes show that global warming has the greatest negative impact on the environment. Wood siding contributes the least to global warming with a total performance score of 0.0005. Brick contributes the most to global warming with a total performance score of 0.0050.

Based on the results from the BEES comparison studies, the exterior wall finish that is overall the most environmentally friendly, and contributes the least to global warming is wood siding. The exterior wall finish that is overall the least environmentally friendly, and contributes the most to global warming is brick. The other finishes, in order from most environmentally friendly to least environmentally friendly from all life-cycle stages combined are vinyl siding, stucco, aluminum siding, and fiber cement siding. Raw material extraction and manufacturing of these finishes are the life-cycle stages which contribute the most to a negative environmental impact. These two life-cycle stages also greatly impact the global warming potential and are the largest contributors of carbon dioxide emissions.

Some information to consider when performing LCA is that values associated with each model are representative of the year of the model. Data originating from surveys and/or forms submitted by industries to governments for national statistical purposes can be incomplete, thus underestimating actual data values. Economic input-output coefficients for stable industries may be similar to past coefficients, but may vary over time for rapidly changing industries. Also, environmental data can vary due to changes in efficiency, pollution regulations, or production levels (Carnegie Mellon University, 2016). In addition, products tend to be grouped into a single industry sector if their production requires a similar process, thus resulting in data and dissimilar products taking on contributions and impacts of another product. While uncertainties in data do not imply that LCA studies are unreliable, these uncertainties should be understood and the LCA results recognized (Williams, 2009).

The house in this study has a surface area of 3,292 ft<sup>2</sup> excluding all doors and windows. Accounting for a 5% material waste and rounding up to the nearest 100 ft<sup>2</sup>, the total surface area increases to 3,500 ft<sup>2</sup>. The cost of materials falls within a price range, so the lowest cost of each material and the highest cost of each material is calculated (Anderson, 2013; RS Means, 2016). The total costs exclude overhead and profit.

Table 1. Costs of Materials and Installations

	Material (\$/ft <sup>2</sup> )		Labor (\$/ft <sup>2</sup> )		Total (\$/ft <sup>2</sup> )		Material Total (\$)		Material + Installation Total (\$)	
	Low	High	Low	High	Low	High	Low	High	Low	High
Aluminum	\$1.63	\$4.73	\$1.96	\$1.96	\$3.59	\$6.69	\$5,705	\$16,555	\$12,565	\$23,415
Brick	\$4.00	\$7.00	\$7.00	\$10.00	\$11.00	\$17.00	\$14,000	\$24,500	\$38,500	\$59,500
Wood (Cedar)	\$3.79	\$6.75	\$1.03	\$1.03	\$4.82	\$7.78	\$13,265	\$23,625	\$16,870	\$27,230
Fiber Cement	\$1.19	\$4.12	\$1.82	\$1.11	\$3.01	\$5.23	\$4,165	\$14,420	\$10,535	\$18,305
Stucco	\$1.00	\$1.00	\$1.30	\$1.50	\$2.30	\$2.50	\$3,500	\$3,500	\$8,050	\$8,750
Vinyl Siding	\$0.72	\$1.62	\$1.48	\$1.41	\$2.20	\$3.03	\$2,520	\$5,670	\$7,700	\$10,605

The costs of the exterior wall finishes in order from the cheapest to the most expensive are vinyl siding and stucco, fiber cement siding, aluminum siding, wood siding, and brick. Each of the exterior wall finishes were compared in various categories. Green represents the best in each category, yellow represents second to best, and red represents the worst in each category. Refer to Table 2 for the category comparisons.

Table 2. Overall Comparison

	Life-Cycle Impacts	Global Warming Potential	Recyclability	Service Life (Years)	Material + Install (\$ Low)	Material + Install (\$ High)
Aluminum	0.0018	1,538	100%	80	\$12,565	\$23,415
Brick	0.0053	45,134	75%	100+	\$38,500	\$59,500
Wood (Cedar)	0.0006	126	0%	40	\$16,870	\$27,230
Fiber Cement	0.0028	2,436	0%	50+	\$10,535	\$18,305
Stucco	0.0015	1,458	0%	100+	\$8,050	\$8,750
Vinyl Siding	0.001	655	0%	40	\$7,700	\$10,605

Not one of the materials scores the best in every category. Therefore, the best material cannot be selected without weighing the pros and cons. Brick has the worst score for life-cycle impacts and global warming potential, as well as the most expensive in cost compared to all the other materials. Brick has an advantage since 75% of it can be recycled at its end of life. Also, brick has a service life that can last over 100 years. However, a house's typical lifetime is about 60 years, so the service life far exceeds the house's lifetime. Aluminum siding does not have the worst scores in any of the categories, but requires continuous painting and can dent very easily. Stucco's life-cycle impacts and global warming potential fall near the middle, so environmentally, it is not the worst material, nor is it the best material. However, stucco is rarely used in the northeast Ohio. Fiber cement siding also falls near the middle range of the environmental impacts, but like aluminum siding and stucco, fiber cement is not a very common material in the northeast Ohio when compared to vinyl siding. Wood siding has the lowest life-cycle impacts and contributes the least to the global warming potential. It is more expensive than vinyl siding and is not typically recycled. Its service life is shorter than that of a house's typical lifetime, so the siding would need to be replaced at least once. Also, wood siding requires continuous painting or staining. While the material does not have much potential for recycling or a long service life, it does well in the other categories. Vinyl siding is a close second to wood as the best material according to life-cycle impacts and global warming potential, plus it is an affordable material. The service life of vinyl siding is

the shortest compared to those of the other materials but it can be replaced at the end of its service life, replacement material can be produced, and it will still have an overall life-cycle impact and global warming potential lower than that of aluminum, brick, wood, and fiber cement. Also, vinyl siding does not require painting or extensive maintenance.

While research shows that wood, fiber cement, stucco, and vinyl siding do not have much potential for recycling at end of life (Lippiatt, 2007), measures are being taken to prevent various building materials from ending up in landfills. Local regulatory measures, disposal fee increases, education, and green building are driving the market toward building material recovery. By recovering used building materials from waste streams, materials can be re-manufactured and refurbished (Liming, 2018).

## CONCLUSIONS

Overall, vinyl siding appears to be the best option from an environmental and cost perspective. Based on the results carried out in this study, the most affordable material is not necessarily the most environmentally friendly. It is difficult to select a material that has both an appealing price tag as well as less of a negative impact on the environment. However, it is possible to weigh the options to responsibly select a material.

## Experimental Study of the Performance of a Double Skin Façade Window under Non-Solar Conditions

Jiayi Zhu, Guoqing He<sup>\*</sup>, Qihuan Luo and Yu Liu

College of civil engineering and architecture Zhejiang University Hangzhou China

*\*Corresponding email: guoqinghe@zju.edu.cn*

### ABSTRACT

This paper reports measured heat transfer coefficient of a double skin façade (DSF) window measured 1.1 m by 0.7 m at varied depth in the absence of solar radiation using a calorimeter box. The results showed that the DSF had better insulation than the double glazing especially with cavity closed. All the studied factors (ventilation, cavity width, and outdoor temperature) had influence on the heat transfer coefficient and such influence could be season specific. Measurements confirmed the existence of an optimal width in winter for best insulation.

### KEYWORDS

Double skin façade, U value, experiments, non-solar radiation

### INTRODUCTION

Double skin façades (DSFs) have received increasing attention in research and in practice since their first appearance in northern Europe (Poirazis 2006). In addition to its freedom in aesthetic expression, the cavity between the two layers offers potential energy savings (Ghaffarianhoseini et al., 2016) and even carbon reduction in a life cycle (Pomponi and D'Amico, 2017). Recent studies explored the performance of varied forms of DSFs, such as phase change material attached blinds (Li et al., 2017), photovoltaic (PV) panel attached blinds (Kapsis and Athienitis, 2015; Luo et al., 2017), fan-coil combined DSF design (Bueno et al., 2017), and pipe-embedded DSF design (Shen and Li, 2016). These studies attempted to make the best of the double layers, which protect solar shading devices and other materials from the outdoor environment while keeping the heat absorbed in the cavity outdoors.

What makes the DSF unique is thought to be the double layers and various ventilation schemes to meet different needs in different seasons, i.e., one design that can work in both cooling and heating seasons, suitable for regions such as the hot summer and cold winter zone in China. Such capability requires the DSF to have good insulation, good shading performance in summer, and good solar heat gain in winter. The installation of blinds and its combination with other new materials aim to meet the later two needs. The double layer structure typically consisting of a double glazing and a single pane presumably provide better insulation than a normal double glazing, whose U values are typically around 2.80 W/m<sup>2</sup>/K. There are limited studies on the U values of DSFs. Recent studies have defined the U value of a DSF window based on total heat transferred through inner surface excluding the direct solar transmittance (here referred as heat transfer based U value, or  $U_{HT}$ ). Luo et al. (2017) reported experimental data of  $U_{HT}$  as 2.2 to 2.8 W/m<sup>2</sup>/K for naturally ventilated DSFs, lower than 3.8 W/m<sup>2</sup>/K reported by Peng (Peng and Lu et al., 2015) for a naturally ventilated DSF with a semi-transparent PV film attached to the outer pane. Note that  $U_{HT}$  is not comparable to the conventional U value defined based on steady state heat transfer without solar radiation because the former includes part of the absorbed solar irradiation on the inner pane of the window which then enters into the room as heat gain by convection or irradiative heat transfer.

Chow et al. (2010) and He et al. (2016) used a different approach where total room heat gain of a window is expressed as a linear function of solar irradiation and the temperature difference between the room and the outside, which is confirmed by experiment in the case of DSF (He et al., 2016). The coefficient of the temperature term is defined as the U value (room heat gain based U value, or  $U_{HG}$ ), which is difficult to measure directly. For common double glazing, Chow et al. (2010) showed that the calculated values of  $U_{HG}$  are close to the typical U values. For DSF, He et al. (2016) determined the  $U_{HG}$  value of a DSF window together with the solar shading coefficient by fitting the experimental data. However, the contribution of heat transfer through the DSF was shadowed by the solar radiation, making it difficult to obtain a U value with meaningful certainty. Nevertheless, their simulations indicated that the U value of DSF windows could be significantly lower than that of the corresponding double glazing indicating improved insulation by the addition of an extra layer.

Previously discussed U values of DSFs reflects the overall heating transfer coefficient in the present of solar radiation. To our best knowledge, there have not been any studies on the U value of DSF in the absence of solar radiation (conventional U values). Given the amount of non-solar time in a day, the conventional U value of the DSF is critical to the performance of DSF. This paper attempts to fill this gap by studying the conventional U value of a DSF window experimentally.

## METHODS

### Experiment setup

Experiments were carried out indoors with the same DSF model and calorimeter described in He et al. (2016). The model box was  $1.3 \text{ m} \times 1.1 \text{ m} \times 0.88 \text{ m}$  (Figure 1) and consisted of a small version of DSF window on one wall. All other three walls, floor and ceiling were 0.1 m thick extruded polystyrene (XPS) panels, each covered by a thin (0.005 m) aluminum sheet outside. The outer layer of the DSF window was a single-pane glazing and the inner layer was a double glazing. All glazing panes were clear float glasses. There were two openings of equal height (0.02 m) at the top and the bottom of the single pane glazing. The double glazing separates the box into two spaces: the cavity of the DSF and the test chamber. By moving the double glazing, the distance between the single pane and the double glazing can be changed. An aluminum micro-channel heat exchanger was used as the heating source with the water flowed in from the bottom and out from the top. Inflow temperature was maintained constant at a desired value by a water bath. The pipe for connection is PPR (Polypropylene-Random,  $\phi 20\text{mm}$ ) tube insulated using rubber foam. A rotameter ( $\pm 2.5\%$ ) was used to measure the flow rate and its accuracy was checked by measuring the volume of the water at a given time.

In total, T-type thermocouples were used to measure temperatures of the aluminum plate (5 sets), double glazing (3 sets), single pane (1 set), room air (1 set), cavity air (3 sets), and test chamber air (6 sets), inflow water (1 set), and outflow water (1 set). For room air temperature measurement, a cup-shaped aluminum foil surrounded the thermocouple to reduce the radiative heat transfer from indoor environment. All thermocouples were calibrated against a platinum resistance thermometer (previously calibrated to  $0.1^\circ\text{C}$  accuracy by the Center of Cryogenic Metrology in Chinese Academy of Sciences) in the range of  $-20$  to  $100^\circ\text{C}$ . The calibration results were used to correct the measured temperature to an accuracy of  $0.2 \text{ K}$ . Temperatures were recorded every 10 seconds using two data acquisition modules (NI 9213 and NI 9219).

Air velocity was measured at three positions (A, B, C) using thermal anemometers (Swema 03,  $0.05 \sim 10 \text{ m/s}$ ,  $\pm 0.04 \text{ m/s}$  or  $\pm 4\%$ ). Position A is 30cm above the top surface of the test

chamber. Position B was 10 cm away from the center of the front glazing pane. Point C was used to measure the air speed inside the cavity at the bottom but 10cm from the opening.

Figure 1. Sketches and photos of the DSF system and the location of measuring point

### Determination of heat transfer coefficients

The energy change in the water flow from the inlet to the outlet is balanced by the heat transfers through the DSF and the envelope.

$$c_p(T_{in} - T_{out})q = u_{DSF}A_{DSF}(T_r - T_a) + u_0A_0(T_r - T_a) \quad (1)$$

where  $c_p$  is the specific heat of the water.  $T_{in}$  and  $T_{out}$  are the inlet and outlet temperatures, respectively.  $q$  is the mass flow rate.  $u_{DSF}$  is the overall heat transfer coefficient of DSF window and  $u_0$  is the heat transfer coefficient of the XPS walls and needs to be determined separately.  $A_{DSF}$  is the area of the DSF and  $A_0$  is the inner surface area of the envelope.  $T_r$  and  $T_a$  is the temperature of the chamber air and the room air, respectively.

The last term in Equation 1 is the heat loss through the XPS walls of the envelope. To determine  $u_0$ , the single glaze pane was removed and the double glazing was covered by two 50 mm thick XPS plates on both sides. With this modification, the heat input by the water is assumed to be balanced by the heat loss through the XPS walls only.  $u_0$  is determined by Eq. (1) with  $u_{DSF}$  being replaced by  $u_0$ .

## RESULTS AND DISCUSSION

### Heat transfer coefficient of the XPS walls

The heat transfer coefficient of the XPS walls ( $u_0$ ) was measured at three different temperature differences ( $T_r - T_a$ ), each repeated at least 12 times (Figure 2). The standard deviations were less than 10% of the heat transfer coefficients indicating good repeatability.  $u_0$  increased with the temperature difference. This is reasonable as larger temperature difference means stronger buoyancy force and convection on both sides of the walls. For the range of temperature considered, the heat transfer coefficient  $u_0$  could be correlated to the temperature difference using the following formula:

$$u_0 = 0.0193 \ln(T_r - T_a) + 0.3391 \quad (2)$$

Figure 2. Plot of means and standard deviations of measured heat transfer coefficient of the XPS walls( $u_0$ ) at three temperature difference.

Although  $u_0$  was determined in the heating mode, i.e., chamber air is hotter than the outside, it is assumed that it applies to the cooling mode as well, where chamber air is colder than the outside.  $u_0$  can be converted to the conventional U value of the XPS walls if the convection coefficients on both sides of the wall can be determined. However this is irrelevant to the objective of this study.

### Impact of cavity ventilation

In the non-ventilation mode, the upper and bottom openings of the outer pane were sealed using duct tape. Experiments were carried out under positive temperature difference and negative temperature difference, corresponding to the winter mode and summer mode, respectively. The range of the temperature difference covers the typical weather conditions in the hot summer and cold winter region of China. At least five repeat tests were conducted at each temperature difference and the results are shown in Figure 3. The repeat points are more clustered at higher temperature difference. In order to reach small temperature difference, the water flow rate had to be increased which resulted a small temperature drop from the inlet to the outlet. At 4 °C difference, the water temperature drop reduced to within 0.5 °C approaching to the uncertainty range of the temperature measurements, resulting greater uncertainties.

In either heating or cooling mode, the non-vented DSF had smaller  $u_{DSF}$  than the naturally ventilated DSF indicating better insulation. The measured  $u_{DSF}$  for the ventilated DSF window

ranged from 2 to 2.4 W/m<sup>2</sup>/K in summer condition and 1.5 to 2.1 W/m<sup>2</sup>/K in winter condition. When the opening was closed, the  $u_{DSF}$  value decreased by an average of 27% and 24% in summer and winter conditions, respectively.

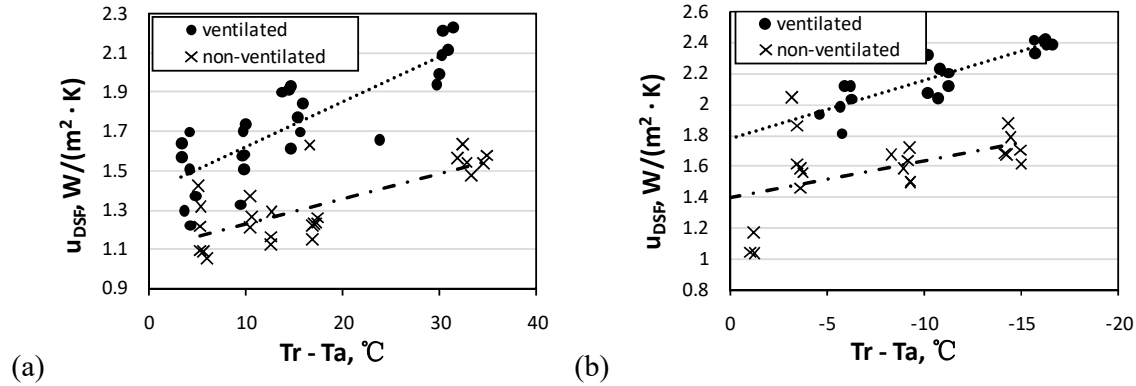

Figure 3. Heat transfer coefficient of the DSF window ( $u_{DSF}$ ) at varied temperature difference with cavity ventilated or not (cavity width = 40 cm). a) winter mode; b) summer mode

Note that the averaged  $u_{DSF}$  under positive temperature difference (winter case, Figure 3a) was 16% smaller than the averaged  $u_{DSF}$  under negative temperature difference (summer case, Figure 3b) regardless the ventilation status. Similar phenomena could also be observed in other experiments. This indicates that downward draft along the double glazing in the cavity in summer is stronger than the upward buoyancy flow along the double glazing in summer. It might be explained by the direction of airflow and gravity. The upward draft in summer was against gravity and thus could be weakened while the downward draft could be strengthened by the gravity.

### Impact of cavity width

Four cavity sizes were studied being 0cm, 10cm, 20 cm, and 40 cm with DSF operation in a ventilated mode and the  $u_{DSF}$  at cavity size of 0cm (pure double glazing) was measured as reference. Each case was repeated at least 3 times (Figure 4).

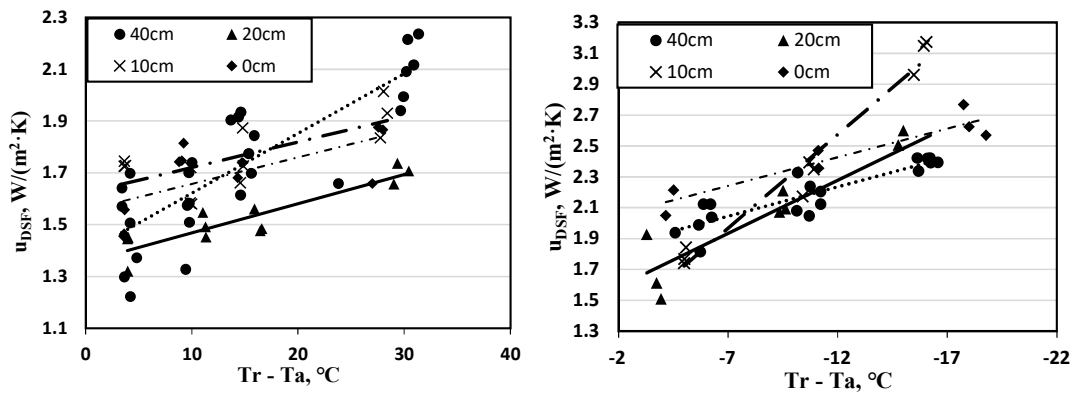

Figure 4. Heat transfer coefficient of the DSF window ( $u_{DSF}$ ) at four cavity width and varied temperature difference. (left: winter mode; right: summer mode)

In the winter mode,  $u_{DSF}$  was lowest at cavity width = 20 cm indicating the existence of an optimal cavity width between 10 cm and 40 cm for the lowest heat transfer coefficient given

the range of the temperature difference. A similar phenomenon, however, was not observed in the summer case. The DSF had better insulation when the cavity was wider at high outdoor temperature while it had better insulation when the cavity was narrower at low outdoor temperature. Although  $u_{DSF}$  decreased in general with the decrease of the temperature, the decreasing rates varied for different cavity width and different season. In the summer mode, the impact of temperature difference tended to disappear as the width decreased while in the winter mode the impact of temperature difference was stronger for the narrower cavity. The results indicate that the cavity width is an important factor to the insulation performance but its influence is dependent on the operation season and the outdoor temperature.

## CONCLUSION

The heat transfer coefficient of a DSF window was measured at different cavity width and at varied temperature in the absence of solar radiation. The results showed that DSF has better insulation than the double glazing especially with closed cavity. All the studied factors (ventilation mode, cavity width, and outdoor temperature) had influence on the heat transfer coefficient of the DSF window and such influence could be season related. Measurements confirmed the existence of optimal width in winter for the best insulation.

## ABSTRACT

The moisture performance of building envelope assemblies has always been a major concern of designers. Building envelope is constantly exposed to moisture loads such as exterior and interior humidity, rain, groundwater, snow and construction moisture. Therefore, it is critical to control the moisture migration mechanism within building envelope walls. Moisture accumulation occurs when the wetting potential of building envelope exceeds its drying potential due to applying inappropriate construction materials or configuration designs.

Moisture accumulation in mid-rise and high-rise concrete buildings has negative impacts on microbial growth, occupants' comfort, energy consumption, freeze thaw and compressive and tensile strength of concrete which lead to spent of millions of dollars on the repair in North America every year. Therefore, evaluation and prediction of moisture performance of building envelope components are important design factors that should be considered to minimize the risk of moisture accumulation in concrete buildings.

In this paper, the hygrothermal performance of a number of concrete wall systems with various configuration of concrete and insulation are studied. The performance of these systems in wet and cold climates of Vancouver and Winnipeg are evaluated using a hygrothermal model. The water content of concrete layers and moisture fluxes at the interior and exterior surface layers are analysed and the overall performance of the systems as related to moisture storage and drying behaviour are determined.

The results indicate that assemblies with thermal insulation placed on the exterior side of concrete have the highest hygrothermal performance while assemblies with concrete layer sandwiched between two wythes of thermal insulations have the poorest hygrothermal performance.

## INTRODUCTION

By rapid growth of construction trends and materials walls have started to turn into more complex assemblies. Thermal insulation from one side and vapour and air barrier materials from other side assemble together to form a whole building envelope system that could perform well in response to different interior and exterior climatic loads. However, there are still confusions and deficiencies exist regarding correct arrangements of materials and barriers in building envelope components (Hemmati et al. 2017).

Precipitation (rain and snow), groundwater, and in-borne humidity form exterior moisture sources while Interior moisture sources come from people, activities, abnormal loads and construction stage moisture. The holistic approach of any moisture management strategy

includes three main stages of deflection, drainage, storage or exclusion and drying (Tariku et al. 2015). Deflection consists of applying approaches or materials to control moisture entry or deposition into and on the wall. Drainage, storage and exclusion focus on limiting moisture accumulations inside the wall. Drying mechanism itself should consider as evaporation of water at surfaces, water vapour transport by diffusion or air movement, drainage and ventilation drying by air exchange. Failure in drying mechanism which results in excessive moisture accumulation that has undesirable influences on building envelope in variety of ways such as discoloration, mould, fungi, deterioration, corrosion and etc. (Lstiburek, 2002). Therefore, it is essential to design walls by applying appropriate materials and layers arrangement such that while limiting vapour intrusion from either interior or exterior, also letting the existing moisture within walls evacuated from timely (Kunzel, 1995).

Principle mechanisms of moisture transport through building envelope materials are vapour diffusion, capillary suction and surface diffusion. The water vapour is transported by vapour diffusion. Driving force of vapour diffusion is water vapour pressure difference. Vapour diffusion control layers (retarders or barriers) with low or none vapour permeability should be placed on the side of highest vapour pressure where this is on the interior side of the insulation in cold climates and this may be on the exterior side of the insulation in warmer climates. Capillary suction pressure acts as driving force of liquid water transport by capillary conduction. Materials with larger capillaries and pores show lower resistance behaviour to liquid water transport through which (capillary active materials). Lastly, the adsorbed water on material surfaces is conveyed by surface diffusion. The driving force of the surface diffusion is relative humidity (RH) difference.

The explanations given above indicate that material properties and their configurations within building envelope systems play significant roles on hygrothermal performance of assemblies. In designing of building envelope details not only energy efficiency of components has to come into account, but also their moisture performance should be considered. In other words, designing high thermal and moisture performance of building envelope systems has to be entirely based on building science principles to prevent improper hygrothermal performance designs that lead to damages to sensitive construction materials, increases of building thermal energy consumption and negative impacts on indoor air quality as well as occupants' comfort.

Comprehensive thermal analysis on a number of common concrete multilayer walls with similar material properties and thicknesses demonstrated that walls with two layers of insulation thermally perform more efficient compare to walls with single layer of insulation (Vaseghi, 2018). Also, it has been shown that among concrete multilayer walls with single layer of insulation, placing insulation material more toward exterior surface increases the thermal performance of wall.

In this research hygrothermal analysis has been performed on a number of common concrete multilayer walls. The goal is to compare moisture contents (MC) of concrete layers in various multilayer walls to indicate the impacts of configurations and properties of materials on moisture performance of walls.

## **SIMULATION SETUP**

In this study, hygrothermal analysis is conducted using WUFI® Pro a simulation program for evaluating moisture conditions in building envelopes in dynamic conditions. WUFI® Pro takes into account hygrothermal properties including built-in moisture, driving rain, solar radiation, long-wave radiation, capillary transport, and summer condensation. The simulations

are performed for 10 years of hourly climate data. The outputs include moisture content of concrete layers.

### Multilayer Walls Design

Seven multilayer walls are presented in this section (Figure 1). The walls are chosen in such a way to be relevant to ASHRAE standard 90.1 and local building code. The multilayer walls include:

- A. Concrete wall with interior XPS insulation wall,
- B. Concrete wall exterior XPS insulation wall,
- C. Insulated concrete form (ICF) with XPS insulation board on the interior and exterior side of the wall,
- D. Split insulation wall with XPS insulation board on the interior and mineral wool insulation on exterior face of the wall,
- E. Split insulation wall with XPS insulation board on the interior and fiberglass on exterior face of the wall,
- F. ICF with EPS insulation board on the interior and exterior of the wall,
- X. Also, a bare concrete wall is considered as a reference case as well

Figure 1. Schematics of multilayer walls, grey represents concrete and blue represents XPS

The hygrothermal properties of material are given as per WUFI material database. Some of the typical hygrothermal properties of the materials that are used in seven multilayer walls are described on Table 1. The total thickness of concrete layer is 0.20 meter while the total thickness of insulation layer for each individual multilayer wall is 0.10 meter.

Table 1. Hygrothermal properties of materials.

Material property	Concrete	XPS	EPS	Mineral wool	Fiberglass
Density ( $\text{Kg/m}^3$ )	2300	40	15	30	73
Porosity ( $\text{m}^3/\text{m}^3$ )	18	0.95	0.95	0.99	0.95
Heat capacity ( $\text{J/kg.K}$ )	850	1500	1500	840	850
Thermal conductivity ( $\text{kg/m.K}$ )	1.6	0.03	0.04	0.035	0.032
Water vapour resistance diffusion factor (WVRDF)	180	100	30	1.3	1.1
Initial MC ( $\text{kg/m}^3$ )	150	0	0	0	0

### Boundary Conditions

For the purpose of this study climate data of two locations of Vancouver and Winnipeg are considered. Vancouver represents a moderate oceanic climate (Köppen climate classification Cfb) while Winnipeg falls into the humid continental climate zone (Köppen Dfb). Simulation are done for south east elevation. For exterior vertical surface, heat transfer resistance of  $0.0588 (\text{K.m}^2/\text{W})$  and for interior wall surfaces, the value of  $0.125 (\text{K.m}^2/\text{W})$  are chosen. Short wave radiation absorptivity is equal to 0.4 while long wave radiation emissivity is 0.9.

WUFI built-in climate data contains global radiation, diffuse solar radiation, normal rain and interior and exterior temperature and RH.

## RESULTS

Results are presented in Figures 2 to 4. Figure 2 represents annual wetting and drying performance of concrete layer over a 10-year period. Figure 3 illustrates total MC comparison of concrete layer for 10 years. Finally, Figure 4 demonstrates ratio of existent MC to initial MC of concrete (after 10 years of exposure).

Figure 2. 10 years MC trends of multilayer walls (top: Vancouver, bottom: Winnipeg)

Figure 3. 10 years MC comparison of multilayer walls (top: Vancouver, bottom: Winnipeg)

Figure 4. Drying performance ratio of multilayer walls (Left: Vancouver, Right: Winnipeg)

## DISCUSSIONS

Studying the results for both climates indicates that wall “C” has the highest MC and the least drying ratio efficiency among the other walls. This is mostly due to the fact that concrete layer is sandwiched between the two low vapor permeable (high WVRDF) layers of XPS that limits the moisture flux and eventually drying potential toward exterior and interior sides of the wall. Following to wall “C”, wall “A” demonstrates fairly low drying performance too. Bare concrete layer in interior insulated wall is in direct exposure to frequent solar and rain which restricts the exterior drying potential. That likewise, explains the high fluctuation of its MC graph. Also, concrete is in direct contact with XPS on the interior side that reduces moisture flux toward inside. Walls “D” and “E” demonstrate a comparable hygrothermal behaviors.

Although both walls have a similar layers arrangement to ICF wall, however, the vapor open insulation materials on the exterior side of the walls increase the exterior moisture flux while protect the concrete layer from direct exposure to rain and wetness. Regarding total MC and drying behavior, wall “F” significantly performs better than wall “C” as EPS is more permeable compare to XPS which allows for more lateral drying potential. Wall “B” with exterior insulation has the best hygrothermal performance. Concrete layer in wall “B” is protected by XPS from rain deposition while it is exposed to interior condition that allows drying by vapor and surface diffusion. For the same reasons, drying performance ratio of wall “B” is slightly higher than reference wall. Although identical multilayer walls in both climates indicate similar wetting and drying trends, however multilayer walls located in Vancouver contain higher amount of MC. Solar heat gain of walls in much sunny weather of Winnipeg effectively increase their drying performance which result in lower existent moisture content compare to walls located in Vancouver.

## CONCLUSIONS

Hygrothermal performance of six indiviual concrete multilayer walls have been analysed. In contradiction with high thermal performance, multilayer concrete wall with two layers of XPS insulation has demonstrated the poorest moisture behaviour. This is an important factor for designers to take into consider that designing high thermal performance building envelope assemblies doesn’t necessarily lead to high efficient moisture performance or vice versa. The attention should be drawn to design building envelope details with “optimum performance” that consider all aspects of building science principles. Also, to increase the drying potential of ICF walls toward inside and outside space conditions, using material insulation with higher WVRDF are recommended. Overall, considering hygrothermal properties of building materials such as vapour permeability (WVRDF) along with their arrangement within the building envelope assemblies are key factors in a proper envelope design. Allowing for drying potential is only achievable by applying appropriate building materials and configurations.

### ABSTRACT

Two kinds of diatomite-based composite phase change materials (the phase change temperature was 35°C and 42°C, respectively) were prepared by incorporating organic alcohol phase change materials into diatomite to form shape-stabilized composite PCMs. Then, diatomite-based phase change wallboards were fabricated, and the wallboards were attached to the exterior surface of the wall from a test small room to study the thermal performance. In this study, we investigated the effects on the wallboards location, the type of materials and the phase transition temperature on the thermal performance of the wallboards. It was found that comparing with the traditional polystyrene plastic insulation wallboard, the external surface temperature of the PCMs wallboards can be obviously lower than that of the traditional insulation wallboards due to thermal storage ability. But the thermal resistance of the PCMs wallboards was too small to reduce the indoor cooling load in summer comparing with the conventional polystyrene insulation wallboard. The suitable phase transition temperature for the PCMs wallboard was dependent on the orientation of the wall. At the same time, the optimal phase transition temperature is not just dependent on the outdoor meteorological conditions, but also relevant to the applied scenarios.

### INTRODUCTION

In China, the building energy consumption has up to 40% of the annual energy production during the last several years, which more attention has been taken to use the renewable-energy resources <sup>[1]</sup>. One of the effective ways to minimizing the building consumption and keep the thermal comfort of the living room is to use the latent heat storage system such as PCMs, which has attracted more and more attention by abounding researchers. Phase change materials (PCMs) can be used storage and release large amount of energy during melting and solidification at a constant temperature.

It is well known that the thermal insulation performance of the envelope is one of the important factors that affect the energy consumption of the building <sup>[1]</sup>. Thus, applying the PCMs to building envelope is a potential way for improving the indoor thermal comfort and energy saving. At the early stage, the combination of PCMs with building envelope, includes two principal types <sup>[2]</sup>: directly incorporating PCMs with concrete or gypsum, and macro-encapsulation. However, the leakage and poor thermal conductivity of PCMs restrict their further application. Recently, there were two main technical routes developed to address above problems <sup>[3]</sup>: 1) Encapsulating PCMs into porous materials to form shape-stabilized PCMs; 2) Another potential way is the encapsulation of PCMs into polymeric or inorganic materials. Comparing the second route, encapsulating PCMs into porous materials is more efficiency and low-cost. Diatomite, also called diatomaceous earth, it was lightweight, high porosity, high absorptivity, high purity, multi-shape, rigidity, and inertness. Both the chemical composition and the physical structure of diatomite make it suitable for many scientific and industrial purposes. Besides, diatomite has excellent compatibility with concrete as the inorganic supporting materials <sup>[4]</sup>.

In this study, diatomite was used as the supporting material. Commercial organic PCMs named MG35(tetradecanol) and MG42 (hexadecanol) was utilized as the working substance to prepare diatomite-based composite PCMs by physical adsorption method. Then the composite PCMs was directly mixed with concrete to fabricate phase change wallboards for test. In the earlier study, phase change wallboards were mainly placed on the interior surface of the wall to regulate the indoor temperature. However, there was few research was reported the application of PCMs wallboards placed on the exterior surface. Comparing with placing the PCMs wallboard on the interior surface, the fluctuates of exterior surface temperature was more obviously, which was helpful for the PCMs to undergo the whole phase transition process [5]. There was a large temperature difference during day and night, which was in favor of the PCMs store and release energy. In our study, the wallboards were attached to the exterior surface of the west wall from a real size room. Polystyrene insulation board and expanded perlite board were tested as a comparison group. The performances of heat insulation and temperature change of the wallboards were investigated.

## MATERIALS & METHODS

### Materials

90% particle size of expanded perlite used in this study was between 0.28-1.25mm. Two commercial PCMs named MG35(tetradecanol) and MG42(hexadecanol) were used in our study. The nominally latent heat of MG35 and MG42 is 178 J/g according to product information. The two materials were tested by the Q100-DSC instrument from TA company. Figure.1(a) displayed the DSC curves, which indicated that the phase transition temperature range of MG35 and MG42 is 33-36°C and 42-45°C, respectively. The main physical parameters of the four functional materials were shown in Table 1.

Table 1 Properties of raw materials

Type	Density (kg/m <sup>3</sup> )	Thermal conductivity (W/m·k)	Phase change Temperature (°C)
Polystyrene	30	0.042	-
Expanded perlite	55	0.0235	-
MG35 (Tetradecanol)	835	0.147	35
MG42 (Hexadecanol)	840	0.148	42

### Preparation of diatomite-based composite PCMs

(1) A simple physical blending method was adopted to adsorb these two kinds of PCMs into diatomite to form composite PCMs, respectively. Briefly, the diatomite was dried at 95°C for 24h. Then the PCMs particles were heated and blended with the diatomite to form composite PCMs. The mass content of PCMs in composite PCMs was 50%, due to the over high content of the PCMs is prone to serious agglomeration and leakage [6].

### Preparation for wallboards

The cement and sand were mixed in a ratio of 5:3 with the addition of composite PCMs. Then, water was added (water/cement ratio is 1:2). Subsequently, wallboard samples were made by filling the mixture into homemade molds. The dimensions of boards and the percentages of composite PCMs were shown in Table 2. After 24h, the pre-prepared wallboards were cured in a standard curing room for 28 days. The prepared wallboards are shown in Figure 1 (d).

Table 2. Parameters of four types of wallboard

Type	Expanded perlite wallboard	MG35 diatomite-based wallboard	MG42 diatomite-based wallboard	Polystyrene wallboard (EPS)	
Size	300mm×300mm×30mm				
Composite PCM and mass percentage	Perlite 40%	MG35 diatomite composite 60%	MG42 diatomite composite 60%	Polystyrene	100%
Density (kg/m <sup>3</sup> )	741	1344	1257	30	
Thermal conductivity	0.26	-	-	0.042

### Test methods

The as-prepared wallboards were respectively attached to the exterior surface of the east and west wall (the wall was built by regular vitrified bricks) of two adjacent test room located at Tongji University. A big frame (1200 × 1200mm) was divided into four small frames (600×600mm), and each small frame was attached with four same wallboards. The distribution of the four small frames with different wallboards was shown in Fig. 2(a). Finally, all the wallboards were coated with a layer of 5mm thick cement mortar. Thermocouples were arranged on the interior and exterior surfaces of each wallboard, and the data was recorded by a data acquisition instrument. The test was last six days from August 30 to September 5, 2016.

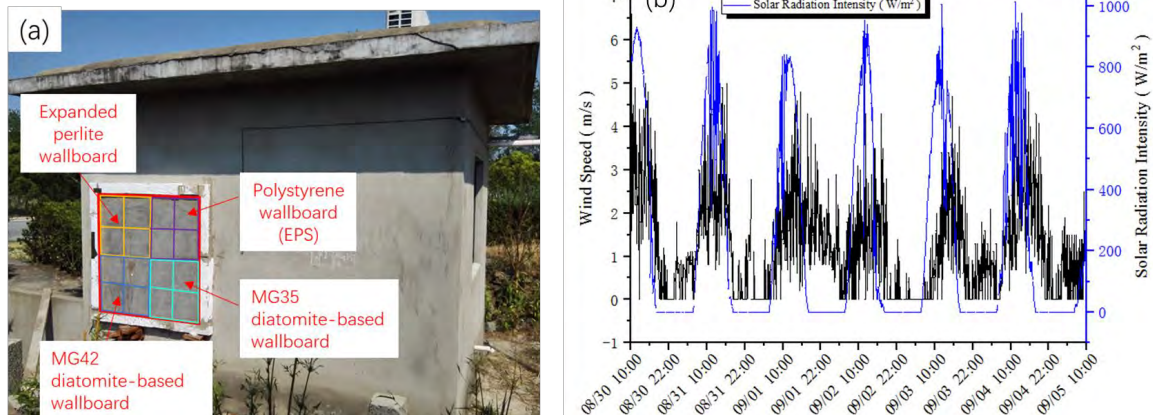

Fig.2 (a) Test room; (b) Outdoor weather data

## RESULTS & DISCUSSIONS

### Outdoor thermal environment

The as-prepared boards were all exposed to direct solar radiation at 14:30 until the sunlight was completely blocked by the tall buildings at 18:00. The outdoor weather data were plotted in Fig.2(b). As Fig.2(b) shown, all the test days were sunny and the total solar radiation intensity up to 1000W/m<sup>2</sup> at midday. The outdoor wind speed was between 1.5-2.5m/s.

### Results of the west wallboard

The temperature history curves of the exterior surface of the four different kinds of wallboards on the west wall were displayed in Fig.3(a). During the daytime, the maximum temperatures of the exterior surface of the four wallboards were in order of the insulation board > perlite board > MG35 > MG42. However, during the night, the minimum temperatures of the exterior surface of the four wallboards were in the order of MG35 > MG42 > perlite board > insulation board. The maximum and minimum temperatures of four kinds of wallboard occurred at around 4:00 pm and 5:30 am, respectively. Comparing with the common wallboard, there was no significant time delay was found from the exterior surface temperature of the PCMs wallboard.

Take the data of September 3 as an example for analysis, the results were displayed in Table 3. It is obviously found that the exterior surface temperature of the conventional polystyrene board could reach 54°C, which was nearly 16°C higher than the outdoor temperature. This phenomenon possible due to the polystyrene board has high thermal resistance and small heat

storage ability. The high temperature of exterior wall face will make people thermal discomfort when people move around the exterior wall because of the high radiation from the exterior wall. For the other three kinds of wallboards, the maximum temperatures of the exterior surface were lower 4-9°C then that of polystyrene board. The reason is that the other three kinds of wallboards have excellent thermal storage ability and high conductivity, which can store the heat from the outdoor radiation to reduce the temperature of the surface during the daytime. During the night, the exterior surface temperature of the insulation board was basically consistent with the outdoor air temperature. However, the exterior surface temperatures of other three kinds of wallboard were slightly higher than that of the polystyrene board. The reason is that the heat storage in the wallboard begins to release to the outdoor environment slowly.

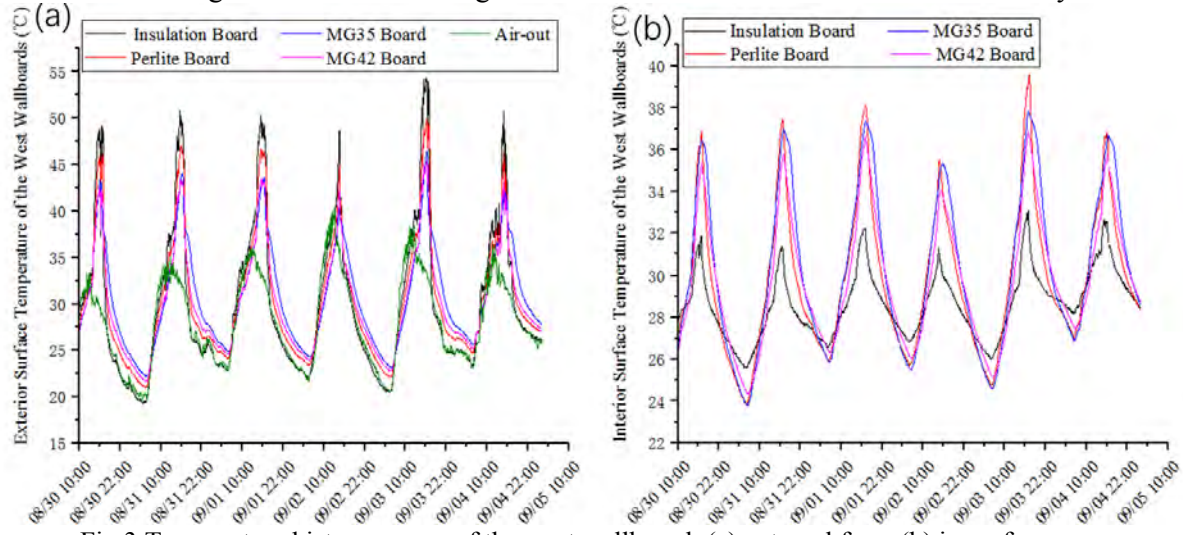

Fig.3 Temperature history curves of the west wallboard: (a) external face; (b) inner face  
Table 3. Comparison of the surface temperature of the west wallboards (°C) (Data of September 3).

Type		Polystyrene wallboard (EPS)	Expanded perlite wallboard	MG35 board	MG42 board
Exterior surface	Maximum temperature (°C)/Time	54/16:00	49.5/16:00	46.5/16:20	45/16:20
	Maximum temperature difference (°C)	0	-4.5	-7.5	-9
	Minimum temperature (°C)/Time	20.5/05:22	20.2/05:30	23.2/05:35	22.9/05:30
	Minimum temperature difference (°C)	0	-0.3	+2.7	+2.4
	Temperature fluctuation range in a day (°C)	33.5	29.3	23.3	22.1
Interior surface	Maximum temperature (°C)/Time	33/17:00	39.5/17:11	37.8/16:37	36.8/17:23
	Maximum temperature difference (°C)	0	+6.5	+4.8	+3.8
	Minimum temperature (°C)/Time	26/06:09	24.7/06:21	24.6/06:21	25/06:30
	Minimum temperature difference (°C)	0	-1.3	-1.4	-1
	Temperature fluctuation range in a day (°C)	7	14.8	13.2	11.8
Temperature difference $T_{in-ex}$ (°C)	Day (Maximum)	21	10	8.5	8.2
	Night (Minimum)	5.5	4.5	1.4	2.1

The maximum temperatures of the inner surface of the four wallboards were in order of the perlite board > MG35 > MG42 > insulation board. This order was different from that of the exterior surface temperatures, and the results were shown in Fig.3(b). The temperature fluctuation of the inner surface of the insulation board was significantly lower than that of other three kinds of wallboards, which means that the insulation board could effectively resist outside heat disturbance. During the daytime, the insulation board has the lowest inner surface

temperature among the four wallboards due to its highest thermal insulation, which was in favor of reducing the indoor cooling load in summer. Nevertheless, during the night, the interior surface temperature of the other three wallboards was about 1-2°C lower than that of the insulation board, which indicates that the other three wallboards were easy to release heat to the outdoor environment at night due to their high conductivities. This advantage also benefits for the wallboards storing part of the cold load at night.

Here, we define the temperature difference between the interior and exterior surfaces of the wallboard as  $T_{in-ex}$ . During the summer daytime, the larger  $T_{in-ex}$  is beneficial for reducing the indoor cooling load, which means the wallboard has good thermal resistance; However, during the summer night, to dissipate indoor heat and wall stored heat to outdoor is necessitous. Therefore, the smaller  $T_{in-ex}$  is favor of reducing the indoor cooling load at night. From the Table 3, it can be seen that during the day and night, the  $T_{in-ex}$  of the insulation board always bigger than that of other three wallboards. After midnight, the average temperature of both phase change wallboards was lower than the phase change temperature, which indicated that PCMs had completely solidified and the latent heat storage behavior of the material had been completed. Therefore, it can be concluded that the conventional insulation board is more helpful to reduce the indoor cooling load in the daytime, and the PCMs wallboards were more helpful to reduce the indoor cooling load at night.

### Results of the east wallboard

When the four kinds of wallboards were installed on the east wall, the temperature history curves of the exterior surface were shown in Fig.4(a). The maximum temperatures of the exterior surface of the four wallboards were in order of the insulation board > MG42 > perlite board > MG35. Comparing with the west wall, the exterior surface temperatures of the MG42 board and the insulation board on the east wall were significantly increased. However, the temperature change trend of the perlite board and the MG35 wallboard on the east wall did not change much. Due to the influence of solar radiation and outdoor air environment, the exterior surface temperatures of the east wall exceeded the phase transition temperature of MG42, so the exterior surface temperature of the MG42 board rise rapidly. Nonetheless, the exterior surface temperature of the west wall was just within the phase transition temperature range of MG42. The process of phase change slowed down the rising rate of temperature. Comparing with the west wall, the exterior surface of the east wallboard was exposed to direct sunlight in the morning, so that the temperature rose rapidly, and the interior surface temperature quickly increased accordingly. As seen in Fig.4(b), the maximum interior surface temperature appeared at about 12 am.

Fig.4. Temperature history curves of the east wallboard: (a) external face; (b) inner face

### **The influence of the phase transition temperature**

When the PCMs wallboard undergoing the phase change process, the temperature rise rate of the wallboard was lower than that of the wallboard was stated in the solid state or liquid. When the PCMs wallboards were applied on the west wall, the largest interior surface temperature of the MG42 board was lower than other wallboards. The probable reason is that the exterior surface temperature of the wallboard on the west wall exceeded the phase transition temperature of MG35 during the daytime, which results in the external part of MG35 board completed the latent heat storage process, and then the temperature rapidly rose. However, when the phase change wallboards were applied on the east wall, the largest interior surface temperature of the MG35 board was lower than other wallboards. The reason is that the interior of MG42 board didn't undergoing the phase change process due to the low internal temperature of the east wall. It can be concluded that when the PCMs wallboards were applied on different direction of the wall should choose different phase-change temperature. Low phase change temperature PCMs is suitable for east wall and high phase change temperature PCMs is suitable for west wall.

### **CONCLUSIONS**

(1) The interior surface temperature of the heat insulation board was the lowest during the daytime, which was good for heat insulation. However, the interior surface temperature of that was the highest during the night, which was unfavorable to the heat dissipation from the room. For the phase change wallboards, although the interior surface temperature of the wallboard was high than that of the heat insulation board, they could store a part of heat during the daytime and store some cold at night. In this study, the minimum interior surface temperature of the phase change wallboard was only 2°C lower than that of the insulation board, and the cold stored was not noticeable. Although, the phase change wallboards have the advantages for thermal storage performance. The thermal resistance of the phase change wallboards was too small to reduce the indoor cooling load in summer when used on the exterior surface of the wall compared with the conventional polystyrene insulation board.

(2) The suitable phase transition temperature for the wallboard on the east wall and west wall was different from each other. In this study, the exterior surface temperature of the east wall was generally higher than that of the west wall, but the interior surface temperature of the MG35 board was lower than that of the MG42 board. Therefore, the optimal phase transition temperature is not just positively correlated with the outdoor meteorological conditions, but it is also relevant to the scenarios applied.

### **ABSTRACT**

Mud wall on bamboo lath is a traditional Japanese method for constructing walls. Although the use of mud walls is environmentally friendly, it is necessary to evaluate the performances of the walls, especially their structural resistance, for broader and safe application. However, the performances of mud walls vary widely with various factors, including the locality, the natural materials used, the construction method adopted, and the quality of workmanship. In this study, the combinations of factors expected to improve the initial stiffness and toughness of mud walls were first determined based on previous studies. Subsequently, to reveal the influences of the bamboo lath configuration and properties of the wall mud on the structural resistance, structural experiments were conducted using full-section-sized specimens, the mechanical behavior observed, and characteristic values calculated. The results indicate that a mud wall of high initial stiffness can be practically achieved by avoiding gaps between the load-bearing elements and using wall mud with large elastic modulus and compressive strength. However, such walls tend to have reduced toughness because of marked delamination at the interface of the layers.

### **KEYWORDS**

Mud wall, bamboo lath, mechanical behavior

### **INTRODUCTION**

Mud wall on bamboo lathing, also referred to as “mud–bamboo wall construction,” is a traditional Japanese method of constructing walls using a timber framework, bamboo lathing, and plaster produced by mixing mud and straw. Although the use of mud wall on bamboo lathing is environmentally friendly, it is necessary to evaluate the performance of the walls, especially their structural resistance, so that they can be used widely and safely. However, the structural resistance of mud walls varies widely depending on factors such as their location, the natural materials used, the construction method adopted, and the quality of the workmanship. Furthermore, the influence of wall mud properties and plastering methods on their structural resistance mechanisms is unclear. This study investigated the fracture behavior and resistance mechanisms of mud–bamboo walls subjected to horizontal forces and clarified the factors that influence their mechanical properties.

### **METHODS**

#### **Mud wall specimen types employed**

The specimens employed had the same cross-sectional dimensions of framework members as those used in real buildings, but were proportionally smaller. The timber framework was assembled using columns, a sill, a beam, and a batten. To create the bamboo lathing, which forms the bed required for the plastering of mud, split bamboo was woven into a grid-like pattern. This bed was created using two types of bamboo. The first type, called “bamboo

furring,” was inserted into holes in the sides of neighboring framework members every 30 cm. The other type, called “flying bamboo strip,” was secured with rope ties at the points where the ties intersect the bamboo furring. The mud–bamboo wall comprised mud layers, including two base-coat and two middle-coat layers in general (Fig. 1). All layers were completely dried before the loading tests were performed.

The specimens are listed in Table 1. Based on the findings of previous studies (Midori and Naoyuki, 2013a, 2013b), the combinations of factors expected to improve the initial stiffness, Specimen No. 1, and toughness, Specimen No. 6, of the mud walls were determined. The factors are described below.

### **(1) Difference in degree of looseness around the end of bamboo furring**

Two types of specimens were prepared, as shown in Fig. 1: (i) with some looseness, Specimen Nos. 1–3; and (ii) without looseness, Specimen Nos. 4–6.

### **(2) Difference in properties of the wall mud**

Previously, we investigated the compression properties of wall mud (Midori and Naoyuki, 2013a) and found that in the case of the base coat, the elastic modulus and compressive strength decreased with increasing straw content, whereas the absorbed energy increased. For the middle coat, in which the mud possessed a higher viscosity and water retentivity, the elastic modulus and compressive strength decreased, whereas the absorbed energy increased because the wall mud required a higher straw content to avoid cracking.

Based on these results, two combinations of wall mud, sand, and straw were adopted for the base and middle coat: (i) both base and middle coat had a large amount of absorbed energy, Specimen Nos. 1-2, (ii) both possessed a large elastic modulus and high compressive strength, Specimen Nos. 3-6. The compositions are detailed below.

(a) Base coat wall mud: we used mud from Kyoto and rice straw cut to a length of approximately 6 cm. Two types of straw content were used: 2.0, labelled “Much straw,” and 1.0 %, labelled “Little straw,” in terms of mass of dry mud.

(b) Middle coat wall mud: the same mud as the base coat was used. The mud was sieved and lumps of fine mud removed, with the resulting mud coarser than the base coat. The straw used was shorter and finer. Two compositions of sand and straw were used: 2.0 % straw without sand, labelled “Much straw,” and 1.0 % straw with sand, labelled “Little straw.”

### **(3) Specimens with differing ratios of layer thickness**

Three combinations of thickness, constituting a total thickness of 70 mm, were adopted. As shown in Fig. 1, the thicknesses of the base-coat layer and both middle-coat layers were, respectively, (i) 50 mm and 10 mm for Specimen No. 1, (ii) 40 mm and 15 mm for Specimen Nos. 2–5, and (iii) 30 mm and 20 mm for Specimen No. 6.

### **(4) Difference in the plastering method “Plastering around framework”**

The plastering method called “Plastering around framework” was investigated to determine whether the wall mud filled the gap between the base coat layer and the framework after shrinkage of the base coat layer. Two types of specimens were prepared (with and without “Plastering around framework”), Specimen Nos. 1–4 and Nos. 5–6.

## **Loading methods**

Fig. 2 gives an overview of the apparatus used for the loading tests. The beam of the specimen was a joint actuator; the sill was a fixed reaction base. Axial force of 9 kN was applied to the two columns. Horizontal force was loaded to the positive and negative sides, alternating every three cycles until the deformation angle, 1/600, 1/450, 1/300, 1/200, 1/150, 1/100, 1/75, 1/50, 1/30, 1/20, 1/15 and 1/10 radian, was reached.

### Calculating the characteristic values

The characteristic values were calculated in conformity with the methods for evaluating the structural resistance required by building regulations in Japan (CBL, 2013). The skeleton curve of the load-deformation relationship replaced perfect elastic plastic straight lines, and the initial stiffness and the absorbed energy until yield point and ultimate deformation were calculated.

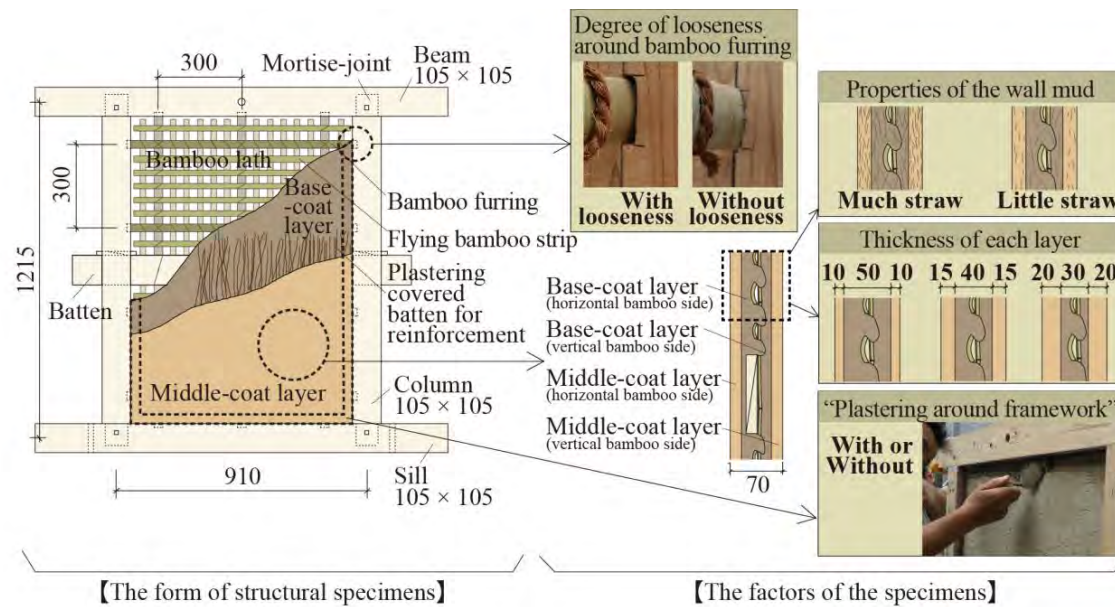

Figure 1. Mud-bamboo wall construction for a real building and for structural specimens.

Table 1. Types of specimens.

Specimen No.	Thickness of batten	Looseness around the end of bamboo furring	Properties of the wall mud		Thickness of each layer (mm)		With or without “Plastering around framework”				
			Base-coat layer	Middle-coat layer	Base-coat layer	Middle-coat layer (with both side)					
1	15	with some looseness	Much straw (2.0%)	Much straw (2.0%) without sand	50	10	without				
2					40	15					
3		without looseness	Little straw (1.0%)	Little straw (1.0%) with sand							
4											
5	10	without looseness	Little straw (1.0%)	Little straw (1.0%) with sand	30	20	with				
6											

Figure 2. Overview of the loading test apparatus.

## RESULTS

### Load-deformation curve, fracture behavior, and mechanical characteristics

Fig. 3 shows the skeleton curves of the positive side, and Fig. 4 shows the state of fracture after loading. The skeleton curves and state of fracture differed with the types of specimens. The state of fracture had two types: with and without shearing crack.

Fig. 5 shows the mechanical characteristics values. It was established that the specimen that increased the initial stiffness had a high “K value,” which is the index of initial stiffness, and that the specimen that would improve the toughness would have high absorbed energy until yield point deformation. The absorbed energies until ultimate deformation did not differ significantly among the specimens.

Figure 3. The skeleton curves.

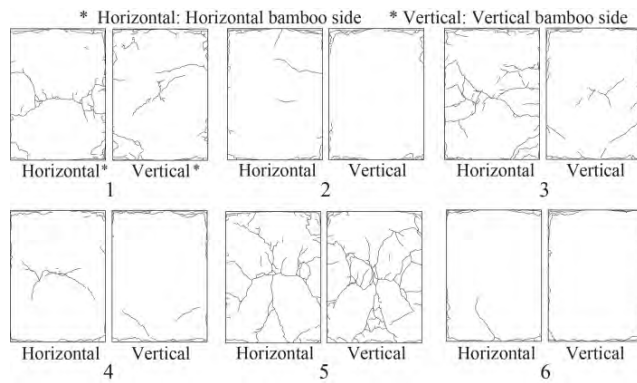

Figure 4. State of fracture after loading test.

Figure 5. Mechanical characteristics values.

### Resistance mechanisms

From the distresses observed during and after testing, we confirmed that four elements contributed to the resistance to the horizontal force observed in previous studies (Masahide et al., 2004). Fig. 6 shows the four elements. First, in the initial stage, even when the framework tilted because of the horizontal force, the plastered mud-wall layer rotated inside the framework without shear deformation. Consequently, the four corners of the mud-wall layers were found to have consolidated (I). Similarly, the mud-wall layer around the upper and lower sides of the batten was consolidated (II). After the rotation increased, the bamboo furring touched the edge of the hole made in the timber, which prevented further rotation. At that point, the bamboo furring began to separate the base-coat layer into the face and back layers (III). As the frame deformation angle increased, the flying bamboo strips began to prod against framework members, at which point the flying bamboo strips similarly caused the front and back sides of the base-coat layer to separate (IV).

A notable point is that there was a degree of looseness around the four resistance elements. For example, gaps related to load-bearing elements I and II were found because of drying shrinkage of the mud. In the case of III, looseness existed between the end of the bamboo furring and the hole. In the case of IV, clearance existed between the end of the flying bamboo strip and the framework member. Furthermore, as shown in Fig. 1, the mud wall comprised four layers. Therefore, the resistance elements that exist in each layer should differ. Table 2 shows the types of resistance elements in each layer.

Figure 6. Types of resistance elements.

Table 2. Types of resistance elements in each layer.

	Types of resistance element			
	I : Corners	II : Batten	III : Bamboo furring	IV : Flying bamboo strips
Base-coat layer (horizontal bamboo side)	○	○	○	○
Base-coat layer (vertical bamboo side)	○	-	○	○
Middle-coat layer (both side)	○	-	-	-

### DISCUSSION

The influence of the factors were considered with reference to Figs. 3, 4, and 5.

#### (1) Influence of the properties of the wall mud (Comparison between Nos. 2 and 3)

The initial stiffness (Fig. 5) of Specimen No. 3 was higher than that of No. 2 for the mud layer labelled “Little straw,” which had a large elastic modulus and compressive strength. The other side, the absorbed energy until yield point deformation (Fig. 5) of “Little straw,” significantly decreased because of the low absorbed energy of the wall mud.

#### (2) Influence of looseness of the bamboo furring (Comparison between Nos. 3 and 4)

The initial stiffness (Fig. 5) of No. 4 was higher than that of No. 3 owing to resistance at the start by bamboo furring (the load-bearing element III). Although shearing deformation of No. 4 happened earlier to resist bamboo furring (III), shearing crack did not appear after the loading test (Fig. 4). This may be because larger delamination between the face and back of the base-coat layer is created without looseness, than that with looseness.

### **(3) Influence of “Plastering around framework” (Comparison between Nos. 4 and 5)**

The initial stiffness (Fig. 5) of No. 5 was higher than that of No. 4 for initial resistance corners (the load-bearing element I) earlier with “Plastering around framework.” Shearing crack appeared with No. 5 in contrast to non-appearance with No. 4 (Fig. 4). This may be because larger delamination between the face and back of the base-coat layer of No. 4 is created by bearing bamboo furring (III) before start to bear corners (I).

### **(4) Influence of thickness of each layer (Comparison between Nos. 1 and 2, and 5 and 6)**

Mechanical characteristics (Fig. 5) showed little difference between Nos. 1 and 2, and 5 and 6. On the other hand, the state of fracture of Nos. 1 and 5 appeared with shearing crack, in contrast to 2 and 6 (Fig. 4). This may be because delamination between the layers occurred before shearing crack was created when the middle-coat layer was thicker.

In summary, a mud wall possessing a high initial stiffness can be achieved by avoiding looseness around the resistance elements and using materials with large elastic modulus and compressive strength. However, such walls tend to develop delamination between the face and back of the base-coat layer, that are difficult to repair, because the behaviors of adjacent layers differ significantly in terms of the different load-bearing elements of each layer. In contrast, the advantage of toughness of mud walls can be maximally exploited by increasing looseness around the resistance elements and using materials that absorb large amounts of energy. Such walls tend to resist serious damage, namely delamination.

## **CONCLUSIONS**

In this study, we conducted structural experiments to investigate the influence of various factors on the mechanical properties of traditional Japanese mud walls on bamboo lathing. The results obtained show that the mud walls developing initial stiffness tend to become seriously damaged because of delamination between the face and back of the base-coat layer. Originally, the Japanese mud walls can keep soundness for a long time period by repairing the slight damages such as around framework and finishing layer, which can easily repair. Accordingly, we should avoid the delamination between the face and back of the base-coat layer, for creating looseness around the bamboo lath.

### **ABSTRACT**

Much has been said about air infiltration, especially of ventilation losses and air quality. There is less information on heat losses through increased convection. This problem particularly concerns on one sided wind washing of the building envelope characterised with seeming airtightness of construction partitions. On the base of measurements undertaken in existing buildings constructed as lightweight timber structures filled with fiber materials it can be seen that air filtration also contributes to increased heat transfer through the building envelope. This paper presents the results of the research on the thermal stability of building partitions insulated with fiber materials and exposed to pulsed air filtration due to the wind load.

### **KEYWORDS**

wind washing, air tightness, frame lightweight constructions, loose thermal insulations

### **INTRODUCTION**

Fibrous thermal insulation materials, such as mineral wool, glass wool or natural materials, are characterized by high porosity. The tendency to reduce thermal conductivity of such materials causes increase of porosity and thus increased air permeability. Finally, thermal properties can be different than planned, because high air permeability increases natural convection in pores, which results in increased heat transmission through thermal insulation (Økland, 1998, Deseyve and Bednar 2006, Gullbrekken et al 2015). In addition, heat losses can also be caused by forced convection, e.g. wind washing. A qualitative and quantitative recognition of thermal losses caused by convection in fibrous insulation materials is particularly important, especially in lightweight frame constructions.

In many buildings the value of the heat transfer coefficient of the building envelope is significantly higher than the results of thermal calculations based on the thickness and thermal conductivity of embedded materials. As observed by the authors, the main reason for this phenomenon is the wind washing the porous thermal insulation. Nowadays, frame constructions are usually covered with barriers protecting against air filtration and wind washing. However, not all countries have the technical requirements for air and wind protection of the partitions. Hence many buildings are still constructed with thermal insulation layer exposed to wind washing. Although in the case of new buildings weather barrier requirements are well understood, the use of an exterior air barrier in existing buildings may not be feasible. What is important is that air sealing of the building envelope from the inside of the building partitions does not guarantee that the heat transfer coefficient of the envelope will meet the energy conservation criteria. If the inner layers (like vapour barrier) are set up continuously, the air tightness test can give a satisfactory result, despite the fact that the entire layer of thermal insulation is unprotected or only partly protected against wind washing (lack of weather barrier). Wójcik and Kosiński (2015) described this phenomena as the seeming air tightness of the building envelope, which is relevant for both existing and new buildings.

## A PROBLEM OF WIND WASHING IN EXISTING BUILDINGS

Figure 1 presents thermograms registered within the attic (4<sup>th</sup> floor) of a public building. The building was renovated few years before this research and the attic was adopted for utility purposes. The knee and interior walls, as well as ceiling were constructed in the lightweight steel skeleton technology. The sheathing was made of single layer gypsum boards, while the thermal insulation consisted of loose mineral wool 12-20 cm thick. On the internal side, between the boards and thermal insulation, a polyethylene film was installed as a vapour retarder. The knee wall construction did not include wind prevention layers while in the roof construction the wind barrier membrane was used but its junctions were not glued (Figure 1a). The air tightness of the attic was measured using the Blower Door test, corresponding to standard EN 13829. The achieved  $n_{50}$  was lower than  $3.0 \text{ h}^{-1}$  for method B, which is claimed in Polish regulations. No leakages between sheathing boards were found, which shows a continuous sheath of polyethylene film. Leakages occurred at the electrical outlets area (Figure 1f) and in few roof window frames. A Flir B335 infrared camera with 50 mK thermal sensitivity was used to assess the thermal quality of the whole attic envelope. The boundary conditions of measurements: average internal temperature  $+17^\circ\text{C}$ , external temperature  $-15.3^\circ\text{C}$  and average wind speed  $3 \text{ m/s}$ .

Figure 1b presents the junction of the interior and knee walls with roof and roof window, while Figure 1c presents the thermogram of this area. Figure 1d presents the junction of knee and interior walls with roof, while Figure 1e presents the thermogram of this area. Figure 1f presents the thermogram of the electrical socket installed in the knee wall during the air tightness measurements at 50 Pa underpressure. The hypothermia of the analyzed areas was caused by the wind washing of the mineral wool filling the frame partitions. Infrared (IR) analysis, based on surface and surrounding air temperature comparison revealed a 75% reduction of thermal resistance of the investigated partition.

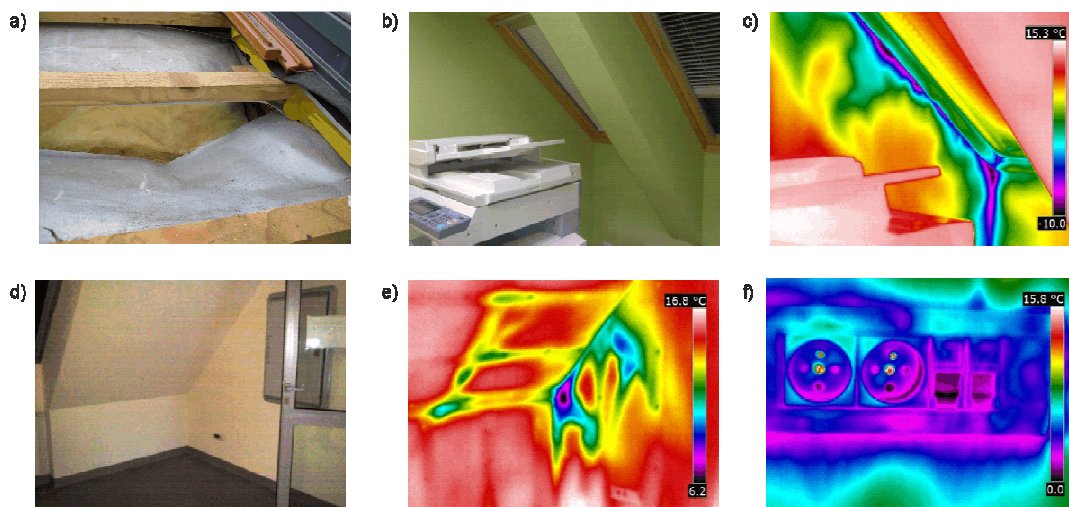

Figure 1. The described roof and attic. a) View of the roof construction, b-c) Problematic area of the walls and roof junction and its thermogram, d-e) Problematic area of the walls and roof junction and its thermogram, f) Thermogram of the electrical socket.

### LABORATORY SET UP

A laboratory investigation was based on the results of air filtration measurements in existing Polish buildings. The purpose of the study was to investigate the thermal stability of

lightweight frame partitions filled with loose mineral wool exposed to wind washing. Figure 2 presents the scheme of the laboratory investigation – the climatic chamber and models.

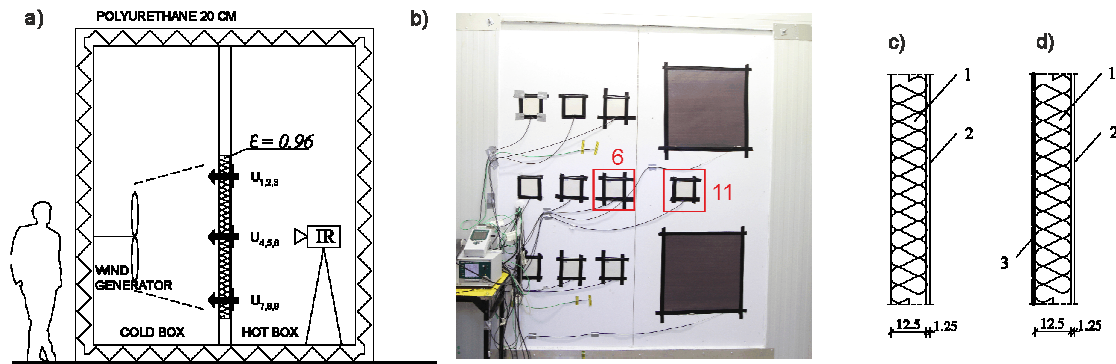

Figure 2. Schematic representation of the laboratory set-up. a) Cross section of the climatic chamber with a mounted specimen, b) View of the inner surface of the wall specimen, c, d) Cross sections of the specimen: c) 1<sup>st</sup> model, d) 2<sup>nd</sup> model, 1 – loose mineral wool, 2 – gypsum board, 3 – partial wind barrier.

For the purpose of this work, two wooden frame model partitions (Figure 2c, d) were investigated in a special non-isothermal climatic chamber at the building physics laboratory at the University of Warmia and Mazury in Olsztyn. The chamber (Figure 2a) allows the measurement of air filtration impact on heat transfer through building elements. Samples of natural dimensions are mounted in an inspection frame between hot and cold sections of the chamber. In the cold part an air supply system of adjustable power is used to generate wind. The chamber is mainly used for carried out tests with the wooden frame partitions filled with loose fiber materials.

The constructed models correspond to existing buildings, where authors found the seeming air tight partitions. The 1<sup>st</sup> model (Figure 2c) consists of frame partition, gypsum cardboards (1.25 cm) on the internal side, insulation (12.5 cm) made of loose mineral wool with a mean density of 120 kg/m<sup>3</sup>. The areas of different density were deliberately made in order to carry out a detailed analysis of the impact of fiber compaction on the thermal stability of partition (in future). The 2<sup>nd</sup> model (Figure 2d) – the same layers as the 1<sup>st</sup>, but with an additional wind retarder made of polypropylene membrane on the exterior side. The membrane junction was intentionally not connected or glued to imitate the leaks for wind washing and is placed at the level of sensors  $U_{1,2,3}$  (Fig. 2a). Heat flux sensors (Figure 2b), thermocouples and thermal anemometers were placed on the wall surfaces. The Ahlborn system was used to measure and record the thermal parameters. During the research, the heat flux density (according to ISO 9869) and the temperature changes were registered in a function of wind speed. Simultaneously, infrared radiation emitted by the test specimen was being detected by the FLIR scientific camera SC7200 with a thermal sensitivity of 17 mK.

Two considered measurements areas (250 x 250 mm) are presented on Figure 2b. Both of them are in a distance from the windproof membrane junction. The 6<sup>th</sup> area is placed almost in the middle of the specimen height, 480 mm from the left and 770 mm from the upper edge of the specimen), while the 11<sup>th</sup> is placed 900 mm from the left and 770 mm from the upper edge. Four wind speeds corresponding to average local windy conditions were generated (0.46 m/s, 1.43 m/s, 2.36 m/s, 3.24 m/s). The wind load was generated in intervals: 4.5-5.0 hours of wind, 18.5-19.5 hours calm. The intervals were determined based on previous measurements

and experience, but a manual control was the reason for the differences in intervals length. The cycle for each wind speed was repeated 4 times. Thermal changes were converted to thermal resistance changes. During the measurements, the door to the hot part of the chamber was intentionally left open to imitate the daily thermal changes in the buildings.

## RESULTS

Figures 3 and 4 present the changes of thermal resistance surface to surface for both models caused by the constant speed of wind washing the insulation. The results are presented for two analyzed areas: 6<sup>th</sup> and 11<sup>th</sup> differing with the position in examined models. The graphs present the results for 44.5 hours, what is almost two full cycles. Figures 3a and 4a present the results of the 1<sup>st</sup> model (without wind protection), while Figures 3b and 4b the results of the 2<sup>nd</sup> model (partial wind protection). The initial thermal resistance for both analyzed areas is approx. 5 m<sup>2</sup>K/W, while theoretical value around 4 m<sup>2</sup>K/W. It can be clearly seen that in the 1<sup>st</sup> model the reduction of thermal resistance starts simultaneously with the wind operating. The higher the wind speed, the faster the reduction.

Figure 3. Changes of thermal resistance at constant wind speeds registered for the 6<sup>th</sup> measurement area for both models.

Figure 4. Changes of thermal resistance at constant wind speeds registered for the 11<sup>th</sup> measurement area for both models.

For the 1<sup>st</sup> model at a wind speed of 0.54 m/s, the reduction of the thermal resistance to the minimum value takes average 3 hours 18 min, for speed 3.24 m/s it is 1 hour 50 min. In the case of the 2<sup>nd</sup> model, the at a wind speed of 0.54 m/s, the reduction of the thermal resistance to the minimum value takes average 3 hours 20 min, while for speed 3.24 m/s it takes 2 hours 28 min. A detailed summary of the time needed to achieve the maximum reduction of the thermal resistance due to the wind speed is shown in a Figure 5a.

Table 1. The maximal reduction of thermal resistance surface to surface during wind washing

Symptom or Condition	0.54 m/s	1.43 m/s	2.46 m/s	3.24 m/s
1 <sup>st</sup> model	52-64%	69-82%	70-80%	60-75%
2 <sup>nd</sup> model	35-49%	48-65%	46-60%	46-58%

The reduction of thermal resistance surface to surface is presented in the Table 1. The time required for the partition to return to the thermal equilibrium after wind washing depends rather on the protection against wind than on the wind speed. For the 1<sup>st</sup> model the needed return time varies in the range 4 hours 50 min - 6 hours 04 min, while for the 2<sup>nd</sup> model varies in the range 2 hours 46 min - 4 hours 11 min. Detailed data are presented in the Figure 5b.

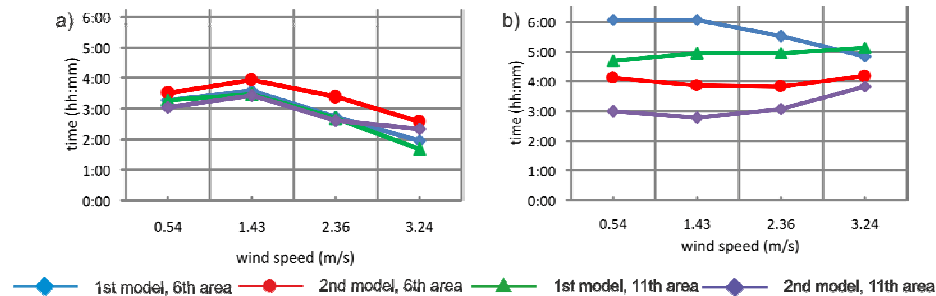

Figure 5. Time needed to achieve: a) Maximal thermal resistance reduction, b) Thermal equilibrium after wind washing.

## DISCUSSIONS

The results of the study are similar to those presented in the work of Wójcik and Kosiński (2015). Slightly lower reduction of thermal resistance in this work results from higher density of loose mineral wool and thus its lower air permeability. The averaging during the data recording was used to eliminate accidental peaks resulting from the use of the building. However, even this procedure did not protect against irregular and various course of the thermal resistance changes curves. This is possible due to both the interaction of the environment as well as the natural convection which occurs in the fibrous thermal insulation even under windless conditions. The character of changes of the thermal resistance allows analysis of changes of its value due to the wind speed. In both models the maximum reduction of the thermal resistance was obtained for the average wind speed of 1.43 m/s, not for 3.24 m/s. This may be due to the loose fibers's susceptibility to deformation under the influence of wind pressure. In the case of the fastest wind the material was compressed and thus it obtains lower air permeability in this area.

The temperature of the cold side of chamber was maintained at the level of 0.5-1.3°C, while of the hot side, depending on the building heating, temperature range was 14.2-18.7°C. Exceptionally, during the test with a wind speed 3.24 m/s on the 1<sup>st</sup> model, the temperature range of the cold side was 3.9-7.9°C, which could have been caused by a cooling system failure. Fortunately, even in this case, the temperature range of the hot side was 17.4-18.7°C

and the temperature difference between hot and cold sides during the windless intervals did not drop below 13.0°C.

The time that models need to return to equilibrium does not depend on the wind speed, but on the reduction of thermal reduction caused by forced convection. The higher the changes the longer the return time. The time required to stabilize the partition is longer than the period of maximal reducing of the thermal resistance. It is also important to analyze the values registered for the maximum wind speed (3.24 m/s). As it is visible in the Figures 3a and 4a, the initial thermal resistance of both analyzed areas for this wind speed was smaller than in the other cases. Just after the second cycle, the resistance value was similar to the other cases. This may have resulted from measurement error or problems with the cooler, or the lack of full thermodynamic stabilization of the model. It should be also noticed that the measurements were conducted on the loose fiber thermal insulation which may deform under the wind load. This can be a source of potential differences between measurement cases.

## CONCLUSIONS

Based on the research it can be stated that the thermal losses induced by wind washing in frame lightweight partitions filled with loose fiber insulation depend on many factors, including wind speed and construction of the partition. The greater the air permeability of the insulation, the more rapid thermal changes due to wind washing. The partial wind barrier causes a minimal reduction of heat losses due to air filtration in the partition, though only fully sheltered areas of partition are characterized by lower heat losses. Several hours of wind washing results in a longer period of transition of the partition into a state of thermal equilibrium, even 3 times longer than time needed to achieve a maximum reduction.

Current research is directed towards determining moisture distribution in the models. This may give an answer on the depth of the wind penetration in the frame lightweight partitions.

### **ABSTRACT**

Title: Lead dust fall deposition rates during deconstruction of wood frame buildings in an urban region in the Northeastern United States.

Objectives: Determine the lead dust fall deposition rate due to hybrid deconstruction (separation and removal of building components) of wood-frame structures, and compare that to the lead dust fall deposition rate from demolition (compression and collapse of building components).

Scope: A city block with a total of 11 wood-frame structures was selected as the location for the deconstruction leadfall testing. Testing was done during the deconstruction of 7 of the 11 pre-1950 homes (mean construction year 1928, mean floor area 283 square meter).

Method: During deconstruction, the lead deposition rate was measured by using the modified APHA 502 method (Mucha et al. 2009).

Findings: The geometric mean deposition rate for the lead dust fall at the property perimeter from the houses using deconstruction was 61.3 ug/sg m/hr. Published values for deposition rates from demolition in Chicago (Jacobs, et al. 2013) are 59.0 and 152 ug/sq m/hr for homes with and without the use of dust suppression. The deposition rate during hybrid deconstruction is similar to the deposition rate during demolition when dust suppression is employed.

Implications: Many older urban areas have abandoned buildings containing lead-based paint. Governments in these regions invest in removing these buildings, using a variety of methods. To avoid further lead contamination in the soil surrounding these buildings, methods which minimize the total lead dust fall must be employed. The proper quantification and evaluation of these methods will help policy makers with their decisions.

### **KEYWORDS**

Environmental lead, soil contamination, lead deposition rate, deconstruction, demolition

### **INTRODUCTION**

During the late 20<sup>th</sup> century major urban areas in US manufacturing regions experienced population loss, and an increase in abandoned homes. For cities in the Northeast and Midwest of the United States, this has become an acute problem. These homes create problems on many fronts, including the impact on investment in the community, use for illicit activities, danger due to arson, and loss of tax base. In many of these urban areas, these abandoned

buildings were built before the 1978 ban on lead paint, and as a result lead can be found on both exterior and interior surfaces.

The removal by demolition and landfilling of these homes can also create significant problems. First, the volume of landfill waste created is significant. Based on a 2014 EPA study, the waste from construction and demolition activities constitutes more than two-thirds of all landfill waste (by weight). Of this construction and demolition waste, more than 90% is from demolition (EPA, 2014). Another problem is that during the demolition of these homes the possibility exists for significant soil lead contamination from lead dust dispersion (Farfel, 2003).

However, many communities are looking for alternatives that will decrease the amount of material going to a landfill, return salvageable materials for new construction, help to provide employment for community members, and reduce the transportation impacts and greenhouse gas releases from materials transported and then left to decay in landfills. One way to do this is through deconstruction instead of demolition (Bell, 2012).

The disassembly and separation of building elements with the intent for reuse or recycling is known as “Deconstruction”. Traditional deconstruction involves an increased amount of labor and expense compared to demolition. However, depending on the costs of disposal, the value of the reclaimed materials, and the relative amount of labor in the process, under certain conditions deconstruction can be a lower cost solution (Pun, 2006). In an attempt to optimize these conditions, an adaptation of deconstruction known as “hybrid” deconstruction has been developed. In this process, the building’s planar surfaces are mechanically separated and then lowered to the ground where workers harvest the most easily separated materials, and avoid expending additional time for small amounts of reclaimed material. The goal of this method is to maximize the amount of materials salvaged per unit of labor invested.

Regardless of the method chosen, the presence of hazardous materials in the structure to be removed must be managed. During traditional demolition, the impact and crushing of the building materials creates a plume of dust that settles around the site. Some demolition contractors use a water stream sprayed at the materials to try to reduce this plume. Nevertheless, researchers have found that lead dust deposition measured around demolition sites represent a significant source of soil contamination. (Farfel, 2003)

The deleterious effects of exposure to environmental lead during childhood are well documented. In their 2015 report on Educational Interventions for Children Affected by Lead, the expert panel compiling the report cites 83 separate studies on the negative neurodevelopmental consequences of lead exposure (Educational Services for Children Affected by Lead Expert Panel, 2015). Results of such elevated childhood lead blood levels can range from anti-social and behavioural problems (Dietrich, 2001) to violent crime (Reyes, 2007). While guidelines from 1960 set safe lead blood levels at 60 µg/dL, recent studies show levels as low as 5 µg/dL, can have impacts on brain development in children (CDC, 2012).

Since the phase out of lead from gasoline beginning in the 1970s, to the elimination of lead from gasoline in 1996, lead blood levels in children have been shown to be correlated to soil lead levels (Johnson and Bretsch, 2002)(Mielke et al, 1997). The deposition of lead on soils from demolition activities has been identified as an important soil contamination pathway. Farfel (2003) found that lead dust fall rates during demolition increased by more than 40 fold from the background levels. In a study from St. Louis, MO., Rabito et al found a significant

correlation between multiple demolitions in a census block, and elevated blood lead levels in children (2007). Gulson and Taylor (2017) found that children's blood lead levels were found to be correlated both to leadfall on interior surfaces (100  $\mu\text{g}/\text{m}^2/30\text{d}$  rate corresponds to an increased in children's blood lead levels of about 1.5  $\mu\text{g}/\text{dL}$ ) and soil increases (0 to 1000 mg Pb/kg soil increase results in an increase of 1.7  $\mu\text{g}/\text{dL}$  of blood lead levels). Results from this study were suggested to be used for "action levels" to monitor activities such as housing demolition.

A study by Ayodle (2014) tracked aerosol lead concentrations and soil deposited lead from five homes in Detroit: One home was demolished, one home was fully deconstructed (ten days), and the remaining three homes were partially deconstructed (over one to five days), and then demolished. This study analysed the dust that was collected using a high volume air sampler. These particles were then analyzed using elemental ratios, and classified. Ayodle found that airborne dust concentration during demolition frequently exceeded National Ambient Air Quality Standards, and recommended dust suppression. The study recommended that the impacts of Deconstruction be measured by measuring lead depositional flux (dustfall rates) using buckets with liquid, rather than by determining the lead dustfall concentration in the soil. Due to the method of the study, the authors were unable to say if the total lead dustfall due to deconstruction was more or less than that during demolition.

Work to reduce pathways for blood lead contamination have shown that significant societal and economic benefits can be accrued from the investment to reduce lead hazards from indoor and outdoor paint using partial to full abatement. Protecting children from lead in buildings by remediating the building has shown to have significant economic benefits, with each dollar invested in lead paint hazard control resulting in a return of \$17–\$221 (Gould, 2009).

The present study proposed to measure the lead dustfall rate during the hybrid deconstruction of seven multi-family homes in an urban area in the Northeastern United States, and compare this to other methods of removal.

## METHODS

A city block (85 m x 85 m) in the city of Syracuse, NY was chosen for the study. Eleven multi-family houses were located on this block and sequentially removed using hybrid deconstruction. During this process, lead dustfall rates were recorded for seven of the homes. The average size of the sampled homes was 283 sq. m., the average year of construction of the homes was 1928, and each of the homes had an interior lead survey performed before the deconstruction was done. The lead survey was performed on interior surfaces using an X-ray fluorescence (XRF) analyser by an accredited testing agency. HUD guidelines (1.0 milligram per square centimeter or greater) were used for the definition of lead paint, and all but one of the homes was found to contain interior lead paint. No testing was done for the presence of lead paint on the exterior. Detailed house information is shown in Table 1

Table 1. Housing characteristics for sampled multi-family homes

Home location	Year Built	Living Area (sq. m.)	Presence of interior lead paint
700 Raynor St.	1950	396	Yes
704 Raynor St.	1920	272	Yes
708 Raynor St.	1924	284	Yes
117 Standart St.	1940	164	No
119-21 Standart St	1922	283	Yes

125 Standart St.	1920	385	Yes
131-33 Standart St.	1922	<b>283</b>	Yes
<b>Average</b>	<b>1928</b>		

The houses were deconstructed over the course of two months, November and December of 2012. The approach selected for this work was a hybrid of demolition and deconstruction. Hybrid deconstruction entailed the planar building surfaces being separated into 2.5 m by 5m panel sections, and these sections being lowered to the ground for disassembly by hand or disposal. In this case, the larger wood members from the floor and roof assemblies were salvaged, while the smaller wood members (studs, plates, lath) located in the wall assemblies were not separated. The result of this approach was that the building could be broken down into these assemblies in one-two days, as opposed to the two-three weeks required for traditional on-site deconstruction.

The study data collection began by sampling the lead deposition rate during the deconstruction process. Previous studies (Mucha, 2009) placed their containers at an average distance of 5 m from the deconstruction activity. Containers for this study were placed just inside the perimeter at distances of 2-5 m from the deconstruction activity. Sampling was done just inside the property perimeter using the method described by Mucha et al. (2009) based on APHA 502. Four polyethylene sampling containers of 0.073 square meters surface area with 1 liter of water were located on portable stands that positioned them at approximately 2 m elevation above grade at the corners of the property. In some cases one or more of the corners of the site was inaccessible, or obstructed by machinery moving on the site. The containers were left open for dust fall for a period of 8 hours each day. At the end of the sampling period, the liquid in each container was transferred to a sterile bottle and transported to the laboratory. In the laboratory the liquid was filtered, and then the filter was dried and digested following EPA SW3050B. The remaining material was analyzed using inductively coupled mass spectrometry following EPA method SW6020. 30 total samples were taken from 7 different properties. Testing of samples included one control and processing included duplicate processing. The IC mass spectrometry measured weight of the lead was divided by the water surface area, and the hours left exposed, and the resulting value is reported as the deposition rate in ug/sq m/hr.

## RESULTS

The geometric mean deposition rates were compared to two other studies, both from Chicago (Mucha, 2009)(Jacobs, 2013). One of these studies sampled lead dust fall at the perimeter of the work site, and the other study sampled the dustfall at an average distance of 5 m from the perimeter.

Table 2. Comparison of results from studies of lead deposition rate during demolition and deconstruction

Location	Condition	Dust suppression	N <sub>samples</sub>	N <sub>address</sub>	Geometric mean ( $\mu\text{g Pb/m}^2/\text{h}$ )	Sampler location	Year
Chicago	Background		18	6	12.9		2009
Chicago	Demolition	Hose	25	5	48	5 m outside perimeter	2009
Chicago	Demolition	None	22	6	74.6	5 m outside perimeter	2009
<b>Syracuse</b>	<b>Deconstruction</b>	<b>None</b>	<b>29</b>	<b>7</b>	<b>61.3</b>	<b>Perimeter</b>	<b>2012</b>

Chicago	Demolition	Hose	84	NR	59	Perimeter	2013
Chicago	Demolition	None	13	NR	152.6	Perimeter	2013

NR = Not Reported

Based on an assumed demolition (without dust suppression) time of 8 hours for a single structure, and an assumed hybrid deconstruction time for primary separation and lowering of materials of 8 hours, the cumulative geometric mean leadfall deposition at the site perimeter would be 1220  $\mu\text{g Pb/m}^2$  for demolition and 490  $\mu\text{g Pb/m}^2$  for deconstruction. Based on the work of Gilson (2017), if these lead levels were left exposed on a surface (e.g. inside an adjacent home) for 30 days, this difference in lead levels would correspond to an additional increase in blood lead level of 10.95  $\mu\text{g/dL}$  for the occupants next to the demolition site. The value of 10.95  $\mu\text{g/dL}$  is well above the 5  $\mu\text{g/dL}$  level of action recommended by the CDC (2012). The corresponding lead deposition due to deconstruction under a similar scenario, would cause a 4.40  $\mu\text{g/dL}$  increase, below the 5  $\mu\text{g/dL}$  level of action recommended by the CDC.

## DISCUSSIONS

The lead deposition rate found in this study falls between the results for demolition with and without dust suppression found by Mucha (2009). The lead deposition rate found in this study is within 4% of the demolition with dust suppression found by Jacobs (2013).

Based on the comparison to both of the previous studies, the use of hybrid deconstruction reduces the lead fall deposition rate compared to demolition without dust suppression. Even in the case of demolition with dust suppression, deconstruction eliminates the water contamination and runoff resulting from dust suppression with a hose.

One difficulty with this study was that it was performed on buildings that were all deconstructed by the same firm. Measurements from hybrid deconstruction done by a variety of companies would provide a more representative sample.

A further difficulty is that location of the collection containers at the site perimeter does not accurately predict the impact on structures at a greater distance from the site.

## CONCLUSIONS

While the result of the work clearly showed a reduction in leadfall deposition during the hybrid deconstruction process, there a number of considerations to note.

First, the deposition rate measured occurred over the eight-hour period of large panel separation and lowering to the ground. However, once on the ground, hand disassembly occurred over a number of days, and the possibility of continued elevated lead deposition exists. Ayodle (2014) found that during the full deconstruction process, aerosol lead increased during the third day when wall plaster and window frames were removed during the separation of wall elements, and the other days of deconstruction showed markedly less airborne dust. Comparison of total lead dustfall during the duration of the work could improve the direct comparison to demolition.

Second, the work that was done in this study set the measurement containers within the project perimeter. Because of this the comparison to other studies where the containers were located outside the worksite fencing is confounded. Jacobs (2013) study included sampling at distances up to 400 ft from the perimeter, and they found elevated levels at that distance.

### **ABSTRACT**

Building envelopes that are hygroscopic and permeable to water vapour can contribute to improve the Indoor Environmental Quality (IEQ) in buildings by reducing indoor humidity fluctuations and the concentration of some contaminants like CO<sub>2</sub>. However, risks of interstitial condensation and mold growth need to be assessed to ensure the durability of such building envelopes. The objective of this paper is to perform hygrothermal simulations of a case study house designed with a Hygroscopic and Permeable Building Envelope (HPBE) and to assess the impact of having a vented cavity compared to a face-sealed wall.

This contribution presents hygrothermal simulations of a wall assembly performed with WUFI Plus and WUFI Pro. The mold index is calculated from the simulation results and the hygrothermal performance of the vented and unvented wall is compared. The resilience of the construction is assessed by introducing leaks within the envelope. Simulation results indicate a satisfactory performance of this wall assembly regardless of the presence of a vented wall cavity. The wall design with a vented cavity seems more resilient when subjected to large leakages, although the wood fibreboard surface seems more vulnerable to mold growth when unprotected by a plaster. Additional simulations and field data are needed for assessing the benefits of having a vented cavity for HPBE.

### **KEYWORDS**

Moisture management, hygrothermal performance, durability, permeable building envelopes

### **INTRODUCTION**

#### **Scientific background**

Sustainable building design goes beyond the achievement of a low energy consumption but also encompasses the creation of a healthy indoor environment while reducing the overall environmental impacts over the entire building life cycle. With around 75% of building failures that are caused by water (May 2005), establishing good water management practices is a key element for ensuring the durability of a building.

Overhangs and gutters, perimeter drains and a vapour retarder on the warm side of an assembly are common recommendations in many jurisdictions for controlling water and water vapour. Vapour retarders slow down the diffusion of water vapour, which mostly occurs from inside to outside in cold weather, hereby reducing risks of condensation on the cold side of an assembly. However, they also hinder their drying potential, which may cause significant moisture damage during accidental leakages (Kunzel 2005). As such, two-way drying is now recommended as a necessary climate change adaption measure, where it is now suggested to avoid interior vapour barriers in all but the most extreme climatic zones (Kesik 2017).

Hygroscopic and Permeable Building Envelopes (HPBE) can contribute to improve the IEQ in buildings by reducing indoor humidity fluctuations (Yang et al. 2014). Besides, the vapour permeability of building materials was found to correlate closely to their carbon dioxide permeability and simulations showed that bedrooms made of building materials with higher water vapour permeabilities experience reduced concentrations of CO<sub>2</sub> (Niemelä et al. 2017).

Surface condensation, visible mould and perceived mould odour are indicators of dampness and microbial growth. Since the relationship between microbial exposure and health effects cannot be quantified precisely, there are no recommended quantitative threshold; only preventing dampness and mould-related problems is recommended (WHO 2009). Recent evidence is showing that visible mould and mould odour are associated with new-onset wheezing in children in a dose-dependent manner, although the underlying mechanisms remain unidentified (Shorter et al. 2018).

A study of 1140 samples of visibly damaged building materials revealed highest median concentrations of fungi in wood and paper materials and lowest in mineral insulation, ceramic products, paints and glues. The percentage of building materials in which no growth was detected ranged from 9-14% for wood to 12-17% for mineral insulation materials. Microbial damage occurred in all material categories included in this study, confirming that microbial growth can occur in a wide variety of building products (Hyvärinen et al. 2002).

### **Vented and ventilated wall assemblies**

Many studies have investigated the impact of ventilated or vented wall cavities on the moisture content and drying rates of building materials. A review about this topic is presented by Straube (2009), from which the main conclusions are presented below.

A vented wall assembly has an air cavity behind the exterior cladding with openings only at the bottom, usually provided for drainage, which also allow for some ventilation to take place. A ventilated wall has openings at both the top and bottom of an air cavity, which promotes higher ventilation airflow rates and drying.

Besides numerical airflow rate calculations, the three main modelling techniques used by researchers to approximate vented/ventilated wall assemblies using hygrothermal models are

1. Ignoring ventilation effects (insertion of a still air cavity)
2. Effective cladding permeance (user selects an increased exterior cladding permeance)
3. Removal of cladding (user removes external cladding, rain and solar radiation loads)

Experimental measurements from Straube showed that techniques # 2 and #3 are in relatively good agreement with experimental results, although the choice of the effective cladding permeance has a significant impact on the results. Thus, the modelling technique #3 was chosen to model the vented wall assembly in this contribution.

While some research reported conflicting results about the benefits of ventilation cladding, this review paper concluded that there was a general consensus in the last years that ventilation cladding can increase the drying potential of a wall, reduce wetting from absorptive cladding and sun-driven moisture.

Most of these studies have been carried with building constructions that included a low permeance layer on the interior. There are insufficient studies to confirm whether having a

ventilated wall cavity can significantly improve the hygrothermal performance of wall assemblies that are made of hygroscopic and permeable materials.

This paper aims to investigate the effect of cladding ventilation for a HPBE in a cold a wet climate such as northern Europe. As a first step, hygrothermal simulations of a house are carried out with WUFI Plus, a validated whole building simulation software (Künzel 1995). The mold index (ASHRAE 2016) is calculated over 2 and 5 years for different wall orientations for a vented and unvented wall assembly. Secondly, the resilience of a vented and unvented wall assembly is investigated by simulating water leakages with WUFI Pro.

## METHODS

A model of a house was created in WUFI Plus V3.0.3.0 in order to investigate the effect of ventilation cladding in a HPBE. This house is located in Holbæk, Denmark, from which field data is currently being monitored. The weather file selected in WUFI is Lund, which is situated 120 km east of Holbæk at the same latitude.

The envelope of the house is made of a wood structure filled with blown-in woodfiber insulation, interior and exterior wood fibreboards, interior clay plaster and exterior mineral plaster. The house has a ventilated roof and crawl space. A floor plan and a south view of the house are presented in Figure 1. The walls do not have a vented cavity except for the south-east living room wall.

The characteristics of the wall assembly are presented in Figure 2. It can be seen that the mineral plaster is the material with the highest water vapour resistance factor with a  $\mu$  of 21. In this given configuration, all layers are considered permeable with a  $s_d$  value smaller than 2 m where the woodfiber insulation provides the greatest water vapour resistance with  $s_d = 0,68$  m.

The building model is divided in 6 zones: the living room (named *stue* on the floor plan) and the rest of the house are modelled as two conditioned zones, accompanied by their respective attic and crawl space, which are simulated as unconditioned zones each with continuous ventilation at 3 ACH. The carport and skylights are excluded from the simulation model.

The wind-driven rain coefficient is set to 0.07 for the walls. This value has been obtained by carrying a linear regression analysis of experimental driving rain data obtained for a 4 m high test wall at the center of the façade (Künzel 1995), which is deemed representative of the current situation. The wall with a vented cavity was modeled by removing the exterior cladding (mineral plaster) and rain and solar radiation loads.

The windows have a glass g-value of 0.55 and an overall U-value of 0.77 W/(m<sup>2</sup>K). There is mechanical ventilation at 0.5 ACH with 60% heat recovery and an infiltration rate of 0.1 ACH. Natural ventilation at 0.5 ACH takes place from May 15<sup>th</sup> until September 15<sup>th</sup> and a fictitious cooling set point of 28°C act as additional natural ventilation to control overheating. The building is occupied by a family of four following a typical occupancy schedule. In the main zone, the moisture generation is equal to 4610 g/day during the week and 8384 g/day during the weekend. In the living room, the moisture load is set at 432 g/ day.

The ASHRAE standard 160 (2016) provides a complete description on how to calculate the mold index at a location of interest in a building assembly. The value of the mold index was computed after two and five years of simulation. The exterior mineral plaster was treated as a medium sensitivity class and the wood fiberboard as a sensitive class.

Figure 1. Floor plan and south view of the building model

Material/Layer (from outside to inside)	$\rho$ [kg/m <sup>3</sup> ]	$c$ [J/kgK]	$\lambda$ [W/mK]	Thick. [m]	$\mu$ [-]	$S_d$ [m]
Mineral cement Plaster	1434	850	0,9	0,006	21	0,126
Ext wood fibreboard	140	2100	0,04	0,06	3	0,18
Wood fiber insulation	50	2100	0,037	0,34	2,5	0,68
Clay board	615	2000	0,128	0,016	7,4	0,12
Basecoat clay plaster	1844	850	0,1	0,003	14,7	0,04
Topcoat clay plaster	1844	850	0,1	0,002	14,7	0,03

Figure 2. Wall assembly materials characteristics for the unvented wall. The mineral cement plaster is omitted in the vented wall section.

The hygrothermal performance of the vented and unvented wall assemblies subjected to internal moisture sources was also investigated. The assemblies were modeled in WUFI Pro, which can allow the introduction of heat, moisture and air change sources within the wall assembly. The vented and unvented wall assemblies were modeled, subjected to the climate of Lund on the exterior side and to EN 15026 conditions on the interior side with medium moisture loads. For modeling the vented wall, the mineral plaster and rain loads were removed, but the solar load remained, since it cannot be switched off in WUFI Pro. In these conditions, the moisture content is likely to be underestimated but the comparison of a vented and unvented wall can still reveal valuable information on the behavior of these assemblies.

Two different kinds of moisture intrusion were investigated: one based on a fraction of driving rain and one based on the IBP air infiltration model (WUFI 2017). The introduction of 0.01% and 1% of driving rain at the inner face of the wood fiberboard was simulated, as well as Class A and Class C air infiltrations (corresponding to  $q_{@50 \text{ Pa}}$  of 1 and 5 m<sup>3</sup>/m<sup>2</sup>h for the whole building and  $q$  of 0.07 and 0.33 m<sup>3</sup>/m<sup>2</sup>h through the component, respectively).

## RESULTS AND DISCUSSION

### Whole building simulations with WUFI Plus

Table 1 presents the maximum mold index (ASHRAE 2016) computed after two and five simulation years of the SE and SW walls of the building model, which have the highest

moisture content. M was calculated at the outer surface, 0.15 cm behind the exterior wood fibreboard and from the average temperature and relative humidity of the fibreboard.

Results show that the unvented wall exhibits a satisfactory hygrothermal performance, with a maximum mold index of 0.01 and 0.02 at the exterior plaster layer for a SE and SW wall respectively. The maximum mold index at 0.15 cm behind the external face of the wood fibreboard is 0.12 or less, well below the critical value of 3.

The unvented wall cavity has a mineral plaster as external rendering, which has a medium sensitivity class, while the external surface of the vented wall has a wood fibreboard as outermost layer, which is classified as a sensitive material. As such, the maximal mold index at the external surface of the vented assembly is higher, and reaches a maximum value of 1.37 over a two year period and of 2.13 over a five year period. A mold index of 3 is likely to be reached by performing simulations over a longer period of time. Therefore, the unvented wall assembly seems less likely to develop mold growth at the external surface. However, the maximum mean mold index is lower for a vented cavity for both wall orientations. Ongoing research will take place to evaluate long-term field performance.

Table 1. Maximum mold index for unvented and vented wall after 2 year (5 years)

Assembly type	Orientation	M, surface	M, 0.15 cm wood f.	M, mean
Vented	SE VSO2 (135°)	1.37 (2.13)	-	0.02 (0.02)
Unvented	SE VSO2 (135°)	0.01 (0.01)	0.09 (0.09)	0.05 (0.05)
Vented	SW VSO3 (225°)	1.37 (2.13)	-	0.02 (0.02)
Unvented	SW VSO3 (225°)	0.02 (0.02)	0.12 (0.12)	0.08 (0.08)

### Hygrothermal simulation under water leakages with WUFI Pro

Performing hygrothermal simulations while introducing internal moisture sources within a wall assembly is a method that allows evaluating its resilience and drying potential under challenging situations. Simulations were performed with the presence of a fraction of driving rain or an air infiltration moisture source. The moisture source was introduced in the last element of the wood fibreboard, on the internal face. The maximum mold index for a SW vented and unvented walls under different moisture sources is presented in the Table 2 below.

Table 2. Mold index for unvented/vented walls after two years with various moisture sources

Assembly type	Moisture source	M, surface	M, 0.15 cm wood f.
Vented	None	1.24	0.89
Vented	0.01% driving rain	1.24	0.89
Vented	1% driving rain	1.24	0.89
Vented	IBP Air inf. Class A	1.24	0.89
Vented	IBP Air inf. Class C	1.24	0.89
Unvented	None	0.02	0.40
Unvented	0.01% driving rain	0.02	0.40
Unvented	1% driving rain	0.03	1.10
Unvented	IBP Air inf. Class A	0.02	0.40
Unvented	IBP Air inf. Class C	0.02	0.41

It can be seen that the maximum mold index at the external surface is not significantly affected by the introduction of the tested moisture sources. Observation of water content profiles and moisture fluxes reveal no significant difference (results not shown). The only significant change of the mold index at 0.15 cm behind the fibreboard is under the introduction of 1% of driving rain, when the index is increased from 0.40 to 1.10 for an

unvented wall. In light of these results, having a vented cavity for this type of assembly seems to increase its resiliency when subjected to significant, recurrent moisture sources.

In reality, leaks are usually localised and not uniformly distributed as assumed in these simulations. The location of the leak is also important in determining how it will be absorbed and redistributed within the building envelope; leaks at only one location have been investigated here. These simulations may be representative of well distributed leaks, but are not representative of substantial and localized leaks.

## CONCLUSIONS

This paper investigated the hygrothermal performance of a vented and unvented permeable and hygroscopic wall assembly. Whole building hygrothermal simulations carried out with WUFI Plus and WUFI Pro indicate that the venting this assembly might increase its resilience and drying potential when subjected to significant moisture sources. However, the external face of the wood fibreboard seems more vulnerable to mold growth when unprotected by the mineral plaster.

From these limited results, it is unclear if providing a ventilated cavity yields significant improvement in terms of hygrothermal performance and resilience of the building envelope. Field data is currently being monitored and will shed additional light on this topic. The results presented in this contribution are applicable only for the specific wall assembly investigated here; additional simulations and field data for different types of hygroscopic and permeable wall assemblies are needed for making general conclusions for such assemblies.

## Improving Durability of Wooden Beam Bearings in Inside Insulated Walls by Tempering the Beam's Heads

Paul Wegerer<sup>1,2\*</sup>, Thomas Bednar<sup>1</sup>

<sup>1</sup>TU Wien, Vienna, Austria

<sup>2</sup>Gassner & Partner Baumanagement GmbH, Vienna, Austria

### ABSTRACT

Improving durability of wooden beam bearings after a thermal renovation via interior insulation is highly demanding for planners. Because of an isolated thermal bridge in the area of the wooden beam head the risk of condensation water forming in this area increases after installing interior insulation. The problem with wooden beam ends has been analysed increasingly in the last few years by many research institutions as wooden ceiling constructions are common in existing buildings. Furthermore, thermal renovation makes a vital contribution regarding improving the energy-efficiency of existing buildings.

In this paper a method to temper wooden beam ends is introduced. It is a patent pending which is currently developed further using laboratory-prototypes in a double climate chamber. This technology is based on thermo conductive types of sheet metal, which are driven into the construction at the joint between the wooden beam and the surrounding masonry. The thermal energy is provided by a heating pipe and fed into the metal. Because of the metal's high thermal conductivity, heat can be fed specifically into the beam's end in order to avoid wood rotting at this crucial point.

Calculating the beam's end temperature control was done using three-dimensional HAM simulations with air flows in the ceiling cavity being taken into account. The results of different measurements in the double climate chamber as well as the HAM simulations clearly show that the durability of an interior insulation can be increased via a temporary and local tempering of wooden beam bearings. At the same time the risk of wood rotting at the ceiling's bearing structure is minimised.

Comparative analyses show that this method of tempering the beam ends is especially energy-saving as the energy input is low due to the special feeding of heat via thermo conductive types of sheet metal.

### KEYWORDS

Wooden beam ceiling, interior insulation, 3D HAM model, local temperature control, double climate chamber

### INTRODUCTION

In-situ-measurements on existing buildings with wooden beam ceilings show that the thermal retrofitting via interior insulation can result in damage by moisture (IBO, 2017). Hygrothermal simulations (Wegerer and Bednar, 2017) prove this to be true and show that accompanying measures are to be made when planning an interior insulation with wooden beam ceilings. The interior insulation leads to the cooling-off of the entire outside wall in winter. The ceiling beams protrude into the cold area and are open to a greater risk of rotting. This can be prevented by a local, temporary heat input. The Research Center for Building Physics and Sound Protection at TU Vienna has developed a technology how the beam head area can be tempered. Thereby, harmful condensate formation can be prevented and thus the construction's durability secured.

At the same time, high energy efficiency and practical feasibility were taken into account. A prototype for a local beam head temperature control was developed and a patent filed (Wegerer and Bednar, 2012).

## METHODS

Extensive tests were made in a double climate chamber on a true-to-life, 45cm-thick brick wall which is equipped with a ceiling connection over the entire length of its warm side (see fig. 1). Temperature and humidity sensors to examine the hygrothermal conditions were mounted on the – altogether five – wooden beam heads (see fig. 2a). In the bearing areas, sensors to measure the surface temperature were adhered directly to the surrounding bricks (see fig. 2b). Additionally, sensors were built into the wall's cross section to also examine the masonry's hygrothermal behaviour. These sensors serve as a reference for the one-dimensional temperature and moisture field. Finally, temperature and thermal flow measuring foils were applied to the wall's surface to gather a reference of the thermal resistance in comparison to in-situ-measurements.

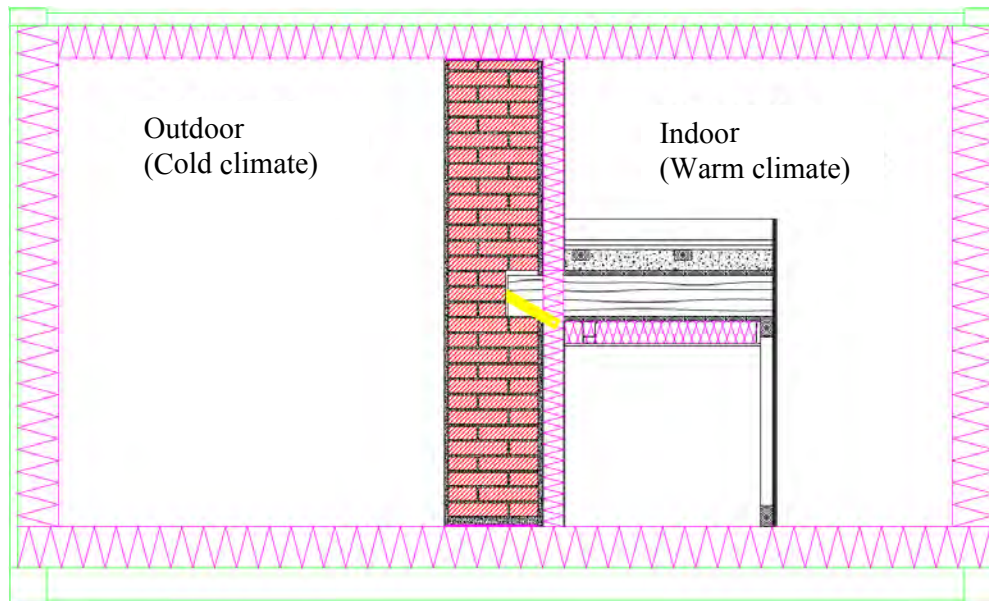

Figure 1. Cross section of the double climate chamber with test wall in middle. Ceiling structure is built into the right/warm climate side.

The tests in the double climate chamber were carried out in three phases. In the first testing phase, measurements were carried out on the test wall without interior insulation and without suspended ceiling. This construction corresponded with a typical existing wall of a Wilhelminian style house as it is found during renovation projects. The results were compared to in-situ-measurements to obtain true-to-life results during later tests with the test wall.

In the second testing phase, the wall was fitted with a 5cm-thick interior insulation made of Xella Multipor sheets. Furthermore, a suspended ceiling was constructed, as is currently usually the case with conventional renovations to improve noise protection. The results of the second testing phase provide information about the thermal enhancement of the existing wall and show the risk of moisture damage owing to the interior insulation. For a detailed analysis of the hygrothermal conditions, various climate scenarios were examined. In doing so, the outside climate was varied and the indoor climate was set with different moisture loads.

In the third testing phase, the beam head's temperature control was installed. Metal sheets made out of copper were driven into the airspace between wood and masonry with every wooden beam. A temperature sensor was stuck onto the outer end of every sheet (see fig. 3a). On the inner side, the heat conducting sheets were connected to a heating pipe (see fig. 4), which was laid in the interior insulation's area.

Figure 2. Sensor arrangement a) on beam head ends, b) in the bearing area, c) beam heads before mounting in brick wall

Figure 3. a) Prototype of heat conducting sheet, b) overhead beams without floor assembly

Figure 4. Installation of heat conducting sheets: a) view from below, b) view from side.

In addition to the measurements in the double climate chamber, hygrothermal simulations were made using Comsol Multiphysics and HAM4D\_VIE. A model with dimensions geometrically identical to the test piece was generated in order to be able to validate the results and variations of every parameter. Besides, the energy demand was simulated and compared to real measurement data from the tests.

## RESULTS

### Temperature conditions at the beam's end

The results of the three testing phases show how the three-dimensional temperature field shapes itself within the different construction variants. The interior insulation's and temperature control's influences can be identified in the evaluations of the temperature field on the beam head's end. In figure 5, the measurement data of beam head 1 during the three testing phases are depicted exemplarily. It is evident that the installation of an interior insulation combined with a suspended ceiling leads to critical temperature conditions in the beam head area. This can be countered by temperature control of the beam head.

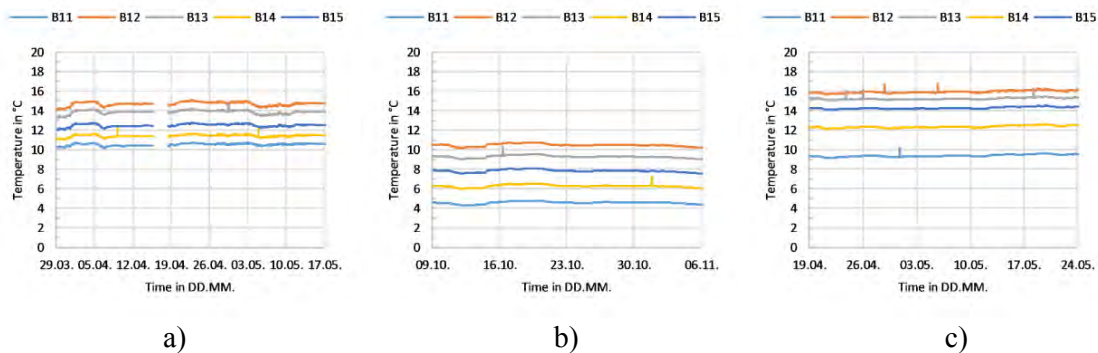

Figure 5. Temperature dispersion on beam head's end at stationary boundary conditions (-10°C outside temperature, 22°C inside temperature). Sensor positions as marked in fig. 2a: a) original construction, b) construction with interior insulation and suspended ceiling, c) construction with interior insulation, suspended ceiling and temperature control

The complex of problems regarding low surface temperatures near the beam head was elaborated by Wegerer and Bednar (2017). As a consequence of the perfusion near the airspace surrounding the wooden beam, warm and humid ambient air may condensate behind the wooden beam head resp. lead to mould growth or wood rotting.

### Heating demand

During the experiments with the tempering of the beam head in the double climate chamber the energy consumption was also measured. The application of energy via all five beam heads' heat conducting sheets could be calculated by taking into account the difference in temperature between the heating line's flow and return as well as the flow rate. Additionally, the surface temperature was measured at every heat-conducting sheet directly at the junction from the heating pipe and at the outer end. The heat consumption and the flow rate as well as the surface temperatures are depicted in fig. 6a. Different scenarios were measured in which the same stationary climatic boundary conditions ( $-10^{\circ}\text{C}$  outside and  $22^{\circ}\text{C}$  inside temperature) were always assured. The flow temperature was being held at a constant  $45^{\circ}\text{C}$  and only the flow rate was being varied. In spite of the sudden changes in temperature due to the flow rate's increase, the heat input into the construction remains almost the same.

To calculate the reference heating demand a simplified simulation model, which provides temperature control of the entire ceiling connection area was generated. It was assumed that a minimum temperature of  $15^{\circ}\text{C}$  at the beam head's end must not be gone below to prevent rotting of wood. The simulation model's geometry is shown in figure 7 and corresponds to the test wall in the double climate chamber. Figure 6b shows the cumulative heat consumption over a year.

Figure 6. Heat consumption at respectively the same boundary conditions and component dimensions: a) energy consumption measured at prototype in the double climate chamber, b) Reference heating demand: simulated energy consumption corresponding to model in fig. 7 with temperature control of the entire ceiling connection area

From the data measured of the heat input per beam head ( $0.07\text{kWh/day}$ ) and assuming a cold spell of two weeks (14 days), a yearly energy consumption of  $1\text{kWh}$  per beam head can be gauged. If this is extrapolated onto a typical Wilhelminian style house, the theoretic energy demand of the beam head's temperature control via heat conducting sheets averages at  $200\text{kWh}$  per year, not considering distribution losses. The comparison of the two temperature control models shows that the local heat input via the heat conducting sheets is distinctly more efficient.

## DISCUSSIONS

The development of the prototype of a beam head's temperature control using a true-to-life brick wall has provided a wealth of data, which are of great relevance for construction practice. Currently, an interior insulation is installed in very little cases of existing constructions' renovations, however, the risk of damage of such construction is relatively high. With the selective temperature control of the beam abutments, greater insulation thicknesses and thus highly efficient renovations with interior insulation can be realised. The planning of such projects was in part dealt with in IEA Annex 55 (Bednar and Hagentoft, 2015), where a probabilistic calculation was developed.

## CONCLUSIONS

In practice, the planning of a beam head's temperature control is of little relevance at the moment. The technology introduced is, however, of great significance when thermally renovating buildings using interior insulation. For its practical implementation, the cost-benefit ratio has to be examined above all. The hydraulic dimensioning and the controlling means of the beam head's temperature control require further research. The calculation by hygrothermal simulation associated with this is currently being processed. Further measurements in the double climate chamber are to provide data for the CFD simulation model's validation.

## ACKNOWLEDGEMENT

The "Austrian Research Promotion Agency (FFG)" and "Gassner & Partner Baumanagement GmbH" supported this research. We are thankful to our colleagues Manfred Grüner and Harald Hofbauer who helped running the measurements that greatly assisted the research.

### **ABSTRACT**

Sorption hysteresis of amorphous cellulose is studied. Cellulose, as a renewable organic biopolymer, is an essential component of various natural composites such as wood. A coupling process between sorption and deformation leads to the hysteresis as observed in sorption and swelling, both experimental and simulated for cellulose and wood in general.

### **KEYWORDS**

Sorption, hysteresis, swelling, cellulose, modelling.

### **INTRODUCTION**

An appealing, but not fully understood characteristic of many porous building materials is the appearance of sorption hysteresis: i.e. the moisture content differs at same relative humidity (RH) depending on the loading history, ad -or desorption. Hysteresis has been commonly attributed to capillary condensation hysteresis and pore ink-bottle effects, where for the latter the pore body can only empty when the smaller neck pore is emptied. Such behavior can appropriately be described using models based on the independent domain theory, where hysteresis originates from hysteretic bottle elements, which do not interact necessarily with each other (see e.g. Coasne et al. 2005, Derluyn et al. 2012, Patera et al. 2016). The assumption of non-interaction and pore independence is for most materials however most likely not valid, and invasion percolation, where a pore can only empty when at least one neighboring pore is empty, has been adopted to model hysteresis. For an assembly of connected pores, invasion percolation effects appear where pores can only be emptied when a percolating path is present (see e.g. Carmeliet et al. 1999).

In the above mentioned approaches, the materials are assumed not to deform, remaining at constant volume and do not incorporate the influence of sorption induced swelling. However, many materials such as soft nano-porous materials as wood show an important sorption induced swelling. Soft nanoporous matter encompasses anthropic materials such as compliant porous solids, foams, intrinsically porous polymers, organic membranes, as well as natural materials such as wood, bamboo, plants, linen, kerogen in gas shale. Owing to their large internal surface area and compliant solid matrix, strong fluid-solid interactions lead to sorption-induced deformation or swelling. For example, cellulose, wood most redundant component, on adsorption of water may swell as much as 30% volumetrically (Mihranyan et al. 2004). An important feature of nanoporous polymers is the hysteresis in sorption isotherms extending to very low RH, a different type of hysteresis to the one associated with capillary condensation, where the hysteresis disappears below a certain RH.

The coupling between sorption and swelling in porous materials has been investigated experimentally and with atomistic simulations (Derome et al. 2011). In parallel, much theoretical effort has been devoted to unify mechanical constitutive equations and surface thermodynamics relationships into the same framework known as poromechanics (Kulasinski et al. 2015). In spite of being successful at describing the coupling between sorption and

swelling, the physical microscopic mechanism behind this coupling is often ignored in studying the hygroscopic behavior of materials like wood. The question arises whether the swelling of the material and the accompanying pore structure changes play an important role in the sorption behavior and are at the origin of the observed sorption hysteresis. In this paper, we will show that this coupling effect is essential in explaining the observed sorption hysteresis effect.

### SORPTION AND SWELLING HYSTERESIS OF SOFT MICRO-POROUS MATERIAL

In this paper, we study sorption hysteresis of amorphous cellulose considering its wide presence in nature. Cellulose, as a renewable organic biopolymer, is an essential component of various natural composites such as wood. Because of its abundance, cellulose is also a popular raw material to design innovative products for science, medicine and technology. Cellulose shows an important hygroscopic behavior because of the exposed hydroxyl sites in the nanoporous polymer. Understanding the hygroscopic hysteretic behavior of cellulose may lead to a better understanding of the origin of sorption hysteresis in wood. We use atomistic simulations to study the hysteresis behavior. Part of the atomistic model of cellulose used in this work is shown in Figure 1. The figure shows the material structure at RH=1 while the blue dashed line shows the non-swollen state of the system before adsorption.

Figure 1 a). Atomistic model of cellulose in saturated state. The sticks are the bonds between the C, O and H atoms in cellulose, red and white spheres the O and H atoms of water. Box size  $3.1 \times 3.3 \text{ nm}^2$ . Blue dashed line shows the system size of dry material before adsorption. b) MD simulation of sorption hysteresis with swelling and adsorption in frozen state.

Water sorption and deformation are simulated with a hybrid Grand Canonical ensemble (GCMC)/ Molecular Dynamics (MD) method. Monte Carlo simulations in GCMC allow studying the sorption process by inserting or deleting a number of water molecules in order to reach the target RH (chemical potential). However, since the system is at constant volume, this method does not allow to study swelling and its effect on sorption. Therefore, MD simulations are consecutively used to obtain the deformation state. As the deformation changes the RH, we iterate between GCMC and MD until the target RH at equilibrium is reached. By using this hybrid strategy combining GCMC and MD, the atom-scale simulations probe adsorption phenomena while allowing for swelling of the host porous polymer.

Figure 2a shows the ad- and desorption isotherms, i.e. the moisture content (kg/kg) versus RH. Figure 2b shows the swelling isotherms, i.e. the swelling strain (m/m) versus RH. Figure 2a shows that the moisture content increases rapidly with RH in the low RH region and then increases less rapidly as initial pores in cellulose get filled. Upon further increasing RH, an inflection point in the adsorption isotherm is observed as pores open up upon swelling and significant subsequent adsorption occurs. The pore sizes in this nanoporous material, even upon swelling (0.2 – 0.4 nm), are too small to allow for capillary condensation (Coasne et al 2005). The sorption curves also exhibit significant hysteresis. The simulation results agree qualitatively well with experimental data (Mihranyan et al. 2004). We note a systematic offset

of the experimental data (around 0.5 moisture content) with our simulations. This offset is attributed to the presence of residual water not being removed in the experimentally dried sample (presence of non-desorbable water).

Figure 2b shows the swelling isotherms. The volumetric strain shows significant swelling strains reaching as high as 36% close to  $RH = 1$ . Large hysteresis in sorption-induced swelling is observed reflecting the hysteretic sorption isotherm. Significant hysteresis in sorption and sorption induced deformation is observed. When we plot the swelling strain versus moisture content (Figure 2c), hysteresis disappears and the data collapse in a single almost linear curve. This is in agreement with experimental observations in wood (Patera et al. 2013). This shows that swelling is a direct consequence of filling of the deforming material with a number water molecules and therefore a linear relation between swelling and moisture content is observed.

The impact of swelling on the sorption isotherms was probed by simulating water adsorption keeping the material non-deformable (frozen material). We found that in this case, much less adsorption occurs (almost 10 times lower) and the hysteresis effect disappears. This indirectly shows that swelling of the material essentially contributes to the total sorption amount, and that hysteretic sorption depends on the swelling

Figure 2. (a) Significant hysteresis in simulated and experimental sorption isotherms. (b) Hysteresis in simulated volumetric swelling strain isotherms. (c) Hysteresis disappears when plotting volumetric swelling strain in function of moisture content.

To better understand the coupling between sorption and swelling and more especially the origin of hysteresis, we further interrogate the systems looking at hydrogen bonding. Amorphous cellulose is a non-cross-linked polymer, where hydrogen bonds are a metric to monitor the interactions inside the polymer system, revealing different configurations of material and water molecules during adsorption and desorption. We study the number and nature of the hydrogen bonds in the material. Three types of hydrogen bonds (HB) are distinguished. In the dry material, polymer chains are interconnected with cellulose-cellulose hydrogen bonds ( $HB^{CC}$ ). Upon adsorption of water molecules, swelling occurs and  $CC$  hydrogen bonds between the polymer chains are broken. Upon breaking the  $CC$  hydrogen bonds, new hydroxyl adsorption sites become available. Increasing  $RH$ , these new sites become occupied with new water molecules forming cellulose-water hydrogen bonds ( $HB^{CW}$ ). Figure 4a-b show the normalized decrease of  $HB^{CC}$  and increase of  $HB^{CW}$  with moisture content. Increasing further the moisture content, water molecules start to form more and more water-water hydrogen bonds ( $HB^{WW}$ ), since only a limited number of free hydroxyl sites is still available. In desorption, first water molecules in water-water hydrogen bonds will leave the system, while the remaining water molecules are attached to cellulose chains. As cellulose-water HBs are stronger than cellulose-cellulose HBs, hydroxyl sites will preferentially remain occupied by the water molecules at lower relative humidity. Cellulose-cellulose HBs between the polymer chains will only reform at lower  $RH$ . This process explains the lower number of cellulose-cellulose HBs during desorption.

In conclusion, at a given moisture content, the polymer system accommodates to receive the

same number of water molecules but distributes them differently as observed by different hydrogen bonding configurations during ab- and desorption. During adsorption process, new sites are created by breaking cellulose-to-cellulose hydrogen bonds between polymer chains due to material swelling. These sites become receptors for new water molecules changing cellulose-to-cellulose into cellulose-to-water hydrogen bonds. However, the recovery of these new adsorption sites back to cellulose-to-cellulose hydrogen bonds during desorption is less likely since the sites more likely remain occupied by water molecules. This coupling process between sorption and deformation leads to the hysteresis as observed in sorption and swelling, both experimental and simulated for cellulose and wood in general. The mechanism documented by observing configurations of hydrogen bonds gives a clear understanding of the coupling between sorption and swelling in soft porous matter that goes well beyond cellulose, wood and other soft polymer materials. While such mechanism was merely hypothesized in the literature, no experimental or theoretical evidence has been reported so far. With our atomistic approach, a clear understanding of hysteresis due to coupling between sorption and swelling in soft polymer materials is shown.

Figure 3. (a) Evolution of number of cellulose-to-cellulose hydrogen bonds with moisture content. (b) number of cellulose-to-water hydrogen bonds with moisture content.

### DISCUSSION ON MODELLING HYSTERESIS USING INDEPENDENT/DEPENDENT DOMAIN THEORY

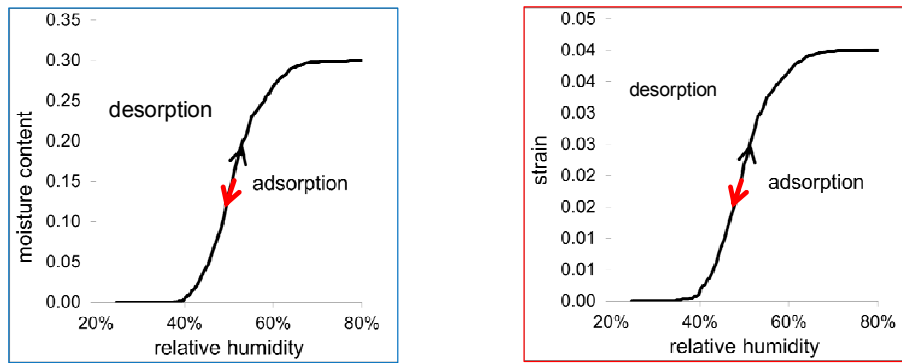

A common approach to describe sorption hysteresis in a phenomenological way is the independent domain theory, where hysteresis originates from local hysteretic elements, that do not interact with each other. In this approach, sorption hysteresis is explained by hysteretic pore scale phenomena like capillary condensation, contact angle or ink-bottle effects caused by smaller size entry pores. Based on these physical explanations, sorption hysteresis is considered to be merely a local pore phenomenon, i.e. sorption at the pore level itself is hysteretic. Thus, in the independent domain theory, pores are assumed not to interact with each other, and changes in moisture content are the outcome of the behavior of an assemblage of independent sorption sites. Different independent domain models have been proposed for different types of materials, where the main difference results from the way the distribution of hysteretic elements is derived from experimental data. These phenomenological models have appeared in different forms and fitted to experimental data. Although these phenomenological models seem to adequately simulate the observed behavior following the experimental data, no direct proof for their physical correctness has been yet given. Our recent atomistic modelling results show that independent theories, which do not include sorption induced swelling in nanoporous soft polymeric materials do not capture the correct physics.

Our atomistic analysis reveals that water molecules first adsorb at free sorption sites leading to a swelling of the material. The swelling is followed by an unravelling of the polymer

chains favoring the creation of new sorption sites. In desorption however, these extra-created sorption sites remain favorably occupied by water molecules and the material remains longer in a swollen state at higher moisture content. The question now remains how to model such a behavior in an elegant engineering way.

Based on the evidence that swelling plays a determining role in sorption hysteresis, a correct hysteresis model should incorporate swelling, which can only be modelled by an elastic dependent domain theory. In such model, the filling of a site depends not only on the relative humidity at the site but also on the strain state of the sorption site. In view of a dependent domain approach taking into account deformation, we assume the material to consist of a set of elastic interacting elements. A distribution of non-hysteretic pores is embedded in the elastic material. In the dry state, most of these pores are not accessible to water molecules since their size is too small to receive a water molecule. However, some smaller accessible pores become filled with water molecules, swell and will exert a swelling strain field on neighboring pores. Pores, which were not accessible before, will now become accessible due to the tensile strain exerted on the pore system. The filling and unfilling of an element is thus not only dependent on RH, but also on the strain exerted on the element. A positive strain originating from an internal strain field will lead to making pores accessible to sorption. Further, the tensile strain on an element is considered to produce extra volume for additional sorption of water molecules, which has also been observed in the atomistic simulations. The behavior of a distribution of such interacting elastic elements is studied by finite elements.

a)

b)

Figure 4. (a) Sorption and swelling isotherm of moisture content and strain versus RH for non-coupled dependent domain approach. No hysteresis is observed. (b) Sorption and swelling isotherm of moisture content and strain versus RH for coupled dependent domain approach, with interaction between filling and swelling process. Hysteresis both in sorption and swelling is observed (Guyer et. al 2011).

Our group in collaboration with R. Guyer from LANL (Guyer et. al 2011) developed such a dependent domain approach for an academic material. General results showing the model

performance are reported here. Figure 4a gives an example of predictions of sorption and swelling isotherms using the elastic dependent domain model of non-hysteretic elements where the coupling between sorption and swelling has been switched off. The curves show a non-hysteretic behavior. When switching on the coupling (figure 4b) meaning the filling of an element depends not only on the RH but also on the strain exerted in the element, we observe a hysteretic behavior both in sorption and in swelling. When plotting the swelling strain versus moisture content (Figure 5), we observe a quasi-linear relation between swelling strain and RH, showing no hysteresis. These results are in close qualitative agreement with our observations in experiments and atomistic simulations for wood components. This means that the elastic dependent domain approach seems to be the correct physical approach to model and predict sorption hysteresis.

In the next future, we will further develop and fine-tune this elastic dependent domain model showing its adequacy for modelling hysteresis of sorption induced swelling of nanoporous polymer materials as wood. Furthermore, we will implement this sorption model in a multiscale approach allowing modelling not only single woods components, but also layers in a wood cell wall like the S2 layer, and even wood. From there on, global macroscopic models can be improved for modelling materials behavior at macro- or structural scale. Final aim is to be able to adequately model sorption induced swelling and hysteresis. The models should be physically sound from one side, but also sufficiently simple to be used in engineering practice.

Figure 5. Swelling strain versus moisture content as determined by dependent domain. No hysteresis is observed (Guyer et. al 2011).

### **ABSTRACT**

In building envelope, the cross laminated timber (CLT) is often used as air barrier layer. The objective of this study was to evaluate the impact of production technologies such as edge bonding, different initial moisture content (MC) of lamination, and number of lamination layers (3 and 5) on the air-permeability properties of cross laminated timber. Air leakage and crack growth in CLT panels were measured after the panels were conditioned in environments with different relative humidity (RH) in progressive steps from humid to dry environments (RH 70%→ RH 50%→ RH 30%→ RH 10%). The test results showed that the most effective technologies for avoiding large crack growth and air leakages through panels were to use 5 layers of laminations with bonded edges. Overall, it can be recommended that for the production of CLT panels it is advisable to use primarily a larger number of layers, at least 5, for smaller growth of cracks on panel surfaces and thereby avoid air leakages during the time of use. The use of bonded edge technology helps to ensure the avoidance of possible air leakage threats, but in the long-term, this beneficial effect might decrease as bond layers may rupture or cracks may form in the middle of laminations.

### **KEYWORDS**

Cross laminated timber, production technology, crack growth, air permeability

### **INTRODUCTION**

Airtightness of building envelope has become an important property of building envelope. The more airtight envelope and more efficient heat recovery with reduced thickness of thermal insulation has a lower construction cost and lower energy consumption, making it financially viable (Saari, et al., 2012). The building envelope is locally sensitive to exfiltration airflow, as moisture convection could cause a remarkable increase in the moisture accumulation rate on the inner surface of the sheathing (Kalamees & Kurnitski, 2010). Kayello et al. (2017) showed that frost accumulation and condensation can happen very easily due to air leakage and pose a significant risk to the integrity of the envelope. In building envelope, the CLT is often used as air barrier layer. Crack formation in CLT influences its water vapour resistance and air permeability (Kukk et al. 2017) as well fire resistance, acoustic properties, and lower the quality (Brander, 2013).

Moisture movement in wood has a major role in crack formation. The important benchmark for the wood properties affected by moisture is the fibre saturation point (FSP). FSP is defined as the point where wood cell lumen does not contain free water but the cell wall is still saturated. Properties of wood, such as volume and mass, change if the MC changes below FSP point. A decrease or increase of MC results, respectively, in shrinkage or swelling of wood.

The unequal decrease of MC in different wood directions (tangential, radial and longitudinal) results in unequal shrinking of wood which causes internal stresses inside the wood. This, in turn, results in the formation of checks and cracks in the wood surface. Changes of MC in the laminations of a CLT panel result in shrinking and swelling of the wooden board's volume, which may cause cracks in board surfaces and also gaps between the edges of the boards. This study is focused on analysing the effects of productions technologies on the air permeability properties of CLT panel. The objective is to study the effects of the number of layers in the panel, bonded edges and initial MC in lumber to crack growth in CLT panels' lamination surfaces and air permeability.

## METHODS

### *Test specimens*

Specimens were produced using three different technologies whose parameters are given in Table 1. Three specimens were made for each technology combination. According to this, 24 specimens of rectangle-shaped cross-laminated timber panels with dimensions of 1300x460mm, a thickness of 30mm and constructed from spruce wood (*Picea abies*) were designed and produced for the air permeability and crack evaluation test.

Table 1. Parameters of specimens produced with different technologies

Edge bonding	Number of layers	
	3 layer panel, thickness of one layer 10 mm	5 layer panel, thickness of one layer 6 mm
Edge bonded panels	Initial MC of laminations $\approx 13.1\%$ (conditioned with RH of 70%)	Initial MC of laminations $\approx 13.1\%$ (conditioned with RH of 70%)
	Initial MC of laminations $\approx 6.2\%$ (conditioned with RH of 30%)	Initial MC of laminations $\approx 6.2\%$ (conditioned with RH of 30%)
Panels without edge bonding	Initial MC of laminations $\approx 13.1\%$ (conditioned with RH of 70%)	Initial MC of laminations $\approx 13.1\%$ (conditioned with RH of 70%)
	Initial MC of laminations $\approx 6.2\%$ (conditioned with RH of 30%)	Initial MC of laminations $\approx 6.2\%$ (conditioned with RH of 30%)

Specimens were marked as follows: P30/70 W/BE 3/5L, where P30/70 defines panels initially conditioned in an environment with RH of 30% or 70%; W/BE- without or with bonded edges panels; 3/5L- panels with 3 or 5 layers.

### *Measurements*

Three following parameters were measured during laboratory test: MC of panels, crack area on panels top surfaces and air permeability. Cracks area results were gained by measuring crack width and length using a crack width gauge and methodology developed by Brischke and Humar (Brischke *et al.* 2014). Air permeability was measured using a hermetic test rig and equipment for regulating and measuring air pressure differences and air flow (EN 12114, 2000), accuracy <5%, see Figure 1(b), (c). Airflow was measured by applying three overpressure impulses at a pressure difference of 550 Pa. To avoid any air leakages from the connection of the test rig and panels, all panels edges were sealed with vapour and air tight tape. Therefore the measurement area of each specimen for air permeability test was considered as 0.56 m<sup>2</sup> (1.25x0.45). The laboratory test process consisted of panel conditioning steps in environments with different RH supplied by a climate chamber, see Figure 1(a).

Conditioning steps for panels initially conditioned in an environment with RH 70% were as follows:

- I step: RH 50% → II step: RH 30% → III step: RH 10%;

And for panels initially conditioned in an environment with RH 30%:

- I step: RH 10%

Before and after each conditioning step all parameters were measured and recorded and corrected with an estimated error.

Figure 1.(a) Climate chamber Climacell 707 for panel conditioning, (b) hermetic test rig for air permeability tests, (c) equipment for measuring air pressure differences and air flow.

## RESULTS

### *EMC of specimens*

All specimens were conditioned equally and the equilibrium moisture content (EMC) after each conditioning step was almost the same in all panels, see Figure 2. Specimens conditioned initially in an environment with RH of 70% had an overall moisture loss after each conditioning step of RH of 10% of about 8%. Specimens P70WBE5L had a moisture loss of 12.2% due to a higher initial EMC. Specimens conditioned initially in a RH of 30% had an overall moisture loss after each conditioning step of RH of 10% of about 2.5%.

Figure 2. EMC of specimens after each conditioning step

### *Growth of crack area*

A big difference in crack area growth between specimens P70 and P30 was expected due to the different number of conditioning steps, see Table 2. While a total crack growth in specimens P30 was from 16% to 55%, in specimens P70 it was from 516% to 22160%. The total crack growth of 22160% appeared in specimens P70WBE3L, which was about 10 times higher than rest of the specimens. Specimens P70WBE3L also had the biggest average crack area of 15456 mm<sup>2</sup> after conditioning steps of RH of 10%.

The smallest average crack area of 193 mm<sup>2</sup> after conditioning steps of RH of 10% was in specimen P30BE5L, and specimen P30BE3L had the smallest total crack growth of 16%. Overall, the greatest effect on smaller crack growth was in specimens with bonded edges and initially conditioned in an environment with RH of 30%.

Table 2. Average crack area and growth of specimens after each conditioning step

Specimen	70% <sub>initial</sub>	50%	Growth, %	30%	Growth, %	10%	Growth, %	Total growth (RH70- 10 %), %
	Av. existing crack area, mm <sup>2</sup>	Av. crack area, mm <sup>2</sup>		Av. crack area, mm <sup>2</sup>		Av. crack area, mm <sup>2</sup>		
P70BE5L	436	655	50%	1162	77%	2686	131%	516%
P70BE3L	194	246	27%	871	254%	2969	241%	1434%
P70WBE5L	202	1982	881%	3151	59%	5382	71%	2564%
P70WBE3L	69	1430	1959%	9064	534%	15456	71%	22160%
	30% <sub>initial</sub>	10%	Total growth (RH 30-10 %), %					
P30BE5L	100	193	48%					
P30BE3L	1300	1551	16%					
P30WBE5L	1306	2918	55%					
P30WBE3L	1457	2677	46%					

#### Air permeability of specimens

The largest air leakages were in all specimens with three layers, when taking into account initial EMC in production and bonded and without bonded edge technology, see Figure 3. The greatest average air leakage of 0.53 m<sup>3</sup>/(h×m<sup>2</sup>) after conditioning steps of RH of 10% were in specimens P70WBE3L. The second greatest leakage of 0.52 m<sup>3</sup>/(h×m<sup>2</sup>) showed in specimens P30WBE3L after conditioning steps of RH of 10%.

Specimens with 5 layers and bonded edges and initially conditioned in an environment with RH of 30% were the most airtight which matched with pre-testing assumptions. Specimen P30BE5L showed an air leakage of 0.11 m<sup>3</sup>/(h×m<sup>2</sup>) and P70BE5L showed 0.25 m<sup>3</sup>/(h×m<sup>2</sup>) after conditioning steps of RH of 10%. Overall, 5 layer specimens had the most considerable effect on air permeability properties as a result of having less air leakages.

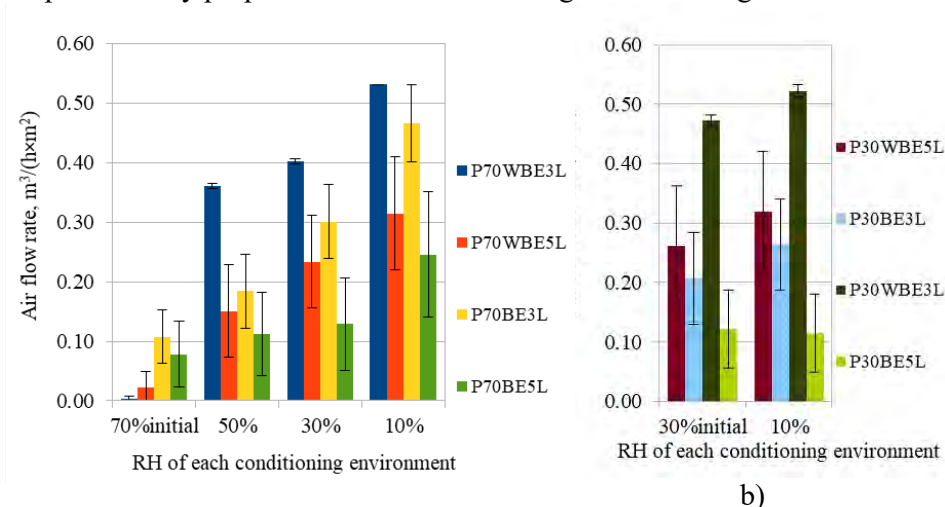

Figure 3. Air flow rate after each conditioning step of specimens a) initially conditioned in an environment with RH of 70%, b) with RH of 30%

The large estimated error of air flow rate results was probably a result of the small number of specimens for each type, quality variation of lumber and manufacturing defects on panels (such as existing gaps between laminations and some degree of uneven distribution of adhesive). Air flow rate of specimens P70WBE3L were measured maximum what used equipment could read and therefore no estimated error is shown in Figure 3.

## DISCUSSIONS

The most effective technologies for avoiding large crack growth were using laminations with bonded edges and lumber initially conditioned in an environment with RH of 30%. Specimens initially conditioned in an environment with RH of 70% had a considerable resistance to crack growth when panels had 5 layers.

Using initially drier lumber together with edge bonded laminations seems to keep wood shrinkage lower and therefore keeps crack growth on the panels surface at a low percentage during the first stages of drying (conditioning steps from RH 30% to 10%). In the longer drying process (conditioning steps from RH 70% to 10%), 5 layer panels considerable resistance to crack growth was probably due to a larger number of bond layers and thinner lamination layer thickness. Bond layers and thin laminations seemed to keep the wood steadier and controlled the formation of internal stresses during the drying process better. Specimens with bonded edges that underwent the longer drying process showed, in the first conditioning steps, a lower crack growth compared to specimens without bonded edges, but during the last step, the growth percentage was higher. This shows that bonded edges can hold the formation of internal stresses due to shrinkage for a short period and later, when bonding connections might have been ruptured or cracks might have developed in the middle of laminations, crack growth can increase over time.

5 layer specimens combined with edge bonding had the most considerable effect on avoiding air leakages through the panel. The greater number of layers helps to avoid any overlapping of gaps between laminations which are possible sources of air leakages (Kukk, et al., 2017). The same argument was confirmed in this study as 3 layer specimens had considerably bigger air leakages, especially the specimens with laminations initially conditioned in an environment with RH of 70%. The reason for better airtightness in panels with a larger number of layers can be the same as it was for low crack growth which was a larger number of bond layers and thinner laminations. The use of bonded edge technology has been also previously recommended for avoiding overlapping of gaps and cracks and it was again confirmed with the results of this study, except specimen P70BE3L, which showed a quite high air flow rate (Brander, 2013) (Skogstad, Gullbrekken, & Nore, 2011).

Current research only covered the first cycle of the drying process and specimens with laminations initially conditioned in an environment with RH of 70% and 30% had different cycle durations. In other words, the results obtained in this experiment have given information about the behavior of the panels at the beginning of their service life. For a better understanding of the air-permeability properties of the panel in long-term of use the repeated test with several cycles is necessary to carry out.

In overall, it can be recommended that for the production of CLT panels one should primarily use a larger number of layers, at least 5, for the smaller growth of cracks on panel surfaces, thereby avoiding air leakages during the time of use. The use of bonded edge technology helps to ensure the avoidance of possible air leakage threats, but in the long-term, the effect might decrease as bond layers may rupture or cracks may form in the middle of laminations. Specimens with initially drier laminations did not show a significant resistance to air leakages but had considerable effect for avoiding large crack growth.

## CONCLUSIONS

In this study, three production technologies of CLT panels were analysed to determine the influence of number of layers in the panel, bonded edges and initial MC in lumber. The main findings of this study were that the most effective technologies for avoiding large crack growth were using edge bonded and initially drier laminations and 5 layer specimens combined with edge bonding had the most considerable effect on avoiding air leakages through the panel. Based on the results it is recommended to primarily use a larger number of layers, at least 5, which helps to minimise the growth of cracks on panel surfaces, therefore, avoiding air leakages during the time of use. The use of bonded edge technology helps to ensure the avoidance of possible air leakage threats, but in the long-term, the effect might decrease as bond layers may rupture or cracks may form in the middle of laminations. Using initially drier lumber helps to avoid crack growth on panel surfaces, but does not have a significant effect on avoiding air leakages.

## ACKNOWLEDGEMENT

This research was supported by the Estonian Centre of Excellence in Zero Energy and Resource Efficient Smart Buildings and Districts, ZEBE, grant TK146 funded by the European Regional Development Fund, and by the Estonian Research Council with Institutional research funding grant IUT1-15.

Participation in the conference was supported by the Estonian Ministry of Education and Research. EU Structural Fund (Cohesion Policy Funds) period 2014-2020, TUT Development Program for the period 2016-2022, Doctoral School of Civil and Environmental Engineering project code 2014-2020.4.01.16-0032 has made publishing of this article possible.

The author wishes to thank Estonian glulam producer Peetri Puit OÜ for helping to produce CLT specimens.

### ABSTRACT

Wood is a well-used building material where the capacity of wood to absorb water leads to swelling and reduced mechanical properties, and also to questions of durability. The origin of the hygroscopic behavior of wood lies at the nanoscale material that composes its cell walls. Using atomistic modeling, we study the hygromechanical behavior of the different polymeric components of wood, separately and in aggregate configurations. We report the coupled effects of water sorption on the hygric and mechanical properties of the S2 cell wall layer and we upscale the findings using a poromechanical framework.

### KEYWORDS

Wood, hygroscopic behavior, swelling, multiscale modeling, atomistic modeling.

### INTRODUCTION

Natural materials, from plant origin, are ubiquitous in our daily environment, where they are exposed to environmental loading like temperature and relative humidity variations. In particular, cellulose-based materials such as wood have been used traditionally and ubiquitously, and are particularly attractive nowadays as they offer sustainable solutions and as they can be a source of inspiration for biomimetic design of new materials. Wood, an orthotropic cellular biomaterial, has the capacity of adsorbing water molecules from the surrounding environment into its hierarchical material structure. This material displays remarkable properties combining low weight, high strength and high toughness, originating from the hierarchical organization of crystalline and amorphous polymers.

Wood is a well-used building material, for structure, façade, windows, indoor finishing and furnishing, etc., where the capacity of wood to absorb water is not only an issue of dimensional stability and modified material properties, but also of durability. In effect, as water molecules are adsorbed into the hydrophilic matrix in the cell walls, the induced fluid-solid interaction forces result in a swelling of the cell walls. The moisture-induced phenomena at cell wall scale are reflected in the hygromechanical behavior of wood at macroscale. Adsorption of moisture in wood, in the hygroscopic range i.e. until around 30% moisture content mass per mass, results in swelling up to 10% volumetrically and reduces considerable its mechanical properties.

We propose a multiscale approach to investigate and understand the hygromechanical behavior of wood. At cell wall material scale, using atomistic modeling, we study the different polymeric components of wood, separately and in aggregate configurations, in terms of the coupled effects of water sorption on hygric and mechanical properties. Then, we upscale the findings using a poromechanical approach. Such properties can then be employed in finite-element modeling to investigate the effects of cellular geometry and ring growth

pattern of wood. The work aims at elucidating the origin of the hygro-mechanical behavior of wood and such complex polymeric materials. In effect, wood is retained as a model hygroscopic material for further understanding of such hygromechanical behavior.

## METHODS

### *Molecular Dynamics (MD) simulations*

#### Materials

Wood cell wall is made of a network of stiff cellulose microfibrils which are embedded within complex matrixing polymers) and the S2 chemical content has been in large part identified. Figure 1 displays the cell wall layers and their components. We aim to reproduce all the main polymers present in the wood S2 layer, namely crystalline cellulose, galactoglucomannan (named GGM below), glucuronoarabinoxylan (referred as xylan below) and the different configurations of guaiacyl lignin.

Figure 1. a) Schematic representation of the structure of wood cell wall, with P primary layer, S secondary layer, ML middle lamella (based on Derome et al. 2012), MF microfibril, A matrix close to fibrils, B lenticular matrix; b) components of S2 cell wall layer for a softwood like spruce.

#### Simulation

Molecular Dynamics simulations are carried out using Gromacs software (Hess et al 2008) with leap-frog algorithm for integration of Newton's equations of motion and the Gromos 53a6 united-atom force field (Oostenbrink et al 2004, Lins and Hünenberger 2005). The initial configuration of the polymer is constructed based on the position of atoms in the monomers and the proportion of different monomers in the chains as documented by previous studies. Using the main chemical components of wood, here softwood, the polymeric systems are reproduced, their hygromechanical behavior determined and analyzed. Nanoscale structures or composite systems are built and analyzed. MD results are validated with available experimental data. We note the capacity with this method to control exactly, as input, the polymeric constituents, their polymeric configuration and the configuration of layered or composite systems. Molecular dynamic provides a wealth of data, on which statistical physics is applied and then compared with theoretical and continuum approaches, like thermodynamics, providing a unique window on the fundamental hygromechanical behavior.

#### Tests

In order to study the different responses of the polymers to water, water molecules are introduced one by one to the system and the system let to equilibrate, as shown in Figure 2. We obtain water adsorption curves using One-Step Perturbation method for the determination of chemical potential. Calculated sorption curves, i.e. moisture content versus chemical

potential, are compared with experimental data for validation, as shown in Figure 3. The swelling of the system at each water insertion leads to the determination of the dependence of swelling coefficient on moisture content. Under mechanical loading (compressive or tensile, as desired), i.e. an anisotropic barostat is applied and the pressure specified, the system finds its equilibrium and a corresponding strain can be measured. We can determine the bulk and shear moduli dependence on moisture content. Orthotropic systems are probed by loading in the different directions.

### Upscaling

We use a poromechanical framework as described in Carmeliet et al. (2013) and Kulasinski et al. (2015c).

## RESULTS

We present MD results for the single components, namely long-chained polymers amorphous cellulose AC, GGM, xylan and an uncondensed lignin uLGN. Then we present one mix of amorphous polymers (Matrix), one cellulose crystal embedded in GGM ( $\mu F$ ) and four cellulose crystals embedded in GGM and surrounded by uLGN (S2).

## Swelling

The introduction of water molecules results in a displacement of the polymeric systems leading to material swelling. For the single components and the matrix system, made of amorphous components, swelling is found to be isotropic. Figure 4 shows that volumetric swelling strains vary linearly with moisture content, after an initial nonlinear behavior, the slope of this relationship yielding the swelling coefficient. Swelling coefficients are ranging from 1.07 for S2 to 2.0 for GGM. The different swelling coefficients stem from the combined effects of initial density and porosity, number of hydroxyl sites and bulk modulus, resulting from the different monomers content and arrangement of each system. As noted, the slope at low moisture content is always smaller and nonlinear.

The volumetric swelling of S2 layer is found to be smaller than those of hemicellulose and lignin alone. The crystalline cellulose acts as a stiff skeleton preventing the system from deformation. This effect is particularly pronounced in the longitudinal direction where, due to cellulose covalent bonds, the swelling coefficient is two orders of magnitude smaller ( $\epsilon_z = 2 \times 10^{-3}$  at maximum moisture content) than in the other directions. This indicates that, for the microfibril systems, anisotropy directly results from the presence of crystalline cellulose that restrains most of the deformation in the direction along the crystal.

Figure 4. a) Volumetric swelling strain ( $\epsilon_v$ ) of four polymers and one amorphous composite system and of  $\mu F$  and S2, over the full range of moisture content ( $m$ ). b) Orthotropic swelling strains ( $\epsilon_i$ ) of  $\mu F$  and S2, in function of moisture content ( $m$ ) (from Derome et al. 2018).

## Mechanical properties

As moisture content increases, all investigated polymeric systems show a decrease in elastic moduli. In single systems, the decrease of the bulk moduli, determined by imposing tensile or compressive stress, is seen to be in the range of factor 3 or 4. Remarkably the decrease in shear moduli is much more substantial, over one magnitude (Figure 5a, b). These lower shear moduli at higher moisture content are in part due to the presence of water layers offering almost no resistance in shear.

For anisotropic composite systems, Young's moduli are determined in the three principal directions. Results in the two directions x and y, perpendicular to the crystal orientation, are very similar. The weaker behavior with increasing moisture content is similar in all directions, but the magnitudes are very different for the behavior parallel to the crystal orientation (Figure 5c, d). The difference between microfibril and S2 is in large part due to the lignin which makes about one quarter of the S2 layer and which was here implemented with a low level of cross-polymerization, and as such is observed to weaken significantly.

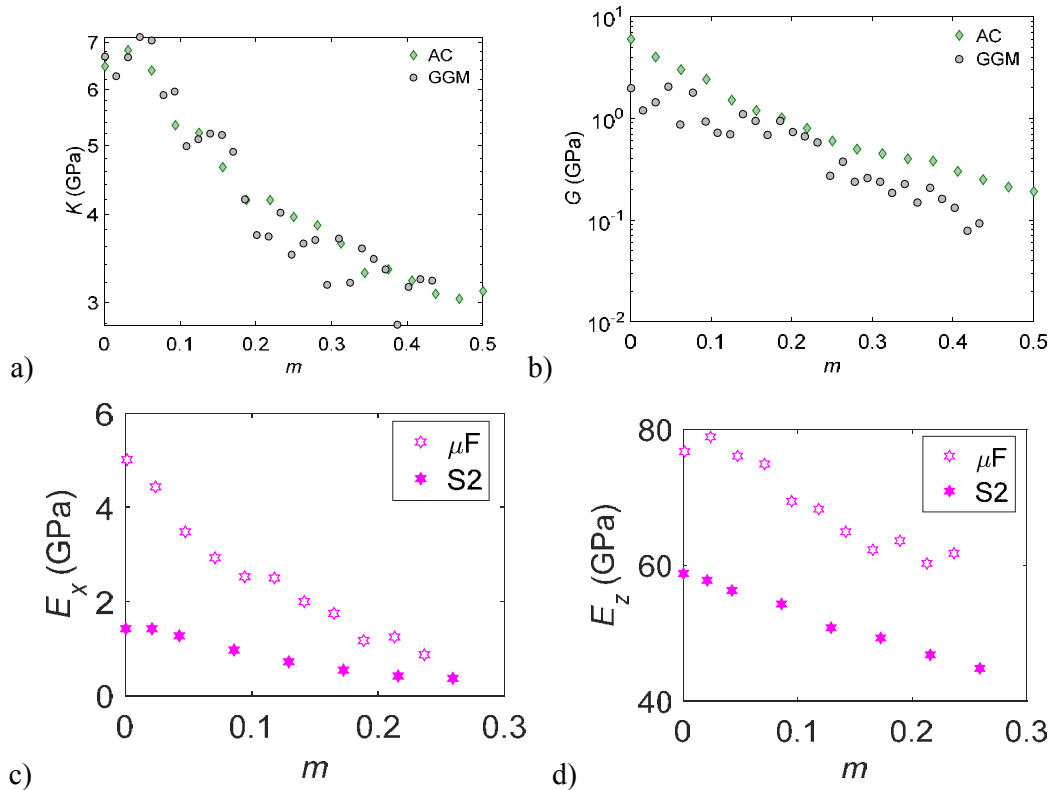

Figure 5. Mechanical properties, a) bulk ( $K$ ) and b) shear modulus ( $G$ ) of AC and GGM, and Young's modulus of  $\mu F$  and S2 ( $E$ ) c) perpendicular and d) parallel to crystalline cellulose, in function of moisture content ( $m$ ) (from Derome et al. 2018).

## CONCLUSIONS

Using Molecular Dynamics (MD) simulations, we construct and investigate atomistic models of wood polymers and of cellulose microfibril aggregates that consists of crystalline cellulose, amorphous hemicellulose and lignin. The atomistic results are upscaled and used in continuum models, using a poromechanical framework thus with full coupling of fluid transport and mechanical behavior. Upscaling to cellular scale is delineated, where the cellular scale is informed through accurate geometrical description using X-ray CT at different relative humidity.

The ensemble of results documents the full co-occurrence of sorption and swelling. This modeling methodology provides the capability to determine material properties and behavior which cannot be directly determined from experiments and to explore new pathways for material development and technology innovation, especially for capacity in terms of moisture-induced deformation.

### **ABSTRACT**

The development of various advanced materials and their subsequent integration into innovative building envelope concepts has the potential to achieve energy savings. Additionally, their usability in practical applications can be enhanced via the use of building energy simulation (BES) methods. Experimental procedures in conjunction with numerical computations could enable the prediction of the future performance of solar thermal façade concepts. The presented study is focused on the thermal response of a transparent insulation material (TIM) incorporated in a façade structure. An experimental prototype of a solar façade element with both a selective and a nonselective absorber was developed for use as part of an opaque building envelope. Experimental measurements were conducted using dynamic outdoor methods with the aim of verifying a BES model. Combined with the measured thermal and optical properties of key materials implemented, an integrated model was developed to simulate the effect on the thermal performance of the TIM-based façade prototype in the EnergyPlus computational engine. This was primarily focused on the capability of the thermo-optical properties of the proposed prototype to respond in an adequate way under transient boundary conditions. In the first part of this study, a specific characterization for the appropriate modelling and simulation of the given solar based prototype is presented. In the second part, the capability of one widely used BES tool is analysed in terms of its ability to model the energy and thermal performance of the presented façade model. The good consistency between the simulation results and the experimental data indicates that the simulation model was reliable when predicting the thermal performance of TIM based façade prototypes, though with some specific limitations. The methodology developed in this study is expected to provide a reference for simulating the thermal and energy performance of TIM-based building elements with two different solar absorbers.

### **KEYWORDS**

Solar façade, Transparent insulation, Selective absorber, Building simulation, Outdoor tests

### **INTRODUCTION**

The integration of transparent insulation material (TIM) as an interstitial structure between glazing panes reduces heat transfer and allows the penetration of solar radiation. It basically provides a combination of different solar and heat transfer processes. In addition, when these systems are also integrated into an opaque building envelope, e.g. as a specific type of transparent insulation façade (TIF) with solar absorber functionality, it can allow a completely different approach to a rather complicated issue. Current building energy simulation programs are not accurate enough to model these complex transparent insulation systems, often because of the simplified thermal and optical models used to solve heat transfer as well as light transmittance. Basically, one dimensional methods are used for both thermal transfer and solar transmittance through these systems (Sun et al. 2018). In practice, with the integration of a

more complex structure within the air cavity of a double glazing unit, there will be a significant effect on the free convection, longwave radiative heat transfer and solar energy transmitted through the system that has not been typically considered. This was recently analyzed by Sun et al. (2017), who comprehensively studied all these aspects in a glazing system with a TIM for building energy saving and daylight comfort. They aimed to develop a comprehensive method of analysing these specific glazing systems (Sun et al. 2017). Specifically, in most of the previously conducted studies, longwave radiation heat transfer, which accounts for two thirds of the total heat transfer across the air cavity (Gan 2001), is neglected within TIM-based structure during numerical modelling. In addition, when integrated in an opaque building envelope with a multilayer construction that employs several low-e barriers, this can result in a completely different situation and give rise to a more complex task that needs to be investigated. Although improved simulation methods have been implemented by Avedissian and Naylor (2008), who used a surface-to-surface model in order to include radiation, they only employed the model to calculate the  $U$ -value of the whole system instead of evaluating the effects of the internal structure on longwave radiative heat transfer. In order to create a proper computational model of a façade construction that contains TIM, it is necessary to determine the thermo-optical physical properties of the material. Through this approach, the required values were obtained from laboratory testing based on spectrophotometer measurements and outdoor in-situ measurements for solar transmittance quantification (Čekon and Slávik 2017). Additionally, the thermal and optical properties were obtained via experimental measurements. All of these are input into the building energy simulation (BES) program DesignBuilder that works under the EnergyPlus computational engine. The main goal of the simulation is to analyse the influence of two TIF prototypes with different solar absorbers on heat transfer through their components using outdoor climatic conditions and subsequently compare the results with real measured data. It is necessary to use this process to properly define the simulation model according to the results of experimental measurements.

## EXPPERIMENTAL TRANSPARENT INSULATION FAÇADE MODELS

Two transparent insulation façade (TIF) samples were designed for the analysis of optical properties behind a transparent insulation system coupled with an additional air cavity layer. Two  $1.19 \text{ m} \times 1.19 \text{ m}$  test prototypes (Figure 1) were built using a system based on the Kapilux (2017) TIM fitted with honeycomb transparent (also may be considered as light translucent) PMMA-based insulation. Each was equipped with a different type of integrated solar absorber (a selective low-e  $SA$  and a nonselective  $nSA$  solar absorber). Thus, the absorber used was the main difference between both prototypes. Both had almost the same solar absorbance level (around 0.94 and 0.96, respectively), whilst their emissivity was diametrically opposite: 0.06 and 0.94, respectively. As a result the difference of the thermal performance between the TIFs is up to 18% due to different solar absorbers. Both prototypes were subsequently tested outdoors throughout the heating season. The TIM system comprises double low-e glazing incorporating honeycomb PMMA transparent insulation with a krypton-filled cavity. The declared thermal and optical properties are as follows: thermal transmittance  $U_g$  is  $0.7 \text{ W}/(\text{m}^2 \cdot \text{K})$ , total solar energy transmittance or solar heat gain coefficient is 61%, and light transmission is 70%. As demonstrated in Figure 1, this prototype may allow the implementation of a ventilation function, though in this study related to the heating period this has not been applied. The second illustration presents a functional scheme of two identical boxes surrounded by a compensation room, in which both samples (reference ( $nSA$ ) and experimental ( $SA$ )) were installed facing south-east at the Central Lab at the Faculty of Civil Engineering at the Slovak University of Technology ( $48^\circ 10' 36''$  north and  $17^\circ 10' 32''$  east). The twin-box measurement apparatus is used to identify and compare the non-steady state

heat transfer through the tested building elements (for more details see Čekon 2013). The monitoring of outdoor ambient temperature  $T_{ae}$ , indoor box air temperature  $T_{ai}$  and the total solar vertical radiation intensity  $I_{gv}$  represents an important part of the tests in relation to this stage of the presented analysis. The compensating room is a zone where both metering boxes are installed; it is controlled in order to eliminate heat flows through the internal box envelopes at a constant interior temperature  $T_{cr}$ .

Figure 1. Test transparent insulation façade (TIF). a) TIF experimental model, b) Test experimental twin-box apparatus scheme, c) BES simulation model

### BUILDING ENERGY SIMULATION MODEL

The simulation model was modelled based on experimental measurements in the building energy simulation (BES) tool DesignBuilder that works under the EnergyPlus dynamic simulation engine. The testing period covered the winter heating season. Real weather data was measured by every two minutes and then implemented in the simulation using the open-source program Elements for creating and editing custom weather files for building energy modelling. An overall experimental setup is assumed for the measured façade elements. It is divided into three zones covering the whole geometry of the simulation model. Each zone is specified and preadjusted with different interior thermal energy management regimes in correlation with real measured values. The façade's TIM component was modelled as a window because it allows solar radiation to penetrate the structure. Accordingly, it was necessary to create another two zones for the appropriate completion of the simulation model. The second zone represents a metering box space with 120 mm thermal insulation all around the envelope, except for the front south-east oriented wall with the measured sample. Depending on outside conditions, the real thermal regime of the zone varied with heat flux values ( $Q$ ) ranging roughly from +50 W (nighttime) to -140 W (daytime) based on response of heating/cooling supply system. This phenomenon was included in the simulation by properly adjusting the schedule of process gains that set the design level of energy consumption due to process activity per unit of floor area. The third zone represents the air cavity between the TIM insulating glazing unit (IGU) and the absorber layer on the wall structure. The TIM IGU was modelled as a triple-glazed window, where the middle glass pane represents the honeycomb TIM with thermo-optical properties. The really small krypton-filled gas cavity (0.01 mm thick) between the outermost glass pane and the middle pane should be created by modelling the obstruction of the interstitial structure so that it is different from the gas cavity. The second larger gas cavity is modelled as a krypton gas cavity according to the dimensions of the façade structure. The innermost glass pane is modelled as low emissivity glass. The dimensions of the modelled glazed structure were completed by a wooden frame.

The above-mentioned methodology for modelling a façade prototype in computer software was implemented in the BES part of this research study. The airtightness of zone structures plays an important role in the modelling of zone air temperature. It is described by the infiltration rate ac/h, which is assumed to be constant throughout the simulation. The most suitable infiltration value in the Twin-boxes zone was set at 1.0 ac/h; the lowest values caused the air temperature to increase in the façade cavity. Additionally, it is more complex to adjust the appropriate thermal conductivity value of the TIM mainly due to its dynamic value – the function of the mean temperature of the TIM and the temperature difference between the two isothermal surfaces (glass panes). The parameters from laboratory measurements taken during a previous study (Čekon and Slávik, 2017) were used for the purpose of configuring thermal and optical properties, as those are considered highly sensitive variables in this study, and characteristics specifically related to transparently insulated components. Table 1 depicts the thermo-optical properties of each layer in both simulated TIF elements.

Table 1. Key thermo-optical properties of TIF elements

Material	Width [mm]	Thermal conductivity [W/(m.K)]	Solar transmittance / absorbance [-]	Outside emissivity [-]

Gypsum board	25	0.2	-	0.9

\* measured according to Čekon and Slávik (2017)

## EXPERIMENTAL AND SIMULATION RESULTS

The experimental results were achieved under outdoor conditions where the maximum sun height above the horizon (about 31°) was at midday. It corresponds to a 31° incline from the normal angle of incidence representing the maximum solar incidence ( $I_{gv}$ ) at the tested location. At the same time, the lowest outdoor ambient temperatures were reached that would allow the results to be used in BES modelling. The testing period was thus specified for the thermodynamic performance analysis of the time-transient winter heating aspect and solar heat gain. The outdoor ambient temperature ( $T_{ae}$ ) varied from a nocturnal -15.0°C up to a diurnal +2.5°C. The incident solar radiation rate ( $I_{gv}$ ) reached a maximum of 900 W/m<sup>2</sup> in the area where samples were measured during totally clear sky conditions. The data presented in the graph below (Figure 2) shows the results of both the real measured (exp) and simulated (sim) values. The difference in the internal air temperature ( $T_{ai}$ ) response and thermal performance of the *SA* compared to the reference *nSA* sample is demonstrated. Although the solar absorbance values of both samples are very similar, the longwave spectrum and thermal emissivity, have a major influence on both obtained results. Low emissivity properties lead to a nearly 2K higher temperature under nocturnal conditions, thus the heat loss due to longwave radiation is recognizably reduced there by the low-e solar absorber. The simulated model *SA* reaches temperatures up to 1.5K higher compared to the real measured data. During the daytime, all simulated values are significantly higher. Here, the calibration of optical parameters seems to be needed in order to match the real measured values. With cloudy conditions and a low level of solar radiation exposure, i.e. the first two days of the study, the peak difference between the measured and simulated internal temperatures is up to 5 K, while between *SA* and *nSA* it corresponds to the measurements. The next two days are characterized

by the maximum level of solar radiation exposure obtained. At the beginning, good agreement was achieved with *SA*; however, *nSA* does not correspond well and additionally both models have their maximum peak at the same level. The second simulated clear sky day does not agree with the measured progressions. Instead, it responds in the following manner: the lower the outdoor temperature was, the higher the indoor air temperatures simulated.

Figure 2. Experimental and simulation results for the presented period

## DISCUSSIONS

The integration of solar based absorbers (selective/non-selective) behind a complex fenestration system enhanced with TIM is a challenge for building simulation modelling throughout the climatic year, mainly due to the difficulty of making reasonable performance predictions. The experimental part of the research demonstrates that the presence of low-emissivity surfaces within a façade air cavity based on Trombe wall principles has a significant effect on the internal space temperatures recorded during the presented experimental measurements. A comparison between experimental and simulation results indicated agreement occurred only during nighttime periods with the *nSA* model. At time periods with high solar radiation the temperature gap between the *nSA* and *SA* models is nearly zero. This leads to the fundamental obstructions of the BES calculation concerning the radiation exchange between surfaces with low-emissivity (view factors). The simulation also showed that the operating temperature of the façade cavity zone has nearly equal values to the air and radiant temperature, which indicates that low emissivity surfaces have a higher effect. In the case where a zone is defined as a cavity, it is also important to adjust the zone's inside convection algorithm in order to properly describe surface heat transfer phenomena. The utilised BES tool provides a "Cavity algorithm" that correctly calculates the convection coefficients for a narrow sealed vertical cavity based on the ISO 15099 standard as well as the "Full interior and exterior solar distribution algorithm" for the transmission of solar radiation through glazing. As the thermo-optical properties of the TIM layer inside the fenestration system were assumed to be static values, they might be used for the proper performance prediction of this façade system. Nevertheless, the above-mentioned complexity of the simulation of the dynamic value of thermal conductivity of a TIM glazing unit with regard to the temperature difference of each surface might be improved in a better manner through programming in the Energy Management System under EnergyPlus.

## CONCLUSIONS

Based on experimental data concerning a transparent insulation façade (TIF) concept with a TIM glazing unit and two different solar absorber types (selective and non-selective), a performance prediction model was created in BES tool. The process of simulation modelling according to experimental measurements is quite a tricky affair but could provide the first insight into the thermal/optical process of a specific solar based building façade. It was demonstrated by this study that thermo-optical properties of the TIM layer inside the fenestration system as static values might be used for the performance prediction of this façade system. Though, the validation of the simulation model determined the causes of deviations between real and simulated outputs of the amount of overall heat transfer through the investigated TIF components. As result of that, current BES programs appear to have problems specifically with surface radiant heat exchange mainly during high levels of impinging solar radiation. BES coupling with computational fluid dynamics modelling could be further step of clarifying of this complex issue.

## ACKNOWLEDGEMENT

This research is under the project GJ 16-02430Y "Contemporary concepts of climatically active solar façades integrating advanced material solutions" of Czech Science Found. and by the Slovak Research and Development Agency under the contract No. APVV-16-0126.

### **ABSTRACT**

Advances in long-span glazed structures and interest in high-performance building design has proliferated semi-conditioned spaces with large areas of overhead glazing. These spaces are often programmed with intermittent occupation where variability of the indoor climate is an intentional factor of the experience. Technological options for glazed canopy structures have likewise evolved, gaining functions such as power generation which diversifies the benefits of overhead glazing beyond weather protection and daylighting. Here we model the multiple benefits of current and emerging toplighting technologies deployed in the overhead glazing of a train station and compare power generation and visual comfort. A common building integrated photovoltaic system comprised of monocrystalline cells embedded in the interlayer of laminated glazing is compared with a dynamic, tracking solar collector technology that concentrates and largely intercepts direct solar energy but is transmissive to diffuse sky radiation. The concentrating system generates 6% more power annually with a 70% higher peak power production compared to a typical fixed PV system while at times significantly reducing glare.

### **INTRODUCTION**

Transparent and semi-transparent canopies are deployed in architecture to hybridize indoor and outdoor environments, providing the benefits of light and open space with some control of the indoor climate. These structures date to the first moments of technical possibility, with the cast iron and ribbon glass pavilions of the Victorian era, such as London's Crystal Palace in 1851. Contemporary designers incorporate emerging technologies into canopies to improve their performance against criteria of aesthetics, comfort, climate control, and the project's net energy use profile. The large surfaces of transportation structures offer unique opportunities to introduce photovoltaic (PV) generation. If employed correctly, PV not only generates power, but tempers the risk of over lighting and over heating the space under a canopy. Glazing-laminated building-integrated PV (LBIPV) has gained traction in this capacity.

The power output of LBIPV relative to fully opaque fixed panel photovoltaics has limited their desirability in larger projects. Alternatives to LBIPV are under development to increase power generation and lighting benefits. An Enclosure-Integrated, Daylighting, Tracking Solar Collector (EIDTSC) is designed to reduce glare and over-lighting by separating direct and diffuse insolation with Fresnel optics (Figure 1). By treating the direct and diffuse forms of

energy differently, sky-sourced luminance is transmitted through the optics to remain useful as light, but direct-beam energy is intercepted, and focused on multi-junction concentrator PV cells. Efficient generation, shading, and diffuse daylighting are simultaneously provided.

**Figure 1. Envelope integrated daylighting tracking solar concentrator, A operational diagram and, B pre-production hardware. Image: HeliOptix LLC.**

With physical mock-ups and testing, the EIDTSC is shown to moderate the solar luminance through a fenestration system, by reducing the intensity from direct sun, predominantly allowing diffuse daylight to transmit, and buffering fluctuations due to passing clouds or external shadows (Novelli et al., 2018). Additionally, simulations indicate the system produces power at levels similar to silicon flat-panel photovoltaics but incorporates less than 1% the semiconductor material (Novelli et al., 2015).

## METHODS

A typical LBIPV system and an emerging EIDTSC system are simulated in the canopy over a transit platform in southern California and compared for power generation and visual comfort. Simulations assume TMY3 weather data from station #722970 with a 85m wide by 318m long canopy, for a total area of ~27,000m<sup>2</sup>, oriented -2.6° from North. To manage simulation times, glare renderings use a subset of the canopy 85m wide by 132m long.

The total number of cells or tracking modules for both systems was non-trivial when deployed across the large area of the train station roof and required material functions and parametric scripting to manage the geometry. Additionally, the EIDTSC system tracks the direct beam of the sun to maintain high optical concentration ratios which requires a dynamic repositioning of the modules and racking in the model for each timestep requiring further parametric scripting. Simulating power generation for the two systems also required distinct methods due to the dynamic nature of the EIDTSC system. Where PV Watts (Dobos, 2014) is used for simulating the power output of the static LBIPV scheme, a custom model is used to calculate the EIDTSC output on an hourly timestep basis (Novelli, 2015). While the EIDTSC concept is capable of simultaneously producing both electricity and useful thermal energy, this study describes a version which is passively cooled and does not actively collect heat. Visual comfort and discomfort glare from train platform views are modeled using Radiance tools (Ward, 1994) and Evalglare (Wienold and Christofferson, 2006). The material representation of the LBIPV system employs a *mixfunc* material with a *perforate.cal* function (Mischler, 1993; Roudsari and Waelkens, 2015) which is suitable to describe the orthogonal array of PV cells in planar glazing. The EIDTSC system uses a custom material to model the concentrating optics also based on a *mixfunc* material with a *icsf4.cal* function (Aly et al., 2015). The *icsf4.cal* function reduces the transmittance to zero within a 2° angle of acceptance to model the concentration and absorption of light by the optical train and receiver assembly. Rays incident at an angle greater than 2° are transmitted according to the base *glass* material.

**Figure 2. Visualizations of the train station canopy using laminated building integrated photovoltaics, LBIPV (left), and the envelope integrated daylighting tracking solar concentrator, EIDTSC (right).**

The 3-d geometry of the train station is modelled in Rhinoceros using the Grasshopper plugin to parametrically generate and position the EIDTSC system geometry. For a glazing unit the custom grasshopper scripts will generate an array of concentrating Fresnel lenses, rear receiver assemblies, and aluminium racking rails based on dimension and clearance tolerance inputs. The EIDTSC array is aligned to track the sun using the Michalsky (1988) solar position algorithm with custom Grasshopper scripts. Additional Grasshopper plug-ins for various supplementary purposes include Elefront, and Ladybug/Honeybee.

Methods for simulating BIPV power generation are well-developed. Here we employ the PV Watts calculations (Dobos, 2014) to simulate the LBIPV, assuming monocrystalline silicon (CSPV) cells laminated into canopy glazing. Simulation of the EIDTSC is based on previous work by Novelli (2015), although the thermal generation described in that work is not modelled, only electricity. Multijunction CPV, Fresnel concentrating lenses, and active tracking is employed in this system. Table 1 lists relevant simulation parameter values.

**Table 1. System simulation parameters for EIDTSC and LBIPV.**

System Simulation Parameter	LBIPV	EIDTSC
PV type	CSPV, full wafer	MJ-CPV, 64mm <sup>2</sup> format
PV or CPV efficiency	20.30%	38.50%
Temperature coefficient	-0.38/°C	-0.05%/°C
Active aperture – glazing area ratio	71%	79%
Cell-glazing area ratio	71%	0.06%
Initial degradation (sun exposure)	1.50%	0%
Wiring losses	2%	2%
Soiling losses	2%	2%
Module mismatch losses	2%	2%
Connector losses	0.50%	0.50%
Deviation from reference conditions	1%	1%
Optical Efficiency		85%
Range of motion limit		72°
Glazing transmittance (external)		87%
Parasitic losses (motor control)		5%

Visual comfort and glare under the glazing canopy of the train station are simulated from South and West facing viewpoints using Radiance validated software tools and Evalglare to calculate the Daylight Glare Probability (DGP) and Daylight Glare Index (DGI) from rendered views (Wienold and Christofferson, 2006; Hopkinson, 1973). Both daylighting systems modelled here require custom material definitions. The individual 0.152 m diameter cells of the LBIPV system are spaced at a distance of 0.16 m for an opaque coverage of 71%.

To reduce the LBIPV model geometry the glazing unit (1.52m width x 4.57m height) is modified with a *mixfunc* radiance material primitive that mixes a *glass* background material with a *plastic* foreground/cell material using the *perforate.cal* function developed by Georg Mischler (1993) to create an orthogonal array of dots to represent the LBIPV cell array with equal percent coverage. The glass material uses a 0.87 transmittance for a 6mm clear/1.52mm PVB/6mm clear laminate built in LBNL Optics. The plastic material uses a 0.02 reflectance material for the silicon cells. This mixfunc material definition allows for an accurate and fast representation of the BIPV array.

While the EIDTSC system cannot be accurately reduced to a bulk material property as is used for the LBIPV, components of the system can. Within a 2° cone of acceptance from the surface normal, the Fresnel concentrating optics focus direct normal solar radiation onto secondary optics and a high efficiency solar cell, while off axis radiation refracts through the lens. In order to model the light loss from the concentrating optics a custom material is defined for the planar lens geometry where transmittance drops sharply to 0 within the 2° angle of acceptance. Details of this material definition can be found in Aly (2015). This material definition allows for a reasonably accurate and fast representation of the complex optics useful glare renderings.

## RESULTS AND DISCUSSION

The EIDTSC system generates 6% more power annually with a 70% higher peak power production compared to the LBIPV system while at times significantly reducing glare. The available surface incident insolation for the two systems is 1304 and 1970 kWh-I.m<sup>2</sup>a respectively. While the concentrating EIDTSC system has a higher effective annual power conversion efficiency of 19.3% it concentrates and converts only direct-beam insolation compared to the LBIPV system which can convert both direct and diffuse insolation. This higher available incident insolation for LBIPV in part accounts for the similar net annual power generation. However, the EIDTSC system generates a significantly higher peak power output of 202 W/m<sup>2</sup> compared to the LBIPV peak power of 119 W/m<sup>2</sup>. Simulated power generation results are described in Table 2 and Figure 3.

**Table 2. Simulated power generation of LBIPV and EIDTSC.**

	LBIPV	EIDTSC	unit
Surface-incident insolation available	1970 (global)	1304 (direct)	kWh-I/m <sup>2</sup> a
Net annual power generation	237	251	kWh-E/m <sup>2</sup> a
Effective (annual) efficiency	12.0%	19.3%	
Peak power	119	202	W/m <sup>2</sup>

**Figure 3. Annual power generation of LBIPV (top) and EIDTSC (bottom).**

At times glare in the space is significantly reduced with the EIDTSC system due to the concentration and absorption of the direct beam component of the sun. This feature of the EIDTS system provides more even illumination under the canopy with less disturbing contrast between directly transmitted sun and diffusely illuminated shadows. However, the reduction in glare is not uniform at all times simulated particularly when the EIDTSC modules do not provide overlapping coverage around noon. At these times the EIDTSC canopy maintains or even slightly increases glare. In both canopies, when the sun is aligned through a gap in the PV cells or concentrating modules with the observer's viewpoint, glare is inevitable.

Figure 4. Daylight Glare Probability and Daylight Glare Index from a South facing viewpoint for the LBIPV and EIDTSC canopies at the solstices and spring equinox.

Figure 5. Daylight Glare Probability and Daylight Glare Index from a West facing viewpoint for the LBIPV and EIDTSC canopies at the solstices and spring equinox.

The DGP and DGI metrics do not always agree in magnitude across the times simulated, however the general trends of reducing or increasing the likelihood of glare are somewhat consistent. While DGP is generally considered to be the metric with better correlation in sidelit office settings, both of these commonly accepted daylight glare metrics may be inadequate for bright toplit spaces (McNeill, 2016). Modelling of the concentrating optics of the EIDTSC canopy may be further improved employing a high-resolution tensor tree BSDF with photon mapping for combined forward and backward ray tracing (McNeil, 2013; Schregle, 2015).

## CONCLUSIONS

The large surfaces of transportation structures offer unique opportunities to introduce photovoltaic glazing canopies. If employed correctly a photovoltaic toplit roof canopy not only generates power but tempers glare in the space. The typical laminated BIPV system and emerging envelope integrated daylighting tracking solar concentrating system simulated here have comparable annualized power generation. However, the concentrating canopy enables a 70% higher peak power output and can at times significantly reduce glare. The EIDTSC canopy may be better suited in climates where direct solar loads dominate thermal and visual comfort. While the glare results are non-uniform for all timesteps simulated, annual simulations, improved optical representation of the concentrating optics, and the further development of metrics for brightly daylit spaces can reduce uncertainty.

### **ABSTRACT**

Santiago de Chile is a city with a semi-arid climate, with prolonged periods of high temperature and solar radiation. In recent years, in this city, office buildings have been built with high window to wall ratio (WWR) facades. 65% of the office buildings built in the period 2005-2014 have a WWR higher than 60%. Only 5% of these buildings showed an efficient glazed façade solar protection device. One of these systems corresponds to an exterior textile solar protection. This type of systems, together with the perforated screens, could be effective solutions for the solar protection of glazed facades, reducing the cooling energy consumption of buildings, without risking the visual comfort of the occupants. The objective of this research is to evaluate the solar transmission and lighting of seven perforated solar protection systems. Three of these systems correspond to external textile solar protections, and the remaining four are perforated metallic screens. The evaluation was carried out by applying an experimental protocol in two different calorimeters that simulate an office space. In one of the calorimeters, the solar protection systems are installed while the other is used as a reference without any solar protection system. Measurements were made with illuminance sensors and pyranometers. The horizontal illuminance sensors from Konica Minolta (T10) were installed outdoor and at different points inside the calorimeters. Near the facade, vertical indoor and outdoor pyrometers were installed (Kipp Zonnen, CMP11 and Sp Lite 2). The measurements on the north facade are made in summer on clear days. The measurements showed a reduction in solar transmission of 82.1% (metallic screen, 40% drilling) to 94.7% (cloth, 3% drilling) and from 70.8% to 95.4% in the transmission of lighting respectively.

### **KEYWORDS**

Complex fenestrations systems, perforated screens, solar protection fabrics.

### **INTRODUCTION**

In recent decades the use of highly glazed facades in office buildings has become widespread. This has caused high cooling energy consumption and severe problems of thermal and visual comfort in users of these buildings. The problem described has also been observed in Santiago de Chile, a city with a semi-arid climate, with prolonged periods of high temperature and solar radiation. Office buildings of this city show a much higher cooling than heating energy consumption. To improve the thermal and lighting performance of these buildings, different external solar protection systems applied on glazed facades have been developed. The geometry and materiality of these systems are varied, and they can be fixed or mobile. The latter may be adapted automatically to the weather conditions of the exterior and the thermal and light standard required in the interior. The solar protection systems can be formed by a non-specular layer (i.e., louver or blinds), or perforated screens, which together with the glass of the envelope form a "complex fenestration system" (CFS).

CFSs may significantly reduce the solar heat gains through glazed facades and allow control of the natural light transmission so that these systems, as they are well designed, can significantly influence in decreasing buildings energy consumption, without affecting visual comfort (Bustamante et al., 2014). Given the possibilities offered by solar protection, in its natural lighting transmission properties, glare control, and outward vision, perforated or semi-transparent systems offer a good option for use on glazed facades. The use of perforated screens as solar and light protection is a current trend in the design of buildings (Blanco et al., 2014), and in Chile, it was with good results. On a completely sunny summer day, in a building in Santiago with an exterior textile screen on a south-west facade (see figure 1), the radiation and horizontal illuminance measured in the vicinity of the façades were reduced by approximately 95% and 75% respectively, about values measured abroad. (Bustamante et al., 2014)

Appelfeld et al. (2012) studied the solar transmission of a micro-perforated protection system and compared it with rollers and venetian blinds. They conclude that the effect of the micro-perforated system similar to venetian blinds. Mainini et al. (2014) studied different perforated and grilled metal screens with 40% perforations. They obtained the values of light transmission and solar experimentally. Blanco et al. (2014) developed a theoretical model to predict the thermal behaviour of double facades that was validated by experiments. The panels evaluated allow to filter the direct radiation and significantly reduce the temperature of the interior glass.

Stazi et al. (2014) studied the impact of perforated aluminum panels as solar protection system (SPS), on energy consumption and thermal comfort in a Mediterranean climate in Italy. Vera et al. (2016) and Bustamante et al. (2017) developed a tool for integrating the energy and light analysis of different solar protection systems with highly complex geometries. In particular, solar protection systems with curved and perforated aluminium horizontal slats are studied to implement the analysis during the early design stages of office buildings. They conclude that the use of this type of SPS allows achieving energy efficiency standards in buildings without risking visual comfort. On the other hand, Vera et al. (2017), in perforated SPS, studies variables such as the percentage of perforations, distance between the slats and the angle of inclination of these to minimize energy consumption ensuring visual comfort.

The impact of SPS on solar and light transmission in CFS has not been extensively studied through experimental techniques. The objective of this paper is to show and analyze the effects on the reduction of solar and light transmission in CFS that have an exterior SPS. To this end, an experimental protocol has been implemented in a laboratory that represents an office space.

## **METHODOLOGY**

### **Experimental setup**

The laboratory of solar protection systems corresponds to two calorimeters that simulate a real-scale office. Wall insulation of calorimeters correspond to 15 cm of polyurethane, and there exists a 100% glazed facade with double glazing, facing north. Dimensions of the calorimeter are 3,7 x 2.6 m, while it is 2,65 m high.

One of the calorimeters always remains without solar protection system, while in the other the protection system to be evaluated is installed, to determine the percentage of indoor reduction of lighting and solar radiation (see Figure 1).

Figure 1: Laboratory for solar and lighting transmission

To perform the measurements, the laboratory has two data acquisition units of Agilent Technologies, 9 lux meters T10 of Konica Minolta, three pyranometers CMP11 and 9 Spile 2 of Kipp & Zonen.

### Illuminance measurements

Each calorimeter has 4 lux meters at the working plane level. Also, an exterior lux meter is available. See Figure 2.

Figure 2. Position of lux meters in test cells

### Solar radiation

The different types of pyrometers are located according as shown in figure 3.

Figure 3. Position of different types of pyrometers in test cells.

### Solar protection systems

The following table shows the sun protection systems that have been evaluated. The characteristics of its transparency or percentage of drilling are presented, together with the day considered for its evaluation. Each system was measured for six continuous days, of which a completely clear day was chosen. This is the day that has been denoted “day of measurement, and that is reported in Table 1. Measurements were made in summer 2016.

Table 1: Evaluated solar protection systems

ID	Description	Commercial name of Hunter Douglas	% of perforation	Day of measurement
1	Fabric 3mm	Texscreen	3%	17-Jan-16
2	Fabric 5mm	Texscreen	5%	21-Jan-16
3	Fabric 10mm	Texscreen	10%	30-Jan-16
4	Metal	Screen Panel XL	10%	21-Feb-16
5	Metal	Screen Panel XL	20%	09-Feb-16
6	Metal	Screen Panel XL	30%	27-Feb-16
7	Metal	Screen Panel XL	40%	02-Mar-16

### RESULTS

Table 2 shows the variation of the illuminance on the measurement day for system 7 (metal screen with 40% of perforation). On the left, test room results with solar protection are shown and on the right the results for test room without solar protection. Also, Table 3 shows the variation of solar radiation in system 7 for measurement day on the test room with and without solar protection respectively. Numbers on the graphs represent the position of the lux meter or pyrometers respectively.

Table 2: Illuminance (lux) for some of the solar protection systems

Table 3: Solar radiation transmission ( $\text{W/m}^2$ ) for some of the solar protection systems

Table 4 shows the percentages of reduction of solar radiation for each protection system in  $\text{Wh/m}^2$ , corresponding to the sum of the total radiation during the day of measurements. The calculations were made based on the results of pyrometers 2 and 7. Table 4 also shows the percentage of reduction of illuminance considering lux meters 2 and 6.

Table 4: Reduction on solar radiation and illuminance due to solar protection systems

ID	% of perforation	Solar radiation in test room with solar protection ( $\text{Wh/m}^2$ )	Solar radiation in test room without solar protection ( $\text{Wh/m}^2$ )	% of solar radiación reduction	% de illuminance reduction
1	3%	33.28	520.92	93.6%	95.4%
2	5%	27.39	744.95	96.3%	96.3%
3	10%	56.48	744.26	92.4%	90.7%
4	10%	42.28	1073.30	96.1%	93.3%
5	20%	82.51	931.60	91.1%	88.2%
6	30%	230.68	1201.90	80.8%	75.1%
7	40%	212.58	1302.20	83.7%	70.8%

## CONCLUSIONS

The results show a very significant reduction in the light transmission (illuminance) and in the solar transmission through glazed façades that have perforated solar protection, compared with the case in which the glazed façade does not contain a solar protection system. Measurements showed a reduction of solar radiation transmission through facades with metallic screens between 96.1 % -when their perforation is 10 % - to 80.8% when they have a 30 % of perforation. Reductions in light transmission over 70% and up to more than 90% are observed in these metal protection systems. On façades with fabric solar protection systems, reductions of over 90% can be observed both in the transmission of solar radiation and lighting. The reductions shown in this report are valid for the period of measurements (summer 2016) and Santiago de Chile (33 ° 27 'S). Also, it is important to indicate that the measurements are made on different days, which present different meteorological conditions and in which the solar angle of incidence on the façade varies from day to day. This avoids a strict comparison of results between systems. However, for the analyzed scenarios, significant solar and light reductions is observed in the different types of perforated facades. This is an interesting property in these systems because together with it, these systems allow the vision to the outside, which is important for the comfort of the people.

Also, the measurements performed consider a north oriented glazed façade. It is recommended to carry out these measurements in different orientations in which the incident solar radiation is more critical, such as east or west orientations.

### ABSTRACT

Net-zero energy buildings oftentimes rely on solar-based building integrated technologies to offset energy use and achieve their goals. However, the value of a particular system is difficult to assess given that these technologies often bring about complex interactions with the indoor environment, and building energy management systems. The approach chosen in this study was to propose and test a simple index called the *Solar Efficiency index (SE index)*, which makes it possible to characterize the performance of building envelopes with integrated solar systems. The index was used to investigate the effect of different configurations of a PV integrated shading device on an office building in Norway. The results provided by the index allowed estimating how much solar energy was converted and how useful that energy was to the building in terms of load matching. This provided a picture of the building's energy autonomy.

### KEYWORDS

Low Energy Buildings; Parametric Analysis; Load Matching; Solar Efficiency Index; Building Envelope.

### INTRODUCTION

Sustainable building concepts such as net-Zero Energy Buildings (net-ZEB) or Zero Emission Buildings (ZEB) have increasingly become part of European building policies (D'Agostino et al., 2016). By definition, in order to reach a net zero balance, ZEBs and net-ZEBs must feed as much excess energy back into the grid as they purchase from the utility (Sartori et al., 2012). This design strategy is based on combining highly energy efficient building envelopes (Justo Alonso et al., 2015) with systems allowing to harvest and store renewable energy sources (RES). But reduced energy use and on-site production of heat and electricity, may lead to a seasonal load mismatch in the balance of energy use vs energy converted (Lindberg et al., 2016). This issue is especially critical in Nordic climates where solar radiation is relatively abundant during the summer while energy use is low, and the reciprocal during the winter.

As net-ZEBs and ZEBs become more popular, there is an increasing need to develop strategies in early design phase to improve load management and grid interactions. Increased energy autonomy can be achieved through energy storage, but isn't currently an economically viable option at single building scale given the techno-economic context (McKenna et al, 2017). Other approaches have been to optimize building systems such as heat pumps, or RES technology size and placement to best cover the energy loads (Dar et al., 2014). From a broader energy management point of view, load matching is an important topic of discussion, and fosters concern regarding the capacity of electric grids to adapt to future needs. In response to this need the International Energy Agency (IEA) in the Annex 67 created an energy flexibility indicator (Grønborg Junker et al., 2018). Previously, the IEA in the task 40 had reviewed Load Matching and Grid Interaction (LMGI) indicators and distributed them into four categories (Salom et al.,

2011). The findings showed that LMGIs are highly dependent on the timescale considered and more often than not, a shorter time step will improve their accuracy (Voss et al., 2011). Designing low-energy buildings with RESs is not a straightforward task and requires careful balancing of parameters; this is because different uses of solar energy may have antagonistic purposes (e.g. visual comfort vs thermal comfort). The study presented in this paper deals with the development and testing of a new metric called the Solar Efficiency index (SE). The utility of the SE index is to characterize the extent to which different RES building envelope designs are able to utilize available solar radiation to reduce the building's energy use, while still maintaining high-quality indoor environments in terms of thermal and visual comfort. The goals of this study are: (i) define a new indicator called the solar efficiency index of the building skin; and (ii), to test the indicator on different envelope configurations in a Nordic climate by assessing its suitability to communicate the performance of the building in terms of solar energy use and load matching.

## METHODS

This work was based on numerical simulations carried out in the dynamic building performance simulation tool IDA ice. The SE index was used to evaluate the simulation results of a case study based on a parametric analysis of the possible configurations for a PV integrated shading device (PVSD). The index was used to evaluate the amount of energy converted and how useful that energy was to the reference building in terms of hourly load matching.

### Description of the reference building model

The reference model used for this study is a conceptual ZEB office building developed by (Dokka et al., 2013). The simulations were run using an EPW file for Trondheim, Norway. The inputs for the HVAC system, internal loads and domestic hot water demand were taken from the Norwegian Standard NS3031:2016 and Norwegian Passive House standard NS3701. A proportional control strategy for artificial lighting based on measured daylighting levels was used in peripheral zones during operation hours to ensure a minimum average of 500 lx at 0.8m from the floor level. Specifics about the building and energy systems are given in Table 1.

Table 1. Characteristics of the base case building model used in the study

Element	Area	Value
Heated floor area/volume	1 980 m <sup>2</sup> / 7 128 m <sup>3</sup>	
Building envelope	2 306 m <sup>2</sup>	
External walls	860 m <sup>2</sup>	U= 0.12 W/m <sup>2</sup> K
External roof	495 m <sup>2</sup>	U= 0.09 W/m <sup>2</sup> K
Floor against cellar	495 m <sup>2</sup>	U= 0.11 W/m <sup>2</sup> K
Windows and doors	WWR 14%	U= 0.75 W/m <sup>2</sup> K
Normalized thermal bridge value		$\Psi''=0.03$ W/m <sup>2</sup> K
Air tightness		N <sub>50</sub> <0.3 ach@50 Pa
Heat exchanger efficiency		86 %
Specific fan power		1.00 kWh/m <sup>3</sup> /s
Heat pump coefficient of performance for heating/ cooling		3 /4.5

### Description of the different building envelope configurations investigated

Using a common basic building geometry, 7 scenarios were defined as case studies where the changing parameters were the presence or not of a photovoltaic shading device (PVSD), its design configuration in terms of spacing between the louvre-blades and angles, the orientation of the building site and the window to wall ratio (Table 2). The PVSD was modelled according to Taveres-Cachat et al. (2017). The conversion efficiency was assumed 15% after accounting for all the system losses, including self-shading and DC to AC conversion.

Table 2. Description of the scenarios investigated in the study

Case	Description
0	Base model with no shading system installed
1	Base model where all the south facing windows are equipped with an external shading system without PV coating. Inter-blade distance 132 mm, tilt angle 15°.
2	Base model where all the south facing windows are equipped with an external PVSD. Inter-blade distance 132 mm, tilt angle 15°.
3	Base model where all the south facing windows are equipped with an external PVSD. Inter-blade distance 111 mm, tilt angle 15°.
4	Base model where all the south facing windows are equipped with an external PVSD. Inter-blade distance 95 mm, tilt angle 0°.
5	Base model where all the south- and north facing windows are equipped with an external PVSD shading system. Inter-blade distance 132 mm, tilt angle 15°, WWR = 22%.
6	Case 1 with the building orientation changed by 90° and PVSD on east and west facing windows

### Description of Solar Efficiency (SE) index

The models were first simulated in a theoretical context without solar radiation (neither direct nor diffuse), giving the hourly energy use  $E_{0\ net}$  (kWh/m<sup>2</sup>). The simulations were run a second time with solar radiation which yielded the energy use defined as  $E_{sun\ net}$  (kWh/m<sup>2</sup>).

These quantities were defined as follows:

$$E_{0\ net} = \int_{t_1}^{t_2} e_0(t) dt \quad (1)$$

$$E_{sun\ net} = \int_{t_1}^{t_2} (e_{sun}(t) - i(t)) dt \quad (2)$$

Where  $e_{sun}(t)$  [W] and  $e_0(t)$  [W] were respectively the electrical power demand required for heating, cooling and lighting for the building with and without the contribution of solar radiation at the instant  $t$ .  $i(t)$  [W] was the amount of electric power being converted at the instant  $t$ .

The solar efficiency index was defined as:

$$SE_{index} = \frac{E_{0\ net} - E_{sun\ net}}{E_{0\ net}} \quad [-] \quad (3)$$

The solar efficiency index was calculated with hourly steps over the period of one year. Index values in the ]0; 1] interval indicated that the building efficiently used solar radiation to lower its energy use compared to a situation with no solar radiation. An SE index value of one meant the building was completely self-sustaining (perfect load match) and any value above one meant excess energy was being sold back to the grid. An SE index value equal to zero implied that either no solar radiation was available, or the building was not able to use solar radiation to reduce its energy demand. Index values below zero indicated that the building had to use more energy to operate when there was solar radiation available than if there was not any.

## RESULTS AND DISCUSSION

The SE index was calculated for all seven cases. The resulting SE index values are plotted as cumulated hourly frequency distributions to help visually assess the performance and identify both situations of under- and over energy production in Figure 1. Horizontal bars delimiting  $SE = 0$  and  $SE = 1$  highlight the different SE index value intervals. For all cases the SE index line crossed the lower threshold  $SE = 0$  before the 0.15 marker, meaning that all configurations partially used solar energy to reduce energy use at least 85 % of the time. As anticipated, cases

0 and 1 performed the worst; crossing the lower threshold last and never yielding an SE index value above 0.7 because of the absence of energy conversion. Case 3 and 5 were seemingly the most efficient at using solar radiation with higher average SEs, but led to an energy surplus 15-20 % of the time. Cases 2 and 4 performed almost identically and provided the least conversion surplus. However, despite this, the values yielded were on average below those of other PVSD cases. Lastly, case 6 had satisfying SE index values with less energy surplus.

Figure 1 SE index for all cases as a cumulated frequency

The SE index results are analyzed further using the individual frequency distributions shown in Figure 2. The comparison of cases 0 and 1 shows that the increase in energy use due to lower solar gains did not outweigh the benefits of a reduced cooling demand, despite the study being in a heating dominated climate. Moreover, the results for cases 2-6 highlight that adding PV conversion was immediately sufficient to reduce the number of hours with negative values. However in case 2, the introduction of PV conversion seemed to have mainly shifted hours from the  $SE < 0$  to the  $SE > 1$  bracket. This occurred without significantly improving the rest of the hourly distribution when compared to case 1; suggesting that the energy converted was most often insufficient to cover the building load. Similarly, only small improvements were achieved in case 4, as the increase in energy use due to reduced solar gains counteracted the benefits of the additional PV material. Case 5 benefited from increased PV capacity and daylight availability thanks to a higher WWR. It yielded a relatively better SE index than the base cases but had the largest amount of hours with energy conversion surplus. Case 6 provided good SE index values, but showed that east and west facing PVSDS configurations are unlikely to be competitive with south facing systems at equal number of equipped windows. Finally, as previously suggested, case 3 which was an intermediate configuration in terms of louver-blade count, achieved the best performance with the highest mean SE index value for a WWR = 14%, and the most hours in the  $0.6 \leq SE \leq 1$  range.

These findings supported the conclusion that the relationship between higher SEs and increased amounts of PV installed is not a linear. Thus, adding more PV material in the shading system using a larger count of blades was beneficial up to a certain point, beyond which the benefits of additional PV conversion no longer outweighed the additional energy use due to low solar gains.

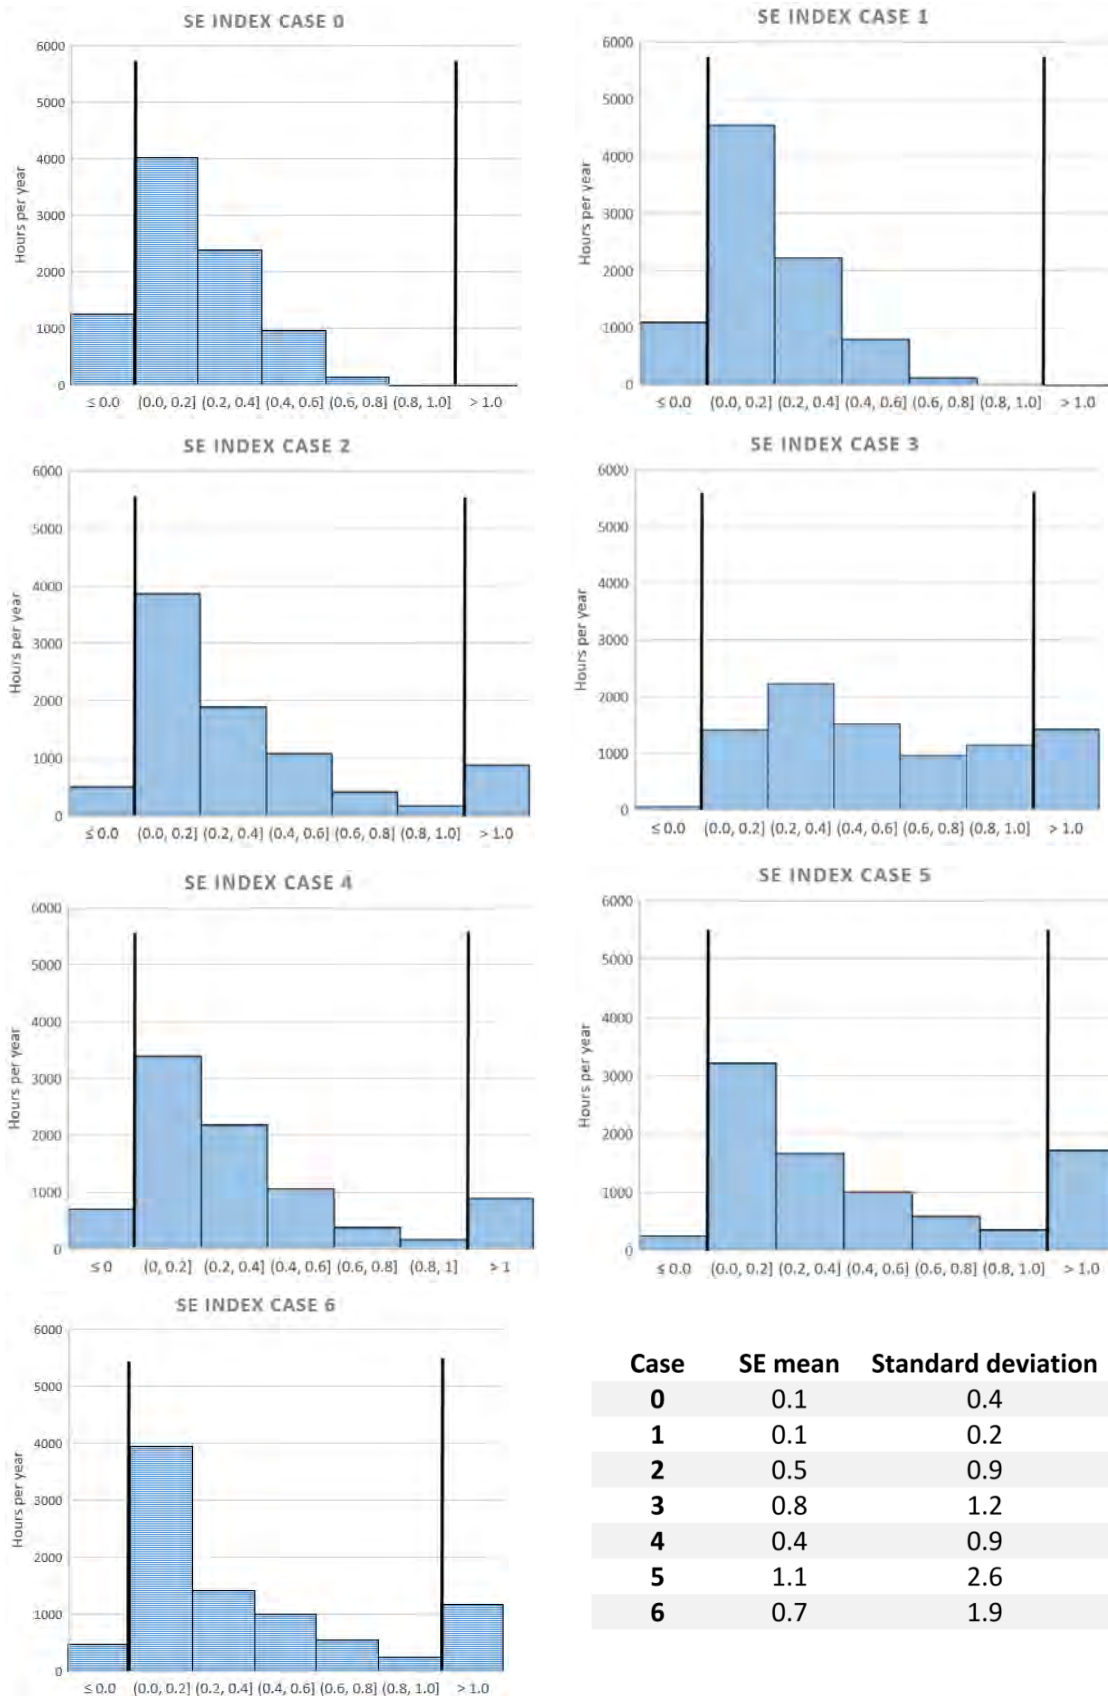

Figure 2 SE index values plotted as frequency distributions for each case.

## CONCLUSION

The SE index was used to evaluate seven different design configurations of a building with PVSD through a parametric analysis. The SE index was successfully able to capture the differences between the cases investigated, and highlighted the most promising configuration. This scenario corresponds to the best balance between increased PV conversion and solar gains reduction, without raising significantly energy use for heating and lighting. Other parameters that could influence SE index results are the load profile of the building (energy use timing), and the total energy use for the building. Refining the index with smaller value intervals might also be useful in some cases, because two scenarios may perform very similarly in reality but may not appear to do so in the result visualization depending on how the thresholds are set. Plotting the cumulated frequency is therefore an important first step. Overall, the SE index is proposed as a simple approach to help communicate and compare the benefits of implementing different solar RESs aiming to increase energy autonomy. SE index results can be improved with control strategies in the building envelope or if integrated energy storage solutions are implemented. The SE index can also be combined with other existing load matching indicators as well as life cycle cost analysis to obtain a holistic view of the building's performance.

### **ABSTRACT**

The development and utilization of new energy has been concerned due to the traditional energy is increasingly scarce. In recent years, solar building has developed rapidly in the construction industry which is a major energy consuming component. As an organic part of the building, the combination of roof and solar energy has become the focus of attention because of its large size, less shielding and other characteristics. Based on the works of recent years' Solar Decathlon, this paper analysed the design and implementation of the integration of solar building's roof and photovoltaic. Meanwhile, taking an office building in Xinjiang, China as an example, the paper analysed the design points and energy-saving situation of the roof photovoltaic building and prospected the application prospect of integrated design method of building's solar roof.

### **KEYWORDS**

Roof, Photovoltaic, Integrated design, Energy-saving

### **INTRODUCTION**

As an organic part of the building, roof is usually used to obstruct the unfavorable weather of outside (Li Baofeng and Li Gang, 2010), protect the bearing and maintain the basic function such as indoor micro climate environment. With the development of building energy-saving concept and the photovoltaic technology, it brings more green connotations into the design of roof (Tao Chengqian, 2004). In the whole life cycle of photovoltaic, it is hard to reduce energy consumption of the upper-middle without big manufacturing technology break through which has reached the limit. But on the other hand, the design quality of photovoltaic power generation system which can be optimized greatly affects the length of the payback period, and it can be achieved to improve efficiency and reduce building energy consumption through the optimal design of the building and photovoltaic. There are still some problems in the design of the integration of roof and photovoltaic, especially many traditional buildings do not reserve enough operation space for developing photovoltaic which makes a high cost of installation of photovoltaic power generation system but the effect is not ideal, such as roof space is not enough, the bearing capacity is insufficient, PV systems cannot select reasonable angle and direction because of the shape of building, components of pollution, severe hot spot effect and so on. At the same time, when designing the photovoltaic array, due to the limit of design method, it is unable to simulate accurately the shadow effect on the components and the component can't be designed toward the matching of peak power generation and peak power consumption, which make the power generation efficiency and profit are reduced greatly.

Up to now, developed countries have accumulated rich experience in the area of integrated design of photovoltaic and photothermal. In 1996, Friedrich Sick showed how to combine photovoltaic and building maximization and summed up the design guideline at the earliest. (Friedrich Sick and Thomas Erge, 1996). Peter Gevorkian put forward a series of main points of solar building design from basic theory to project planning, cost estimation and implemen-

tation methods (Peter Gevorkian, 2007). Bernhard Weller discussed the relation between integration of solar building and architectural design, and introduced the detailed design of several typical cases in detail (Bernhard Weller, 2010). Peder Vejsig Pedersen described the application of photovoltaic technology in the renovation of the new buildings in Copenhagen and the old buildings with low energy consumption (Peder Vejsig Pedersen et al, 2015). Hai Tao introduced the combination method of integration of roof and photovoltaic, and analysed design and energy saving effect of solar energy building (Hai Tao and He Jiang, 2015).

In summary, the scholars in various countries have a lot of theoretical research achievements in the field of integrated design of photovoltaic system and building. However, there are few researches on the application of photovoltaic technology in roof. Particularly, there are less researches discuss that how to combine photovoltaic systems better with roof from the perspective of architectural design.

Based on the current situation, it is important to summary and refine the current technical strategy and problems of integration of roof and photovoltaic, which aims to form the design idea of aesthetic, technology and energy-saving, through analysing the existing integrated design methods of different forms of roof, the paper put forward an integrated design method of roof and photovoltaic based on energy saving and increasing power generation efficiency.

## **METHODS**

Through investigation and survey, the paper summarized the integrated design of roof and photovoltaic, classified design methods and analysed their characteristic based on the Solar Decathlon competition in recent years. In this paper, the integrated design method of photovoltaic and roof is divided into traditional design method and special design method, and the paper illustrated each design method by analysing concrete cases.

Through the summary and analysis of the current research results, the paper analysed the design points and energy-saving situation of the roof photovoltaic building and put forward a design method by using SKETCHUP and PVSYSYSTEM. Based on the characteristics of office buildings, such as large energy consumption, huge electricity supplement, most building load on day time, and higher photovoltaic matching rate, and also, South Xinjiang is endowed with abundant solar energy resources by nature, so we select Turpan, a city in cold area of Xinjiang Province in China, as the research area of office building, which is aimed for a qualitative comparison through the quantitative analysis concluding of the determination of the office building's materials selection and PV component's parameters, and simulating the photovoltaic power generation of the office building.

## **RESULTS**

### **The implementation of integrated design methods**

With the continuous development of roof design ideas, it no longer stay in the passive energy-saving design, but more positive active capacity design appears. In Solar Decathlon competition in recent years, the function of the system which on top of the roof is not overlooked with the limitations of human perspective. Meanwhile, in the architectural design, different roof forms can be used, the integration of solar energy system on the roof is divided into the integrated design of the flat roof, slope roof and curved roof.

### **Integrated design of flat roof**

The solar radiation to the surface of the earth will be at a certain angle to the ground with the change of the longitude, latitude and time. Therefore, the integration of solar energy system and flat roof should generally make the solar angle equipment to adapt to the sun's angle of change, and the system should be set with a certain angle on the flat roof (Zheng Cunyao, 2007). Such as TUC separated the monocrystalline silicon battery array from the roof with the inclination is 2° by using the stent on the flat roof, which ensuring the safety of the system as

well as ensuring power generation efficiency by reducing the backside temperature of the battery (As shown in Figure.1). Many new forms of design arised based on the method of installing solar energy system on the flat roof directly which uses no inclination, such as the University of Florida team put the photovoltaic system directly on the top of the building structure system, which can save costs and cover the living room and the bedroom which have different elevations, so as to make the building to form a whole and to acquire a good physical environment and a unified architectural style (As shown in Figure.2).

Figure1. Overhead PV panel of TUC

Figure.2. Photovoltaic roof of Florida

With the improvement of the solar energy system integration technology, the design of electro-optical system coupling has developed rapidly. For example, HFT has adopted the electro-optical heat collectors (PVT) on the flat roof. It covered PVT collectors as a building exterior finish on the flat roof surface, which replaced the building materials and reflected the high integration design. At the same time, the radiation boards are set under the dark black monocrystalline silicon cell array, it can not only generated electricity, but also recycled the heat generated by photovoltaic power generation to provide hot water. And the vacuum tube collectors installed on the glass ceiling of the "air gap" between the modules also provide heat, diffuse light and shading for the interior, as well as obtain special beauty as the application of the new material in the building (As shown in Figure.3).

Figure3. PVT collector and vacuum collector of HFT

### Integrated design of slope roof

For the slope roof, with the development of integration, the system of solar energy utilization can be directly used as building material for the roof, instead of the additional installation design (Guo Juanli et al. 2012). For example, BER laid the monocrystalline silicon battery assembly directly on the roof of the building, supported by the southward corrugated aluminum and aluminum frames, which is integral with the exterior finish of the building and completed simultaneously with the construction of building, so that reducing the cost and difficulty of repeated construction. At the same time, the building material type's system of solar energy utilization also has the abilities of rain-proof, corrosion resistance, building decorative appearance and strength requirements (As shown in Figure.4).

### Integrated design of curved roof

Considering the characteristics of photoelectric system, it is not suitable for integration on curved roof, but with the continuous development of technology and the improvement of efficiency, some new attempts have been started. For example, in 2013, the works "halo" integrated solar photovoltaic systems on the roof of the building (As shown in Figure.5), it uses a whole new solar technology that make the solar battery as the roof itself rather than fixed on the roof, so as to avoid the limitation of application of the traditional solar battery module

brings. The works can get maximum annual energy efficiency gains without summer housing overheating through the angle of roof for precision design. The roof consists of an area of  $82\text{m}^2$  polycarbonate film, and converting 18% of solar radiation to building usable energy through the integrated single crystal silicon solar cells. Meanwhile, there is a transition area under the eaves of the north and south, which provides a comfortable space for outdoor living.

Figure.4. Slope roof of BER

Figure.5. Curved roof of Halo

### Special design

#### Obscure component boundary

In 2015, SURE HOUSE adopted a photovoltaic roof and a movable shading panel integrated with photovoltaic, not only provided the power, but also provided the building shading and natural lighting control. PV panels are not just a power generating device, but are designed to be a part of the roof. In daily weather conditions, the double folding anti-storm baffle is used to provide the function of shading for building, while in stormy weather, it serves as a major barrier to protect the building. Storm baffle is made of a lightweight composite glass fiber and a structural foam core, which can withstand the load required by the design, and can adjust the indoor light environment through manual operation. The panels are equipped with PV panels which can absorb solar energy and provide energy for the building.

#### Design of double-skin roof

Armadillo Box is designed by GRE. The interior roof of the building is built on an internal load-bearing frame, composite oriented strand board, and filled with thermal insulation material. The exterior roof is made of steel frames, supporting monocrystalline silicon solar cells, photovoltaic modules and low radiation sun curtains, so that a good ventilation corridor is formed between the inside and outside building roofs. (As shown in Figure.6) The low temperature radiation protection layer and the evaporation cooling system for spraying water by using water and rain water on the outside of the inner roof can be used to solve the ventilation problem between the double roofs. The interior of the building is also protected from adverse weather conditions due to the protective effects of the exterior roof. The photovoltaic square itself is controlled by the separation of the double roofs to achieve its own back temperature, while the power generation efficiency is guaranteed. (As shown in Figure.7).

Figure.6. SURE HOUSE

Figure.7. Analysis of double-skin roof of GRE

### Analysis of design method of roof and photovoltaic for an office building in Xinjiang

#### Determination of orientation and dip angle parameters of photovoltaic module

Due to the hot summer in Turpan, the design is mainly aimed on diminishing the heat gain of enclosure, so the glass wall and lighting roof structure should not be considered. The paper built a building model with 1:1 scale that has flat roof and slope roof which laying solar pan-

els (As shown in Figure.8). Due to the angle and slope roof system has fixed, we mainly focus on the best angle and orientation of the flat roof. With the optimizing of PVSYST software, we can conclude that the 39 degrees is the best angle (As shown in Figure.9).

Figure.8. Model for analysis

Figure.9. Inclination angle

At the same time, using the solar plugin SKELION to simulate the arrangement and shadow analyze, then choosing 9 to 15 o'clock to simulate without shading, providing the spacing of 3 meters (As shown in Figure.10). There are two kinds of measures to reduce shadow and hot spots loss. The first one is the shadow elimination, which is able to realize the unblocking during the specific time, but it will reduce the use of roof, another is to choose horizontal or vertical arrangement according to the shape of the shadow.

Figure.10. Model component layout in SKETCHUP and the sun time path diagram in Turpan

### Calculation of photovoltaic power generation

Using PVSYST software for simulation and calculation, and arranging the number of PV modules by using SKETCHUP. The type of PV modules we choose is monocrystalline silicon component with the size of 1680\*990\*50, and its power is 240W. There are 468 pieces on the slope roof whose rated power is 120kw and there has an installing area of 750 m<sup>2</sup>. And there are 41 pieces on the flat roof whose rated power is 11.3kw and there has an installing area of 375 m<sup>2</sup>. The total rated power is 131.3kw, and we calculating respectively the power generation of flat roof and slope roof (As shown in Fig.11).

Figure.11. Calculation results of power generation from flat roof and curved roof

The calculation results show that the PV annual power generation of flat roof of the office building is 17081 kWh, and the figure for slope roof is 176782 kWh. Due to the characteris-

tics of office building that most of its power consumption is concentrated during the daytime which matches the high efficiency period of PV power generation. Therefore, the integration of solar building's roof and photovoltaic with optimized design will effectively reduce office building and other buildings' energy consumption (Yang Shanqin. 1997).

## DISCUSSIONS

Through the above analysis, we can conclude that the integration of roof and photovoltaic has many forms based on the roof's type and the design concept, but these designs rarely synthetically consider aesthetics, technology and energy saving, which caused many problems such as roof space, hot spot, unreasonable PV panels' angle and direction. The paper put forward a new design method which synthetically used SKETCHUP and PVSYSYSTEM that can solutes problems which are common in the design of integration of roof and photovoltaic aims to aesthetics, technology and energy saving.

## CONCLUSIONS

The integration of roof and photovoltaic not only makes architecture an energy consumer, but also an energy provider. A scientific and appropriate design of integration design will make a great contribution to energy-saving. Meanwhile, besides paying attention to form and style, meeting the elemental functions such as protection and isolation, the design should also be an integrated design based on the building which focusing on the use of environmental advantages, unifying with the whole structure of the building and paying more attention to the roof system's energy-saving design. With the development of the utilization of solar energy and integration of architecture, new design methods of roof integration are derived from many cases that the roof design is not only a traditional addition or a design with covert attitude anymore. This integrated design still should be an exploring direction which should not only ensure efficiency, meet demand and overall consideration of cost, but also truly integrate design with the building to achieve the perfect combination of technology and art.

### **ABSTRACT**

Considering physical properties, transparent or translucent building components like windows or glazing facades are the weakest elements of building envelope. The heat transfer coefficient of such elements is approximately four times higher than for opaque partitions, which causes considerable increase of heat loss during winter. In summer relatively high solar transmittance is a source of heat gains which results in undesirable overheating. Application of phase change materials in glazing components affects its thermal performance by the increase of its heat capacity and decrease of solar heat gains, with regard to the current physical state of the PCM.

The aim of this paper is investigation and determination of the thermal performance of PCM-glazing unit, under real, moderate climatic conditions in summer season. Analysis conducted by the authors aims to find the proper arrangement of PCM-glazing unit and proper material properties design, allowing effective overheating control.

To meet the stated goals, dynamic simulations of thermal performance of triple-glazing unit were carried out, using ESP-r software. It was assumed that one chamber, filled with PCM will adjust the solar heat gains flux while the second one will assure required thermal resistance of the partition. Original model of heat transfer through transparent partition, taking into account latent heat storage by effective heat capacity method was applied. Different phase change materials, characterized by various phase transition temperatures were considered in the analysis.

Based on the obtained results it can be concluded that application of a PCM in the external cavity of the triple glazing window effectively affects the thermal performance of the component, stabilizing the diurnal temperature fluctuations. Simulation results revealed that transition temperature should be close to the assumed cooling set point.

latent heat, façade, simulation, overheating, solar energy

### **INTRODUCTION**

Transparent elements of the facades, in terms of physical parameters, are one of the weakest link of the building envelope. Because of approximately four times higher value of heat transfer coefficient for windows than for opaque partitions, glazing elements are the cause of the most heat losses during the winter. In addition, in the summer, their relatively high solar transmittance is a source of unwanted heat gains that cause overheating of single rooms and entire buildings. Moreover, during the whole year, the asymmetry of radiation in the areas next to the windows causes deterioration of thermal comfort conditions. Transparent elements cause both higher heat losses in winter and are the source of undesirable heat gains from solar radiation during the summer. An additional disadvantageous physical feature of these elements is their very low heat capacity due to which dynamic processes occurring in the glazing are reflected in the dynamic changes of parameters of the internal environment. On

the other hand, the transparent components are indispensable elements of the external partitions, ensuring the required amount of daylight in the rooms and the visual contact with the external environment, which is necessary for the users.

Modification of the optical and thermal properties of glass components using PCM is a relatively new issue. Nevertheless, some simulation analyses and laboratory-scale studies on this subject can be found in the literature. The first theoretical and experimental analyses concerning the determination of solar transmittance by double-glazed component filled with air and PCM were published fifteen years ago (Ismail and Henriquez, 2002). Similar studies, investigating the possibility of limitation of both heat losses and heat gains through transparent partitions by their modification with PCMs, were presented by Weinlader et al. (2005). In recent years, theoretical considerations to determine the thermal effect of PCM application with different transition temperatures under specific climatic conditions (Zhong et al. 2015) and their experimental validation (Li et al. 2014) have been also conducted. However, despite many attempts to develop the numerical model of the multi-pane system (Goia et al. 2012), the majority of experimental work was carried out for double glass unit (Goia et al. 2014) or commercially available glazing component with PCM (Grynning et al. 2015). Another important issue is analysis of the optical properties of transparent elements modified with PCM (Heim, 2011). The considerations presented in the paper start research project aiming to develop a translucent multi-layer component, adjusted for selected locations. In the framework of the project it is planned to develop and test a solution that, thanks to the use of PCM, will improve the energy efficiency of the transparent partition while maintaining (at least periodically) the physical characteristics of the translucent barrier. Theoretical analysis, presented in the paper, was carried out for moderate climate conditions, for the location of Lodz, Poland. The location have been selected due to the further experimental part of a research in a real scale, which will also be used to validate the numerical model of the developed PCM-glazing component.

## **MATERIALS AND METHODS**

### **PCM-glazing arrangement**

The scope of the analysis presented in the paper covers the design of the PCM-glazing parameters that will contribute to the reduction of overheating of the building under moderate climatic conditions. Similar concept was proposed by (Komerska et al. 2015), when PCM layer was used as a part of external dynamic solar shading system. In order to meet the stated goal of the research, preliminary analysis of the PCM-glazing arrangement was conducted. Furthermore, for the stated component composition analysis of the PCM melting temperature was done.

In accordance to the current requirements regarding thermal insulation of windows, it was assumed that for moderate climatic conditions, triple-glazed windows should be considered. Such window construction gives also the possibility of filling one of the window cavities with a phase-changing material, while the second one provides required thermal insulation. Two possible PCM-glazing arrangements allowing to meet the stated assumptions were presented in Figure 1.

Besides the possibility to regulate the daylight access, the main purpose of the PCM application was to decrease the energy demand for cooling by the reduction of the excessive solar heat gains. Based on the preliminary analysis it was stated that for summer conditions PCM should be placed in a cavity located from outside (Fig. 1a). In the cooling season the PCM will play a role of dynamic insulation by storing solar energy during a period of substantial solar heat gains. In that case the active layer (PCM) is located in a distance from indoor environment. The inner cavity limits the heat transfer from PCM layer to the room. During the night when external temperature drops down below solidification point the heat

will be released into external environment by conduction and radiation. Additionally, in a solid state the material is characterised by lower solar transmittance what will additionally contribute to the reduction of solar heat gains. Due to the further plan of experimental research, it was assumed that the case designed for the cooling period will be analysed for the east oriented façade, characterized by a significant heat gains in the morning hours.

Fig. 1. Two possible arrangements of PCM glazing: a) PCM located from outside, b) PCM located from inside.

To confirm the above considerations, a simulation analysis was carried out, which allowed to compare distributions of the mean temperature in the three cases: reference one – without PCM, with PCM filling external cavity and with the PCM filling internal cavity (Fig. 2). It can be concluded that replacement of highly insulating but low capacity gaseous medium with PCM contributes to the lowering the temperature in the window. Moreover, PCM placed in the external cavity reveals greater ability to reduce the temperature rise due to solar radiation incidence on the facade, which confirms assumptions of preliminary analysis.

Fig. 2. Distribution of mean temperature in traditional window, PCM-glazing filled with external and internal cavity filled with PCM during cooling season.

### Case study

Analysis of the transition temperature of the PCM was conducted for the single zone, office room with only one external wall equipped with centrally positioned, square window (1 m wide and high). Regarding considerations presented above, triple glazing unit with external cavity filled with PCM was further analysed. Numerical analysis was conducted in ESP-r computational environment (Clarke, 2001). Latent heat accumulation due to PCM application was calculated using effective heat capacity method, which was previously validated by the authors for opaque elements (Heim and Wieprzkowicz, 2016). Additionally, change of optical

properties of PCM-glazing was included in the analysis. Values of visible transmittance, absorbance and reflectance of solar radiation for the window component filled with liquid and solid PCM were determined based on the previously conducted measurements.

The materials considered in this research were selected based on the climate conditions analysis. It was assumed that, since the phase transition is triggered by the temperature rise, melting temperature of PCM placed in external cavity of the window should be suited for external temperature fluctuations (according to Typical Meteorological Year) characteristic for the analysed location (Lodz, Poland) and period of time (June-August). Thermal performance of the PCM-glazing window with four different paraffins (Table 1) was compared with the reference case of the triple glazed window with both cavities filled with argon. It was assumed that change of optical properties occurs at peak melting temperature, but material undergo phase transition in the whole given temperature range.

Table 1. Thermal properties of analysed paraffins.

PCM	Peak melting temperature [°C]	Phase transition temperature range [°C]	Latent heat capacity [kJ/kg]	Specific heat [kJ/kg·K]	Density [kg/m <sup>3</sup> ]
RT18HC	18	17-19	260	2000	880
RT22HC	22	19-24	190	2000	880
RT25HC	25	18-26	230	2000	880
RT28HC	28	26-29	250	2000	880

## RESULTS

The analysis of the potential of PCM-glazing to limit the excessive solar heat gains was made based on the numerically calculated temperatures inside of the glazing unit and adjacent zone (Figure 3).

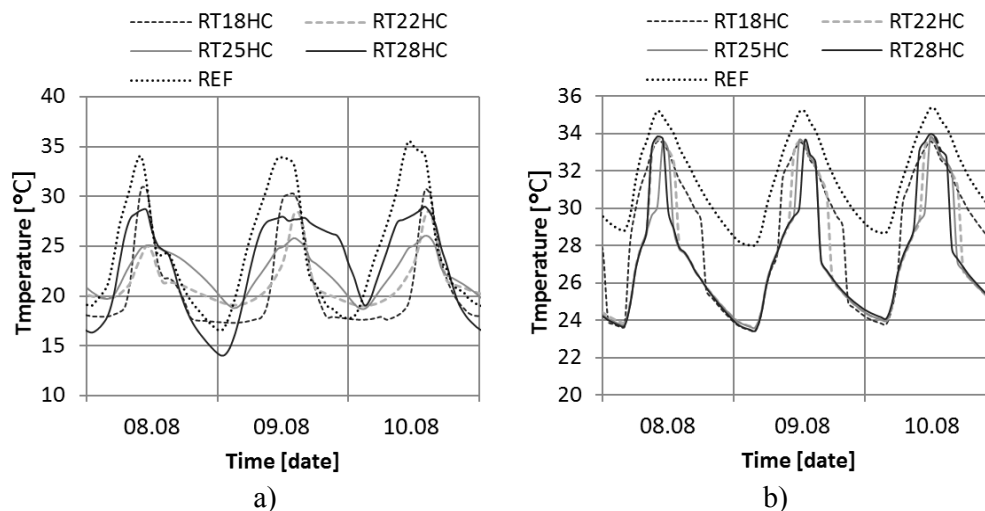

Figure 3. Temperature changes during 3 selected days: a) in the external glazing cavity, b) inside the room adjacent to the façade equipped with PCM-glazing.

Based in the results presented in Figure 3a it can be observed that in each case of PCM application the temperature is stabilized at the melting temperature level, during specific periods of time, during analysed days. It means that in all analysed cases the phase transition and latent heat accumulation occurred, but with different thermal effect. Analysing the

temperatures in the external cavity of the window, it can be observed that the highest daily peak temperatures were obtained for the paraffin with the lowest melting temperature, which stores the thermal energy mostly in the night hours. The lowest daily peak temperatures in that location were obtained for the paraffin RT25HC, which allowed to keep the temperature in the thermal comfort range for almost whole analysed 3-days period of time.

As the main purpose of the PCM application in the glazing unit was reduction of the temperature inside the adjacent room the results presented in Figure 3b reflects the thermal performance of four analysed paraffins compared to the reference case. Due to diversified melting temperatures, the increased rate of temperature rise can be observed in a different moments of the day. The material that allows to keep the possibly lowest zone temperature is paraffin with the melting temperature around 25°C.

Further, quantitative evaluation of the thermal effect of PCM-glazing application on the overheating control inside adjacent zone was done using the value of Degree-Hours of Overheating (*DHO*), which reflects the time and level of exceedance of maximum temperature of thermal comfort, calculated as:

$$DHO = \sum_{i=1}^n (T_i - 25) \cdot t \quad [\text{degC} \cdot \text{h}] \quad (1)$$

where  $T_i$  is instantaneous value of the room temperature [°C],  $t$  is length of the time step of calculation [h],  $i$  is subsequent number of the time step [-] and  $n$  is number of the time steps of analysis [-].

Additionally, number of hours of overheating was calculated (Fig. 4b), which showed that none of the analysed materials filling the cavity of glazing unit is able to totally prevent from overheating. For all analysed paraffins very similar number of hours of overheating was obtained, which confirmed the phenomena that could be observed for 3 selected days presented in Figure 3, that temperature below 25°C was register during the same periods of time. Together with the analysis of the calculated values of *DHO* parameter (Fig. 4a), it also proves (for the whole analysed period of time) that application of PCM contributes to the reduction of overheating but efficiency of such solution depends on the transition temperature of the material. The lowest value of *DHO* was obtained for the paraffin with melting temperature around upper limit of thermal comfort. Application of such kind of PCM in the glazing component allowed to obtain twice lower value of *DHO* parameter and reduces number of hours when overheating occurred by 26%.

Figure 4. Calculated values of: a) Degree-Days of Overheating, b) Hours of overheating, for 5 analysed cases.

## CONCLUSIONS

The paper presents the results of the theoretical analysis aiming to determine the basic technical parameters of the translucent construction component and thermal properties of the PCM filling the external window cavity. It was assumed that the component is to be designed for storing thermal energy of solar radiation and reducing overheating. The PCM-glazing arrangement dedicated to the selected location and the characteristic climatic conditions have been analysed. The main purpose of the presented research was selection of the phase change materials that could effectively reduce heat gains through a transparent partition.

On the basis of the analysis of the material transition temperature, the material recommended for further experimental investigation was selected. It was stated that the most effective performance was observed for paraffin with melting temperature of 25°C, which will be further experimentally tested in the real scale PCM-glazing component under moderate climatic conditions.

## ACKNOWLEDGEMENT

This work was funded in a framework of ERANet-LAC 2nd Joint Call on Research and Innovation by NCBiR as part of the project entitled: Solar hybrid translucent component for thermal energy storage in buildings (acronym: SOLTREN).

### ABSTRACT

Model-based optimal control (MOC) methods have strong potential to improve the energy efficiency of heating, ventilation and air conditioning (HVAC) system. However, most existing MOC methods require a low-order building model, which significantly limits the practicability of such methods. This study develops a novel model-based optimal control method for HVAC supervisory-level control based on the recently-proposed deep reinforcement learning (DRL) framework. The control method can directly use whole building energy model, a widely used flexible building modelling method, as the model and train an optimal control policy using DRL. By integrating deep learning models, the proposed control method can directly take the easily-measurable parameters, such as weather conditions and indoor environment conditions, as the input and controls the easily-controllable supervisory-level control points of HVAC systems. The proposed method is tested in an office building to control its radiant heating system. It is found that a dynamic optimal control policy can be successfully developed, and better heating energy efficiency can be achieved while maintaining the acceptable indoor thermal comfort. However, the “delayed reward problem” is found, which indicates the future work should firstly focus on the effective optimization of the deep reinforcement learning.

### KEYWORDS

Deep Reinforcement Learning, HVAC Optimal Control, Energy Efficiency

### INTRODUCTION

Heating, ventilation and air conditioning (HVAC) system is the major energy consumer in US office buildings. As a result, model-based optimal control (MOC) strategies become popular in the building industry in recent years due to its potential to save HVAC operation energy consumption. The most popular type of MOC is model predictive control (MPC) which, in real-time, uses a model to predict the future evolution of a process and calculates the optimal control decision for the current time step. However, MPC requires the model to be low-order, which is difficult for multi-zone buildings. This significantly limits its practicability. Therefore, some studies focus on using whole building energy model (BEM), a widely-used flexible physical-based building modelling method, in the predictive control of HVAC. However, the slow computational speed of BEM is the major limitation (Zhang and Lam, 2017).

Reinforcement learning (RL) is another alternative for the optimal control of HVAC systems. A standard RL control problem involves a learning agent (hereafter called “RL agent”) interacts with the environment in a number of discrete steps to learn how to maximize the returned reward from the environment, as shown in Figure 1 (Sutton and Barto, 2017). RL is a “model-free” method because the model is used as a simulator offline to let the RL agent learn

the optimal control policy. The slow computational speed of BEM is no longer a problem because of the “model-free” feature. However, conventional RL methods need the expert knowledge to design the algorithm and cannot be easily scaled for complicated control problems.

Figure 1. A Standard Reinforcement Learning Setting (Sutton and Barto, 2017)

Deep reinforcement learning (DRL), which uses deep learning models as the core of RL, becomes popular in recent years. DRL makes the "end-to-end" control possible, i.e. the DRL agent can take raw observations as the input and provide raw control actions as the output. Comparing with the conventional RL, DRL no longer requires the expert knowledge to design the algorithm and can be easily scaled for different control problems. However, HVAC optimal control using DRL is studied at an infant stage of research with very limited existing studies using only simple hypothetical building models as the case studies (Li et al., 2017; Wang et al., 2017; Wei et al., 2017).

This study proposes a framework (named “BEM-DRL”) that uses DRL to develop the optimal control policies of HVAC systems based on BEM. The processes, including building modelling, model calibration, DRL training, and control deployment, are explained by using a real-life office building as the case study. The energy efficiency and thermal comfort performance of the proposed control method are analysed using the building model. In addition, the optimization problems of the DRL training are discussed.

## METHODS

The BEM-DRL framework is shown in Figure 2, which includes four steps:

1. BEM modelling: The building and its HVAC system are firstly modelled using BEM tools. In this study, EnergyPlus (Lawrence Berkeley National Laboratory, 2016) is used as the BEM tool.
2. HVAC model calibration: The BEM needs to be calibrated against real HVAC operation data. In this study, Bayesian calibration using the method proposed by Chong *et al.* (2017) is used.
3. DRL agent training: The DRL agent will be trained off-line using the calibrated BEM to learn the optimal control policy. The DRL state, reward and action design will be determined based on the building sensor data availability, control optimization objectives and HVAC system control capability. Asynchronous advantage actor critic (A3C) (Mnih et al., 2016) is the DRL training algorithm using this study. A3C surpasses other methods in its smaller computational memory usage and faster computational speed using only CPUs.
4. Control deployment: The trained DRL agent will be deployed to the actual HVAC system using the existing building automation system (BAS) infrastructure.

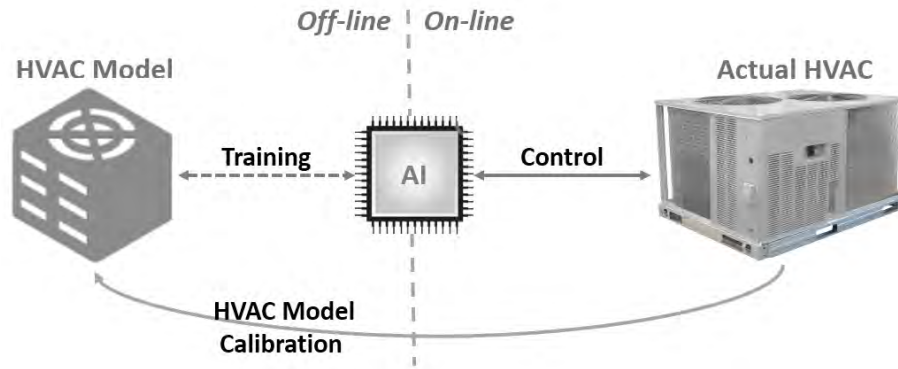

Figure 2. BEM-DRL Framework

## RESULTS

The BEM-DRL framework is demonstrated using the Intelligent Workplace (IW) building located in Pittsburgh, PA, USA to control its heating system.

### BEM Modelling and Calibration

The case study building, IW, is a one-level office building built on top of an existing building in 1997 with a complete building automation system installed. It has an area of approximately 600m<sup>2</sup>, with about 20 regular occupants and a 30-person classroom.

IW uses a water-based radiant heating system that is integrated with the mullion of the window frames. The hot water for the radiant system is supplied by a steam-to-water heat exchanger in the campus. The hot water flow rate is constant while the hot water temperature is variable to respond to different heating demands. The hot water temperature setpoint is currently calculated by a PID controller based on the difference between the zones' average indoor air temperature and its setpoint.

Table 1. Modeling Errors after Calibration

Item	MBE	CVRMSE
Average Indoor Air Temperature	5-min: 0.52%	5-min: 4.82%
Heating Energy Consumption	Hourly: 0.43%	Hourly: 35.96%, Daily: 10.46%

MBE: Mean Bias Error, CVRMSE: Coefficient of Variation of the Mean Squared Error

The BEM of IW is calibrated for the heating energy consumption and indoor average air temperature. Three months measured data in the heating season of Pittsburgh, Jan 1st 2017 to Mar 31st 2017 with 5 minutes interval, is used for the calibration. The heating energy consumption is a calculated value based on the measured radiant system inlet/outlet water temperature and water mass flow rate. The modeling errors after the calibration is shown in Table 1. It is shown that the average indoor air temperature and aggregated heating energy consumption have been calibrated with the acceptable errors.

### DRL Agent Training Setup

A DRL problem is defined by the design of the state, action and reward.

The state is a vector representing the environment observations, which includes the following items in this study:

*[time, outdoor air temperature, outdoor air relative humidity, wind speed, wind direction, diffuse solar radiation, direct solar radiation, IW steam heat exchanger on/off status (HXOp),*

*IW average PPD (PPD)<sup>1</sup>, IW Mullion system supply water temperature setpoint (MULLSSP), IW average indoor air temperature (IAT), IAT setpoint (IATSSP), IW occupancy mode flag (OCCU)<sup>2</sup>, IW heating demand ( $E_{hvac}$ )*

All items can be easily accessed through the BAS of IW.

The action space includes the discretized Mullion system supply water temperature setpoints from 20 °C to 65 °C with 5 °C interval, and an action to turn the IW steam heat exchanger off.

The reward function determines the control optimization objective. The objective of the study is to minimize the heating energy consumption and maximize the thermal comfort. The design of the reward functions may significantly affect the convergence of the deep reinforcement learning and the final control performance. An empirical reward function combining the heating energy consumption and the indoor thermal comfort is shown in Equation (1):

$$reward = - \begin{cases} [\tau * ([PPD - 0.1]^+ * \rho)^2 + \beta * E_{hvac}]_0^1 |_{Occu=1} \\ [\tau * [Stpt_{low} - IAT]^+ * \lambda + \beta * E_{hvac}]_0^1 |_{Occu=0} \end{cases} \quad (1)$$

where  $\tau$ ,  $\beta$ ,  $\rho$ ,  $\lambda$ ,  $Stpt_{low}$  are the tunable hyperparameters.  $\tau$  and  $\beta$  control the relative weight between the HVAC energy efficiency and the indoor thermal comfort for the optimization;  $\rho$  is a scale factor to penalize large PPD value;  $\lambda$  is the penalty level for the indoor air temperature violation during the unoccupied hours,  $Stpt_{low}$  is the indoor air temperature penalty threshold. Note all parameters are normalized.

The calibrated BEM of IW is used for DRL training and testing in this study. The DRL agent is trained in heating season (Jan to Mar) using the TMY3 weather data. The trained DRL agent is tested also for heating season but using the actual Jan-Mar weather data of 2017. The BEM simulation time step and the control time step are both 5 minutes. The  $Stpt_{low}$  in Equation (1) is the indoor air temperature setpoint calculated by the IW BAS control logic.

Table 2. DRL Simulated Control Performance in Heating Season (selected experiments)

#	Hyperparameters		Training Model			Testing Model		
	Action Repeat <sup>3</sup>	$\tau, \beta, c^4$	Heating Energy (kWh)	PPD <sub>mean</sub> (%)	PPD <sub>std</sub> (%)	Heating Energy (kWh)	PPD <sub>mean</sub> (%)	PPD <sub>std</sub> (%)
<b>Basecase</b>	N/A	N/A	45302	10.48	4.48	43709	9.46	5.59
<b>1</b>	1	1.0, 1.5, 20	52806	8.72	4.31	47522	8.23	2.46
<b>2</b>	1	1.2, 2.5, 20	44549	11.58	5.35	39484	11.11	4.53
<b>3</b>	1	1.0, 2.5, 10	40101	16.09	9.46	37238	14.20	8.65
<b>4</b>	3	1.0, 1.5, 20	42255	11.46	4.26	38550	10.63	3.34
<b>5</b>	3	1.0, 1.5, 20	43532	10.63	4.23	39109	10.44	3.75
<b>6</b>	3	1.0, 2.5, 10	42104	11.49	4.24	37131	11.71	3.76

<sup>1</sup> PPD is short for Predicted Percentage of Dissatisfied, which is calculated by the BEM engine with the assumptions  $C_{lo} = 1.0$ ,  $Met = 1.2$  and  $V_{air} = 0.137\text{m/s}$ .

<sup>2</sup> The occupancy mode flag is determined based on a fixed schedule (the occupancy mode flag is 1 between 7:00 AM and 7:00 PM of weekdays, and between 8:00 AM and 6:00 PM of weekends)

<sup>3</sup> Action repeat means the DRL agent repeats the same control action for multiple time steps.

<sup>4</sup>  $\rho$  is determined by a function  $\rho = 1/(PPD_{thres}/100 - 0.1)$ .  $\rho = 20$  and  $\rho = 10$  correspond to  $PPD_{thres} = 15$  and  $PPD_{thres} = 20$  respectively, meaning the reward function (Equation (1)) returns the minimum value if the PPD exceeds the  $PPD_{thres}$ .

### Simulated Control Performance

The energy consumption and indoor thermal comfort (evaluated by the mean of PPD and standard deviation of PPD) of different DRL agents trained with different hyperparameters are shown in Table 2. The basecase in the table uses the current control logic in IW. Four key hyperparameters are tuned including action repeat, and  $\tau$ ,  $\beta$ ,  $\rho$  in the reward function. Action repeat benefits the DRL training stability but lowers the flexibility of the trained optimal control policy.  $\tau$ ,  $\beta$  controls the relative weight on the energy efficiency and thermal comfort in the DRL training, and  $\rho$  determines the constraint for the maximum PPD during the DRL training. As shown in the table, the relationship between the hyperparameters and the control performance may not be intuitive. This is caused by the delayed reward problem of the DRL training, i.e. the control actions may not take effect soon because of the slow thermal response of the radiant heating system. Further study is needed for the delayed reward problem. Out of the six experiments in Table 6, case 6 performs comparably the best, which saves 15% of the heating energy with only slightly worse indoor thermal comfort quality in the testing model.

### Control Deployment

The deployment is based on the existing building automation system (BAS) of IW using BACnet as the communication protocol. Figure 8 shows the deployment architecture. The DRL agent overwrites the Mullion supply water temperature setpoint every 15 minutes through BACnet, and the internal control logic of the BAS controls the three-way water valve to reach the defined water temperature setpoint. A phone app (OpenHAB) is used to collect the occupants' thermal sensation feedbacks. Occupants can select one of the 7 choices from "warmest" to "coolest" reflecting how they want the indoor thermal environment to be. The collected feedbacks are passed to the DRL agent for the control calculation.

Figure 3. Deployment Architecture of the IW Case Study

### DISCUSSIONS

The IW BEM has been calibrated with small error on most metrics, except the hourly CVRMSE for the heating energy consumption, as shown in Table 1. This may be because the hourly heating energy consumption of IW has large variance, which cannot be effectively captured by the BEM. However, aggregated energy consumption (e.g. daily) is more important than spot energy consumption (e.g. hourly) for energy efficiency research.

The slow thermal response of the IW radiant heating system causes the delayed reward problem in the DRL training. Therefore, the hyperparameters of the DRL must be tuned. It is found in Table 2 that some combinations of the hyperparameters can lead to better energy efficiency while maintaining the acceptable thermal comfort. However, no obvious trend has been found in the hyperparameter tuning. Structured method or guideline should be

developed, such as better reward function that can re-reward previous actions based on the future evolution of the controlled process.

The DRL agent has been deployed to IW using the architecture proposed in Figure 3. However, by the time this paper is written, the actual control performance test is not yet finished. Future work will study the actual control performance of the DRL agent.

## CONCLUSIONS

This study develops a method to use deep reinforcement learning for the BEM-based HVAC optimal control. The method is demonstrated in a case study building with a radiant heating system. An EnergyPlus model is created for the building and calibrated using the Bayesian method. A3C is used to train a DRL agent to develop the optimal control policy for the system supply water temperature setpoint. By simulation, it is found that the optimal control policy can save about 15% heating energy while maintaining the acceptable indoor thermal comfort. This agent is deployed in IW through BACnet protocol and a phone app is used to collect the thermal sensation feedbacks from the occupants. Future work includes analyzing the actual control performance of the IW case study and developing a structured method to solve the delayed reward problem of the DRL training.

## ABSTRACT

This paper presents some experimental results of a new device for low energy/low exergy air conditioning system. The device can realize both dehumidification and sensible cooling of external air, and it is designed for very low pressure drops, drastically reducing the electricity consumption for the driving fans. It is composed by a finned coil heat exchanger, coated with a SAPO-34 zeolite layer, that handles both heat and mass transfer in a single component. During the adsorption a cold water flow at 20 °C circulates through the coil, cooling the air and realizing in a single step a complete air-treatment. Hot water produced with evacuated solar collector is then used to regenerate the zeolite.

**Keywords:** adsorption dehumidification, solar cooling, adsorption heat exchanger, experimental

## 1 INTRODUCTION

Cooling demand for air conditioning (AC) has continuously increased in the last decades. This because more and more buildings are provided with space cooling system to satisfy indoor comfort demand during warm and hot season (Werner, 2016) (Jakubcionis and Carlsson, 2017). Solar cooling is an alternative solution to traditional system that may attenuate the increase of electric consumptions associated to the cooling demand, and one of the simplest technology are the Desiccant Evaporative Cooling system (DEC). They are thermally-driven open cooling cycle, based on evaporative cooling and adsorption processes. In this technology, the dehumidification process is commonly carried out using desiccant rotors impregnated or covered by adsorption material (i.e. silica gel or lithium chloride) (Daou et al., 2006). Warm and dry air obtained from this step, is typically cooled using an indirect evaporative cooling module. Solar energy is used to regenerate the desiccant material, that dehumidifies moist air adsorbing vapor. Alternative configurations of the dehumidification component, the adsorption heat exchangers (ADS-HX) were explored (Finocchiaro et al., 2016), (Simonetti et al., 2016, 2017), (Zhao et al., 2016). These are static components in which there is the contemporaneous exchange of heat and mass between the air and the sorption material, and the heat between the adsorption material and a secondary fluid vector. The disposition of the adsorption material in a finned coil heat exchanger, typically used in air conditioning, can be different: surface coating on the fin or granular dispersion in the void volume. The goal of this research is to explore the use of renewable thermal energy, at temperature level between 55-80°C, to satisfy the latent load of the air conditioning using this type of technology in alternative of vapor compressor chillers. Savings in electricity consumption are attended.

## 2 METHODS

### 2.1 Adsorption heat exchanger

The component here presented is a fin and tube heat exchanger, typically used in HVAC system, in which all the exchanging surface, by tubes and fins, is coated with a zeolite. The advantage of this component, with respect to fixed packed bed (Finocchiaro et al., 2016), is the possibility to have contemporaneous heat and mass transfer between the air, the adsorptive mass, and a secondary thermal

vector fluid. The two working mode are represented in the scheme of Figure 1. During the **regeneration**, the heat is provided by hot water flow inside pipes of the heat exchanger. Then water vapor, previously captured by the zeolite, is released and transported by the air flow. The operation continues until the adsorption mean reach a sufficient level of drying to start the successive phase of dehumidification. After this operation the hot water flow is stopped and substituted by a cold water flow, circulating through the pipes of the same heat exchanger. This phase is the **cooled adsorption**: water vapor capture by zeolite reduces the moisture content of the air and produces heat, that is comparable with the latent heat of water evaporation. Previously tests of this component showed that the residual heat coming from the regeneration phase of the component influences significantly the dehumidification performance during the adsorption (Simonetti et al., 2016). This aspect combined with the heat generated by the adsorption phenomena result in low performance of the system. By cooling the coil during the adsorption, the increase of air and zeolite bed temperature is avoided and the material operates at its higher water adsorption capacity (Figure 2). Temperature level of water and flow rate regulates the equilibrium condition and the final temperature of the air at the outlet of the heat exchanger. Controlling these parameters, different air outlet condition can be achieved.

Figure 1. Scheme of the regeneration and adsorption phase of the zeolite SAPO-34 heat exchanger.

Figure 2. Comparison of the adsorption isotherm between pure zeolite SAPO-34, and the mixture coated on the surface of the heat exchanger (Simonetti et al., 2016).

The type of zeolite used for this case study is the SAPO-34. Such material, belonging to the (silico) aluminophosphate family, shows a regular pores system, a three-dimensional network similar to zeolites and unusual adsorption properties regarding polar molecules, typically exhibiting a type V water vapor adsorption isotherm (Ng et al., 2008). These properties result in moderately low regeneration temperature (60-100 °C) and a reduced desorption heat, while maintaining high performance within the adsorption cycle (Henninger et al. 2010). The coating procedure of the ADS-HX involves different steps (Simonetti et al., 2016), that influences the properties of the adsorption material. In particular the adsorption properties are slightly reduced respect to the pure SAPO-34, as showed in Figure 2. The final result of this manufacturing process is showed in Figure 4 and Figure 5.

## 2.2 Experimental set up

The experimental facility consists of two AHUs (Air Handling Units) that can process air flow rate ( $Q$ ) in the range  $100 \div 1500 \text{ m}^3/\text{h}$  (measured with calibrated flanges) controlling outlet temperature and humidity. Air temperature ( $T_a$ ), humidity ( $X_a$ ) and water temperature ( $T_w$ ) sensors are distributed along the adsorption unit, as showed in Figure 3. In Table 1 the list of sensors and their accuracy employed in

the experimental activity is shown. The heat for regeneration is provided with 10 m<sup>2</sup> of evacuated solar thermal collectors and into a 500 lt thermal storage, equipped with an auxiliary electrical resistance of 3 kW. In Table 2 are reported the geometric characteristics of the finned coil heat exchanger, and the zeolite coating thickness is lower than 1 mm.

### 2.3 Test procedure

The tests aim to explore the transient dynamics of adsorption/regeneration cycle measuring air and water operational parameters at growing air flow rate. At the begin of each adsorption test the zeolite starts in a dry initial condition. The AHU prepares the air at the desired temperature and moisture content. Then adsorption tests start cooling down the zeolite with the cold-water loop; during this phase the air flow is mechanically driven by the fan of the AHU. When the air dehumidification goes below 1 g/kg the adsorption test ends. Then the fan of the AHU is stopped, and the water flow switched from cold to the hot circuit connected to the storage, fed by solar collectors. The same criteria of adsorption phase is used to stop the desorption one. During the regeneration natural ventilation of the heat exchanger occurs, thanks to the positive buoyancy, thermally generated. Air temperature and humidity as hot and cold water temperature and air pressure drops are continuously monitored and logged.

### 3 RESULTS

First, the adsorber air pressure drops were measured at different temperature (15 to 35 °C) ranging air velocity ( $v$ ) from 0.2 to 1.6 m/s: the higher value is lower than 12 Pa (Figure 6). Further, three different operational tests have been carried out: air flow rate ranges from 220 to 430 m<sup>3</sup>/h; average regeneration temperature is 60°C; average cooling water is 20 °C; the water flow was around 2.7 liter/min throughout regeneration, and 22.4 during adsorption. Other information, such as operation time and moisture content are reported briefly in Table 3. The test 2 is depicted in Figure 7, to illustrate the behavior of all the physic parameters monitored during adsorption and regeneration.

Table 3. Average and deviation of the input test condition

	phase	time	Q	T <sub>a-in</sub>	RH <sub>a-in</sub>	T <sub>w</sub>
		min	m <sup>3</sup> /h	°C	%	°C

Figure 6. Zeolite SAPO-34 heat exchanger pressure drops

Figure 7. Behavior of the air and water physical parameters, temperature and moisture content, during an adsorption (time<0,4) and regeneration (time>0,4) test carried out on the adsorptive heat exchanger.

Adsorption had a duration of around 20 min, with an average dehumidification of 4 g/kg, and a maximum value of more than 8. Except for the initial transient, outlet temperature was always lower than the inlet. Regeneration had a similar duration, but with less than 1/5 of the adsorption air flow rate. Figure 8 and Figure 9 report the difference between a not cooled (with similar air inlet condition and flow rate of test n°2) and a cooled adsorption are showed. It can be observed how in the initial transient ( $t < 1$  min) the cooling operation results in a higher exploitation of the zeolite, showing higher moisture removal, and a fast heat removal shifting air temperature below the inlet condition in less than 5 minutes. Increasing air flow rate, from the first to the last test, with similar air inlet condition during adsorption, has two significant results: a reduction of the maximum value of air dehumidification (from more than 8 to 6.5 g/kg), and an increase of the slope of the curve, as can be seen in Figure 10. This leads to a progressive reduction of the duration of the adsorption phase, from 30 to around 20 minutes. All these

characteristics are clearly depicted and summarized in Figure 11, in which the total thermal power (latent and sensible) exchanged between air and the ADS-HX is showed.

Figure 8. Differences on dehumidification curves in an adsorption test with and without cooling, at same air flow rate.

Figure 9. Differences on air temperature variation in an adsorption test with and without cooling, at same air flow rate.

Figure 10. Effects of the air flow rate increase on air dehumidification during cooled adsorption, for the three different tests.

Figure 11. Thermal power exchanged between air and the ADS-HX during both adsorption (left part) and regeneration (right part), for the three different tests.

#### 4 DISCUSSION

The integration of this component in traditional HVAC system (in particular for small size applications), to cool down and dehumidify humid air gives the possibility to directly exploit renewable energy. The low temperature of the hot source, 60°C, is compatible with the use of solar thermal systems to regenerate the component. In Figure 12 is compared the air transformation between the cooled adsorption and a typical condensing and re-heating process. Dehumidification by cooled adsorption ( $\Delta h_{4-1} = -37$  kJ/kg) needs lower cooling energy at higher temperature ( $T_{\text{cold water}} = 18-20$  °C) than traditional system ( $\Delta h_{4-1} = -45,3$  kJ/kg and  $T_{\text{cold water}} = 7-12$  °C). The temperature increase of the cold source enable the use of natural heat sink like groundwater. In order to guarantee a continuous supply service of cooling and dehumidification like in the graph, more components in parallel (at least two) have to be managed in a batch process. The frequency of switching between adsorption and regeneration is influenced by operational (temperature and vapor pressure) and geometric parameters such as the total exchange surface; the total amount of adsorbing mass; length of the exchange path. The optimization of these parameter need to be evaluated including the cost of the adsorbing material and installation costs related to the control system. A smarter geometric shape than the coated fin should lead to higher exchange surface per volume unit against a reduction of the manufacturing costs. Low switching frequency generally reduce the complexity of the control system resulting in a lean managing equipment.

Figure 12. Comparison between cooled adsorption with traditional systems.

## 5 CONCLUSIONS

The coated-coil configuration presented is able to exchange heat and mass with the same device. The tested prototype can sustain for around 20 minutes an average dehumidification effect in the range 7-5 g/kg. Cooling the adsorption phase increased the dehumidification effect by around 30%, with evident benefits for the outlet air temperature. Similar devices can be considered for future applications in air-handling units substituting electrical consumptions of traditional cooling technologies with a sustainable heat demand, provided by solar energy and natural sink. The development of the prototype leads to increase performances and cost in order to obtain a more feasible solution for commercial applications.

### ABSTRACT

The demand for nursing homes has increased recently due to an increase in the aging population in Japan. Nursing homes are generally equipped with hot water supply and heating systems for bathing, preparing meals, and heating rooms. This equipment utilizes a considerable amount of energy. Few studies have measured heat loss from the hot water supply and heating systems in such facilities. This study evaluated the hot water supply and heating systems of a nursing home located in a cold climate area in Japan.

The temperature and flow rate of the hot water were continuously measured, and the energy consumption and heat loss for each subsystem were calculated. These results clarified that the energy consumption in the hot water supply subsystem was slightly larger than that in heating subsystem. Inefficiencies of the system were also continuously evaluated throughout the study. Heat losses in piping attributed to 38% of the total energy consumed by the hot water supply subsystem. Subsequently, a thermal analysis of the hot water subsystem was performed. The calculated return temperature agreed with the measured return temperatures when the resistance of thermal insulation was decreased by an average of 45%; this result was possibly due to the deterioration of thermal insulation materials or the presence of thermal bridges.

### KEYWORDS

Hot water supply, Energy consumption, Heat loss, Nursing home

### INTRODUCTION

The aging population in Japan reached 26.7% of total population in 2017 and is expected to continue rising, thereby demanding more nursing homes for accommodation (Ministry of Health, Labor and Welfare 2016). These nursing homes consume a significant amount of hot water for bathing and preparing meals, thereby increasing the energy consumption. In addition, heating subsystems that use hot water are popular in cold regions, such as the location of the surveyed facility. While energy conservation in newly constructed buildings is being widely promoted, the importance of commissioning, which is a process to verify that the adopted building system is performing as planned, and energy management for existing buildings has attracted attention. The energy consumed by hot water supply systems accounts for 24%~38% in homes wherein energy consumption is <30 GJ/year (Murakami 2006). However, only a few studies have evaluated the hot water supply systems for nonresidential buildings. Nursing homes, in particular, have not been extensively studied; therefore, energy-saving strategies in such facilities are unavailable. Therefore, a quantitative evaluation of energy usage and heat loss from hot water systems in existing nursing homes will contribute to future energy conservation efforts in nursing homes.

In this study, we measured the temperature and flow rate for each part of the hot water supply and heating systems for a nursing home in Hokkaido, a cold region in Japan, and calculated

energy consumption based on the measurements. Furthermore, we identified the cause of heat loss in the hot water subsystems via numerical analysis.

## CALCULATION OF ENERGY USED IN SYSTEMS

### Methods

The surveyed building is a special nursing home for the elderly with a day service center situated in a cold region wherein the average temperature in the winter falls below 0°C. The building comprises a central part, which includes an office room, a meeting room, a day service room, a machine room and bathrooms, along with western and eastern wards with a total of 29 rooms for residents. Fig. 1 outlines the building.

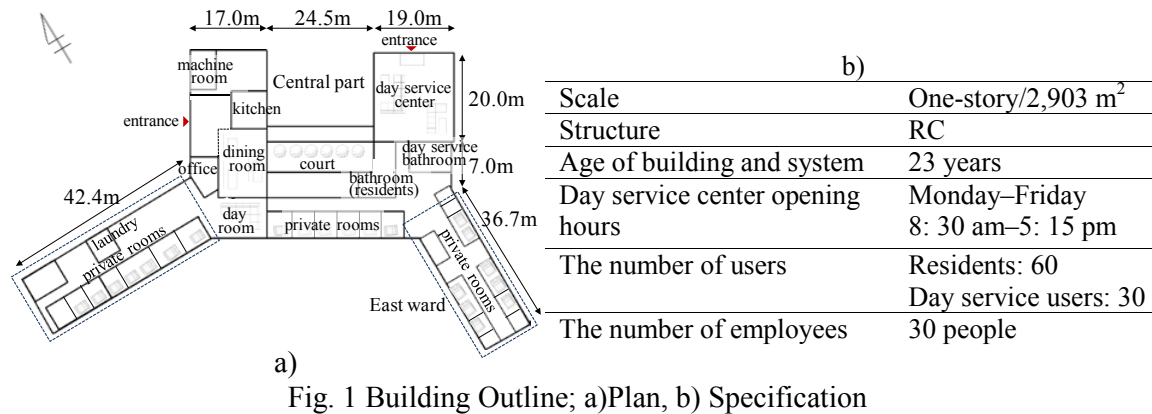

Fig. 2 shows the schematic of the hot water supply and heating systems. The hot water is heated by two heavy-oil-fired boilers in the machine room and then used by the three subsystems. The first subsystem named “hot water supply subsystem (HWSS)” supplies hot water to each room. The second subsystem, named “heating subsystem,” circulates hot water to all hot water radiators and floor heating equipment throughout the facility. The third subsystem, “bathtub heating subsystem,” supplies heat to bathwater via a heat exchanger.

### Measured items

In this study, the hot water temperature, the flow rate in each subsystem, and the electric current for the pump were measured. The measurement points are shown in Fig. 2. T-type thermocouples were attached to the outer surface of the steel pipe, which was covered by thermal insulation material. The temperatures were mainly measured near the inlet and outlet of each component of the system, such as boilers, the hot water tank, hot water headers, and heat exchangers. The flow rate of the supplied hot water was measured continuously because it was not kept constant. On the other hand, the flow rates in the heating subsystem and bathtub heating subsystem were set to be constant, so measurements taken over a relatively short duration were used to estimate energy consumption. Since the pump was ON/OFF controlled, even in a subsystem with a constant flow rate, we determine the time when the hot water is flowing by the electric current for the pump. The measurements began on September 22, 2016, and the measurement interval was 1 min. The accuracy of T-type thermocouple is  $\pm 0.5^\circ\text{C}$  and that of ultrasonic flowmeter is  $\pm 1.0\%$  of flow rate. Taking these errors into consideration, the maximum error of heat amount is estimated to be  $\pm 13.5\%$ .

### Use of heavy oil in each subsystem

Fig. 3 classifies the energy usage in the hot water supply and heating systems. Energy consumption indicated by the thick-lined frame was calculated by equations (1~5) using the measured data. We did not calculate the heat loss caused by the exhaust gas from the boilers or the heat release dissipation from the boiler surface.

Fig. 3 Classification of energy use in hot water supply and heating systems

$$Q_{\text{sup}} = \sum_1^{1440} (T_{21}(t) - T_{22}(t)) \cdot F_{22} \rho c \Delta t, \quad (1)$$

$$Q_1 = \sum_1^{1440} (T_{23}(t) - T_{20}(t)) \cdot (F_{23}(t) - F_{24}(t)) \rho c \Delta t \quad (2)$$

$$Q_2 = \sum_1^{1440} (T_{23}(t) - T_{24}(t)) \cdot F_{24} \rho c \Delta t, \quad (3)$$

$$Q_3 = \sum_1^{1440} (T_{11}(t) - T_{16}(t)) \cdot F_{11} \rho c \Delta t, \text{ and} \quad (4)$$

$$Q_7 = \sum_1^{1440} (T_1(t) - T_2(t)) \cdot F_2 \rho c \Delta t. \quad (5)$$

In the HWSS, hot water is temporarily stored in the hot water storage tank ( $Q_{\text{sup}}$ ).  $Q_{\text{sup}}$  is mainly transferred to the water as heat ( $Q_1$ ), but some of the supplied heat is lost in the hot water pipes over the whole circulation pathway ( $Q_2$ ) or from the hot water tank. The heating subsystem is comprised of four branches for office space, public space, private space and floor heating. Heat loss from the pipes occurs during both *on* and *off* operation. From the measured data, the total amount of heat consumed (including losses) during operation for the office space ( $Q_3$ ) can be calculated. The heat consumption for the other spaces ( $Q_4$ ,  $Q_5$ , and  $Q_6$ ) are calculated in the same manner as Equation (4). In the bathtub heating subsystem, as with the heating subsystem, the total amount of heat during use ( $Q_7$ ) can be calculated.

However, since the pumps are frequently *off* in this subsystem, it is necessary to take the heat loss during *off* operation into consideration. “T” and “F” in the equations correspond to those in Fig. 2, Q is the daily heat consumption [MJ/day],  $\rho$  is the water density [ $\text{kg}/\text{m}^3$ ], c is the specific heat of water [ $\text{MJ}/(\text{kg} \cdot \text{K})$ ], and F is the flow rate [ $\text{m}^3/\text{min}$ ].  $\Delta t$  is time interval [min].

### Results and discussion

Fig. 4 shows the annual heavy oil use every week from Dec 1, 2016 to Dec 31, 2017. The bar graph shows each energy usage. While the energy consumption for the heating subsystem accounts for 17%, the HWSS accounts for 21%. Moreover, Heat losses in piping account for 38% of the energy consumption for the HWSS. The line graph shows the total energy consumption calculated based on heavy oil consumption. The difference between the sum of each energy usage and the total energy consumption can be 61% and is likely related to heat loss from the boilers. In this facility, the ON/OFF of the boiler was found to be very frequent. Every time the boiler is turned ON/OFF, it caused air purging to remove impurities, placing a large load on the boilers. In addition, a high air-fuel ratio of 1.3 or more is set. Heat loss from the boilers must be examined in detail in the future.

Fig. 4 Use of annual energy consumption of heavy oil in facilities

From Fig. 4, it can be seen that the energy consumption for the HWSS is quite large throughout the year, thus it would be efficient to lower the hot water set temperature. However, since the heat loss is also large, the hot water temperature may drop below a certain level ( $45\sim 50^\circ\text{C}$ ) during the hot water circulation, which may no longer inhibit *Legionella* bacteria (JAHMEC Guideline 2017).

### NUMERICAL ANALYSIS ON PIPING HEAT LOSS

In order to investigate measures to reduce the heat loss from the HWSS, a thermal analysis of the subsystem was conducted, focusing on the performance of the thermal insulation material, the construction situation in situ, and the heat bridge of equipment.

With reference to the equipment drawing of the facility, the HWSS was modeled as shown in Fig. 5. The specifications of the carbon steel piping and the thermal insulating material (fiberglass insulation) are listed in Table 1 and Table 2, referring to JIS G 3452 and JIS A 9504, respectively. The measured temperatures and flow rates used for calculation are listed in Table 3. The temperature just after the hot water tank exit (T23) was used as an input in this calculation. Then the calculated and the measured return temperatures just before entering the hot water storage tank (T24) were compared. The deterioration of the insulation materials and the portion without thermal insulation were considered to be the primary causes of piping heat loss. In this facility, there was no insulation at the holes of the building base and the floor slab through which the pipes run. These uninsulated segments, about 10 cm long each, were found every 5 to 8 m, and the total length was estimated to be 5 m of the 350 m total piping network. These uninsulated segments were taken into consideration in the simulation model. The calculation cases are given in Table 4. The calculation was carried out for 6 hours starting at

midnight on December 1st, during which the hot water is circulating at the constant flow rate (98 L / min). The heat balance equation of the hot water in the pipe and the boundary condition between the hot water and the underfloor air are given as follows:

$$C_w \rho_w \frac{\partial T_w}{\partial t} = \frac{\partial}{\partial x} \left( \lambda_w \frac{\partial T_w}{\partial x} \right) - C_w J \frac{\partial T_w}{\partial x}, \quad (6)$$

$$-\lambda_w \frac{\partial T_w}{\partial n} = K_w (T_a - T_w), \quad (7a)$$

$$K_w = \frac{\frac{1}{r_p}}{\ln \frac{r_i}{r_p} + \frac{1}{\lambda_i r_i h_a}}, \quad (7b)$$

where  $x$  is the direction of water flow [m],  $J$  is the flow rate [ $\text{kg}/(\text{m}^2 \cdot \text{s})$ ],  $C$  is the specific heat [ $\text{J}/(\text{kg} \cdot \text{K})$ ],  $\rho$  is the density of water [ $\text{kg}/\text{m}^3$ ],  $T$  is temperature [K],  $\lambda$  is the thermal conductivity [ $\text{W}/(\text{m} \cdot \text{K})$ ],  $h$  is the heat transfer coefficient [ $\text{W}/(\text{m}^2 \cdot \text{K})$ ],  $K_w$  is the overall heat transfer coefficient [ $\text{W}/(\text{m}^2 \cdot \text{K})$ ],  $r=D/2$  ( $D$  is outer diameter [m])  $\frac{\partial}{\partial n}$  is the normal direction differential on the boundary between the pipe and insulation material, and the subscript  $w$ ,  $a$ ,  $i$  and  $p$  are water, air, insulation and piping, respectively. Equation (7b) refers to Transport Phenomena 2002.

Hot water supply temperature	T23 (near the hot water tank)
Underfloor temperature	20°C (constant)
Hot water supply flow rate	98L/min(constant)

Table 4 Computational condition

Case 1	no deterioration of thermal insulation and no insulation defect
Case 2	no deterioration of thermal insulation and 5 m insulation defect
Case 3	45% deterioration of thermal insulation and 5 m insulation defect

### Calculation result

Fig. 6 shows the calculated results for the three cases compared with the measured results. In

Case 1, the return temperature of the hot water is 1.0°C lower than the supply temperature, while the measured return temperature decreased by 1.5 to 2.0°C. There is almost no difference in the return temperature between Case 1 and Case 2, although the heat loss at the uninsulated segment is about 2.2 times larger than the normal (insulated) pipe. This is probably because the total length of the uninsulated segments is very short compared to the total length of the hot water pipe. Since the actual length of the uninsulated segments has not been confirmed over the whole crawl space, a detailed check is necessary in the future. In Case 3, the calculated temperature agrees very well with the measured temperature. One possible reason that the thermal resistance of the insulation may have decreased by 45% on average is that the insulation material was wound up on the pipe too tightly (Masuda 2014). Another possible reason is that heat loss at thermal bridges such as piping flanges and hanging metal hooks may have a significant influence.

Fig. 6 Comparison of calculated and measured return temperatures of the hot water

## CONCLUSION

We surveyed the annual heavy oil consumption in one nursing home, which served as reference data for energy conservation measures and performance verification of other facilities for elderly people. In the case of this considered building, we observed that piping heat loss in the HWSS was significant throughout the year. We investigated reasons for the large heat loss by conducting a thermal analysis and concluded that the heat insulation performance might have decreased by 45% on average. To identify the causes and locations of the heat loss, future work should consider temperature distribution in the underground space through which the hot water pipes run.

## ACNOWLEDGEMENT

The authors would like to thank the related parties of elderly nursing home, and Public Interest Incorporated Foundation LIXIL JS Foundation for the generous cooperation.

### ABSTRACT

Indirect evaporative cooling has exciting implications for air based thermal comfort. With recent advances in the research and commercialization of Maisotsenko Cycle (M-Cycle), or dew-point, evaporative cooling, thermodynamics can be fully leveraged to provide effectively free air cooling. However, few studies seek to generate cool surfaces by evaporation for radiant cooling. As a method to reduce building energy consumption, such an evapo-radiative system would maintain occupant thermal comfort at higher ventilation air temperatures and provide cooling at low cost. This study explores an analytical model for an M-Cycle evapo-radiative cooling system that derives a 1-D temperature profile throughout an experimental module and compares the outputs to experimental data to begin the model validation process.

### KEYWORDS

Radiant Cooling, Thermal Comfort, M-Cycle, Evaporative Cooling

### INTRODUCTION

Maintaining comfortable conditions in buildings accounts for a significant portion of energy use and carbon dioxide emissions, both in the United States and around the world. According to the US Energy Information Administration, nearly 40% of total energy consumption in the US is accounted for by commercial and residential buildings (EIA, 2018); of total building energy use, 19% is used for ventilating and cooling building spaces (EIA, 2012). At a global scale, the International Energy Agency reports that the residential sector consumes approximately 20% of world energy demand (IEA, 2015).

Current air conditioning technologies rely on cooling air by exchanging heat with a refrigerant vapor compression cycle. Air conditioning refrigeration cycles typically have coefficients of performance, COP, between 2 and 4, and the compressor in the refrigeration cycle and the fan which circulates the building air account for the majority of the system energy demand (Duan et al. 2012). Using water for evaporative cooling is a common strategy for heat rejection and cooling.

Conventionally, the wet-bulb temperature is the maximum temperature depression achievable by conventional evaporative coolers, which are viable options only in very dry climates. But advancements in heat and mass exchanger integration and geometry have led to dew point evaporative cooling, known as the M-Cycle. The M-cycle was initially conceptualized by Valeriy Maisotsenko as a performance-enhancing modification of traditional IEC heat

exchangers (Duan et al. 2012). Both processes cool product air via heat exchange with a wetted working air channel, usually through a metallic plate separating the two channels. Whereas in the traditional process the working air is completely separate from the product air and is at the same temperature at the inlet, the M-cycle diverts some of the product air to the working air channel. This pre-cools the working air and the higher temperature difference between the two streams drives more effective heat exchange. This modification allows the M-cycle to approach much lower temperatures than the traditional process, which is desirable for a radiant panel because the temperature of the radiant surface determines its ability to cool effectively.

Hydronic radiant cooling systems have been gaining traction in the United States and abroad for providing comfort during cooling conditions. Traditionally, chilled water is circulated to cool ceiling panels, which condition spaces through both radiative and convective heat transfer, and are often effective at reducing energy consumption compared to forced air systems. However, radiant cooling still faces significant challenges, namely the need for precise temperature control and humidity sensing to prevent water from condensing on the panel and falling on building inhabitants below. The hydronics for a radiant system are rarely integrated with an evaporative system.

This project seeks to simultaneously address challenges to both hydronic radiant cooling and indirect evaporative cooling systems by developing a dew-point evaporatively cooled radiant panel. Using evaporation to cool the radiant surface promises to be more efficient than circulating chilled water and inherently avoids the possibility of condensation, as the lowest temperature that can be attained by evaporative cooling is above the dew point of the inlet air. Such a technology links surface temperatures in the room to air temperature and relative humidity, further simplifying controls and leveraging other low exergy technologies, such as desiccant dehumidification, to control for comfort using air dehumidification and subsequently lowered radiant temperatures for occupant control rather than air conditioning.

## METHODS

Few studies exist on indirect evaporative cooling conducted in an integrated manner for radiative cooling. Younis et al. (2015) model such a similar system for small office environments, however the primary mode for occupant comfort is through chiller-based air conditioning. In this study, we propose a design methodology maintaining occupant thermal comfort in the absence of a chiller using a truly integrated approach to radiative and evaporative cooling requiring only control of the relative humidity of the inlet air.

In our integrated evaporative-radiant cooling system, it is crucial to have a highly conductive, but also easily tunable, material for thin film formation of water in the wet section. We suggest a boehmite nanostructure on an aluminum surface as a key material for the cooling system. Aluminum, when exposed to high temperature water, forms a nano-scale porous layer of aluminum oxide. A stable boehmite phase is achieved for a sufficiently high and also wide range of temperature of water (Bernard and Randall, 1960; Vedder and Vermilyea, 1968; Abdollahifar et al. 2015; Rani and Sahare, 2015); we choose the hydrothermal synthesis at  $\sim 80^\circ\text{C}$  for 24 hours as a standard treatment (Shim et al. 2018). The presence of the boehmite layer provides changes not only to the chemical composition of the substrate, but also to its physical structure, in terms of crystallography and surface roughness, which naturally turn the aluminum surface from hydrophilic to superhydrophilic (Shim et al. 2018). Such a superhydrophilic surface improves evaporative cooling performance by keeping the thermal mass of coolant (water) low compared to the regular hydrophilic aluminum surface.

Generating a thin film of water allows a large ratio of evaporating area to volume, which can be one of the most effective ways to enhance evaporative heat transfer.

### Analytical Model

Figure 1: Section (top) and plan (bottom) drawings of the M-Cycle test apparatus, showing sensor locations and air flow directions. Starting from the top, the first and third horizontal plates are acrylic, chosen as an insulator; the second and fourth horizontal plates are wetted boehmitized aluminum. Air flow splits in the rounded baffle to the right, and flow can be modulated between 0 and 100% of supply air to either top or bottom stream.

A one-dimensional model tracking bulk average values was chosen to assess the performance of the prototype evapo-radiant device shown in figure 1. Because of its simplicity and relative accuracy (less than 10% error in the temperature of the product air), a previous simulation used by Hasan (2010) to model regenerative (M-cycle) evaporative coolers was used as a conceptual basis for the model developed here.

The conceptual basis is straightforward: air enters the panel (via the dry channel inlet) at ambient temperature and humidity and is cooled by heat exchange with the wet channel through the aluminum plate. At the end of the dry channel, the air flow is split into two streams that recirculate along the wet and radiant channels, respectively, at the end of which the air is collected and exhausted from the building. Thus, the bulk heat transfer equations account for (1) heat exchange between air in the dry channel and air in the wet channel, and (2) exchange between the room (via radiation and natural convection) and air in the radiant channel. The equations model the variation of the temperature, enthalpy, and humidity of the air streams with position in the panel (which is expressed synonymously by area  $dA = Wdx$ ). Beginning with exchange between the dry and wet channels, the overall energy balance is given by:

$$M_w \frac{dh_w}{dA} = M_d C_p \frac{dT_d}{dA} \quad (1)$$

The heat (enthalpy) lost by air in the dry channel is given by Fourier's law as:

$$M_d C_p \frac{dT_d}{dA} = U(T_d - T_f) \quad (2)$$

where  $U$ , the overall heat transfer resistance from the dry air to the water film-wet air interface, is given by adding the heat transfer resistances of the air, aluminum, and water film, respectively:

$$U = (1/\alpha_d + \delta_{Al}/k_{Al} + \delta_f/k_f)^{-1} \quad (3)$$

The enthalpy gained by the air in the wet channel is given by both latent (water vapor mass transfer) and sensible (heat transfer) components:

$$M_w \frac{dh_w}{dA} = \alpha_w(T_f - T_w) + \beta(W_s - W_w) \quad (4)$$

However, assuming that the Lewis relation (5), which compares energy and mass propagation rates, can be taken as unity under these conditions, this equation can be simplified as an enthalpy driving force (6) between the water film and the bulk air as shown in Hasan (2010):

$$Le = \frac{\alpha_w}{\beta C_H} \approx 1 \quad (5)$$

$$\dot{M}_w \frac{dh_w}{dA} = \beta(h_s - h_w) \quad (6)$$

Solving equations (1), (2), and (6), and (7) will require relating the enthalpy and humidity of the saturated boundary layer at the air/water interface with the temperature of the water film. These relationships are tabulated in Chapter 6 of the 2001 ASHRAE Fundamentals Handbook and can be approximated as linear over the temperature range of interest with little loss of accuracy, the novel contribution to the field in this model. Thus, we can write the following linear relationships:

$$h_s = a_{s,h} T_f + b_{s,h} \quad (7)$$

Because the dry channel is insulated from the radiant channel by an acrylic plate, these equations fully define the temperature, humidity, and enthalpy profiles in the wet and dry channels. Before they can be solved, the heat and mass transfer coefficients need to be defined; for laminar flow between parallel plates, Burmeister (1983) gives the Nusselt number:

$$Nu = \frac{\alpha D_h}{k} = 4.861 \quad (8)$$

Thus, the heat transfer coefficient can be calculated, from which the mass transfer coefficient is known by the Lewis relation. Equation (1) can be integrated, which allows us to solve equations (2), (6), and (7) for the dry channel temperature, water film temperature, and wet channel enthalpy. The only difficulty here is in initial conditions; though the ambient conditions are known, none of the outlet conditions are given. Thus, we cannot set  $x = 0$  to be the inlet of the panel because initial conditions would not be known for both the wet and dry air streams. Instead, we must guess the temperature at the recirculation point (the outlet of the dry channel where the air flow splits and recirculates to the wet and radiant channels). We can then calculate the outlet temperature and compare with known ambient conditions in order to adjust the guess and iterate to a solution. Heat transfer between the room and the radiant channel were then addressed to calculate the steady state temperature profile of the evapo-radiative M-Cycle apparatus for a given plate area and convective and radiative exchange with a fixed room condition. First, we assume that the heat transferred from the room to the water film is equivalent to the enthalpy lost by the water film to the air flow in the radiant channel:

$$\frac{dq_{room}}{dA} = \dot{M}_r \frac{dh_r}{dA} \quad (9)$$

The enthalpy gained by the air flow is analogous to that in the wet air channel, so we can write:

$$\dot{M}_r \frac{dh_r}{dA} = \beta(h_s - h_r) \quad (10)$$

Finally, the heat gained from the room is given by summing radiant and convective contributions. As shown by Lienhard and Lienhard,[3] radiant heat transfer can be expressed with a heat transfer coefficient analogous to that of natural convections for small temperature differences, so we can write an overall heat transfer coefficient:

$$U_{room} = (1/(\alpha_{radiant} + \alpha_{convective}) + \delta_{Al}/k_{Al} + \delta_f/k_f)^{-1} \quad (11)$$

$$\frac{dq_{room}}{dA} = U_{room}(T_{ambient} - T_f) \quad (12)$$

Equations (9), (10), and (12) can be solved analogously to the wet channel/dry channel case by first solving for  $T_f$  and then integrating.

## RESULTS AND DISCUSSION

Initial experiments of the M-Cycle model produce intuitive results with reasonable outputs. Certain initial criteria were chosen to facilitate model validation in future experimentation. Figure 2a shows 9 data points where the ratio between air flowing to top and bottom wet channels is varied between 0 and 1. For example, a ratio of 0.25 indicates that 25% of the air supplied in the dry channel is diverted to the top wet channel, and the remaining 75% is diverted to the lower wet channel with the radiant panel facing the room. The y-axis is the average temperature across the lower radiant plate exposed to the room. Points are placed at the lowest average temperature value, with the entire dataset extending to the right y-axis to show the initial inlet air temperature. For all runs, the initial inlet air absolute humidity was 9 g/kg. Additionally, three runs of the model were conducted with plate spacings of 3.5, 6, and 10 mm.

Figure 2b shows experimental data compared to model outputs for the wet and dry channel temperatures as well as surface temperature data for the exposed panel. This data was taken at an air flow ratio of 0.23 and an inlet temperature of 20.7 °C and absolute humidity of 6 g/kg. Airflow was at a Reynolds number of  $Re = 90$  inside the apparatus.

Figure 2: (a-left) The optimal ratio for air flow between top and bottom wet channels for producing a cold lower plate for three inlet air conditions and plate spacings. (b-right) Experimental data points compared to model outputs.

The wet bulb temperature for the experiment's inlet air was 13 °C and the dew point was 7 °C. The average measured radiant surface temperatures from figure 2b was 16.0 °C for a wet bulb efficiency of 61% and a dew point efficiency of 34%. These low efficiencies of the test apparatus could be explained by the apparent ineffectiveness of the wet channel at remaining

wetted, which was visibly confirmed and shown in the data with the higher than expected temperatures for the wet channel compared to the model. This indicates that not enough precooling of the air occurs for the air entering the wet channels, and the lower channel is effectively a wet bulb radiant cooler rather than a dew point radiant cooler. Optimizing the setup was outside the scope of the experiment, as the ultimate goal is to begin validation on the analytical M-Cycle evapo-radiative cooling model. However, we will re-examine the surface wetting to make sure the physical data represents the modeled evaporative phenomena.

## CONCLUSION

A major goal of the study was to develop an analytically solvable model for M-Cycle enhanced evapo-radiative cooling apparatus. The model is an exciting advance for describing this type of system. Linking air temperature, humidity, and surface temperatures is an innovative concept for control purposes, as fewer degrees of freedom simplify control and system response. Future work will be conducted to fully validate the model, drawing conclusions for the system design parameters, such as optimal airflow ratios between the channels, controls for comfort conditions based on climate data, and eventually an energy budget for the entire system.

### **ABSTRACT**

Dynamic insulation (DI) can recover heat lost in conduction by drawing cold outdoor air into indoor through an insulation wall in winter. A “breathing DI” system we proposed in the past has functions both as an insulated envelope and as a highly efficient heat exchanger for ventilation. It is alternated periodically that the outdoor air is drawn through half of walls made of breathable inorganic concrete (BIC) and the indoor air is exhausted through the other half of the BIC walls. In order to put the breathing DI system into practice in housing construction, this paper presents some studies from various points of view in addition to the past studies on heat and moisture transport based on laboratory experiments and numerical simulations. We first experimentally studied the filtering efficiency and clogging of a BIC panel. This showed that approximately 30 % of the atmospheric dust can be captured by a BIC panel and no clogging would occur for at least 10 years. We also measured the sorption and desorption of formaldehyde by a BIC panel to confirm the effectiveness of a BIC wall to sorb gaseous state formaldehyde. We furthermore constructed a new test house at Ibaraki, Japan, to confirm the thermal performance of the breathing DI system based on full scale experiments.

### **KEYWORDS**

Insulation, ventilation, heat recovery, indoor air quality,

### **1. INTRODUCTION**

Dynamic insulation (DI) can recover heat lost in conduction by drawing cold outdoor air into indoor through an insulation wall in winter (Jensen, 1993; Taylor and Imbabi, 1997; Taylor et al. 1997; Dimoudi et al. 2004). A “breathing dynamic insulation” system (Abuku et al. 2012; Murata et al. 2015) we proposed in the past has functions both as an insulated envelope and as a highly efficient heat exchanger for ventilation. It is alternated periodically with a certain time interval that the outdoor air is drawn through half of walls made of breathable inorganic concrete (BIC) and the indoor air is exhausted through the other half of the BIC walls. After the heat in the exhaust air is stored inside the BIC walls, the stored heat in addition to the heat lost in conduction through the BIC walls is recovered by the supply air.

Our past numerical study (Abuku et al. 2012) showed that the inside surface temperature of the BIC walls can be kept the same as that of conventional “static” insulation walls and the recovery efficiency of the heat in the exhaust air can be improved to up to more than 90%. It was also experimentally shown that the BIC wall under study has recovery efficiencies of

almost 90% of the heat in the exhaust air, 18 to 35 % of the heat lost in conduction, and approximately 80% of the moisture lost through the BIC wall (Murata et al. 2015).

In order to put the breathing DI system into practice in housing construction, this paper addresses some other aspects of the system. We first experimentally studied the filtering efficiency and clogging of a BIC panel. We also measured the sorption and desorption of formaldehyde by a BIC panel to confirm the effectiveness of a BIC wall to sorb gaseous state formaldehyde. We furthermore constructed a new test house at Ibaraki, Japan, to perform full scale measurements of the hygrothermal performance, ventilation, energy consumption, and indoor air quality.

## 2. BREATHING DYNAMIC INSULATION SYSTEM

The breathing DI system consists of two distinct spaces that are enclosed by BIC walls and fans between the two spaces as illustrated in Fig.1. BIC has a high air permeability, a high insulation performance and a relatively large thermal storage. In this system, the outdoor air is drawn through half of the BIC wall, while the indoor air is exhausted through the other half. Intake and exhaust of air through the two halves of the wall are periodically alternated. An airflow from one space to the other is controlled by fans. After the heat in the exhaust air is stored inside the BIC walls, the stored heat in addition to the heat lost in conduction through the BIC walls is recovered by the supply air. Consequently, the “Breathing DI” system has functions both as an insulated envelope and as a highly efficient heat exchanger for ventilation.

Figure 1. Schematic of the breathing DI system (slightly modified based on Murata et al. 2015). a) One operation mode with airflow in one direction, b) the other operation mode with airflow in the opposite direction.

## 3. FILTERING EFFICIENCY AND CLOGGING

The filtering efficiency of BIC panels for dust was measured outdoor. The measurement was conducted on the flat roof of building #34, Higashi-Osaka campus, Kindai University, Japan during October 24, 2016 – January 31, 2017. The building is located near busy roads and highways. The schematic of the experimental set-up is given in Fig. 2. The set-up is composed of wooden panels and frames, an electronic fan, a BIC panel (30 cm x 30 cm x 8 cm) with an air filter as well as a hygro-thermometer and a digital dust monitor both in and outside the box. The air filter was attached to the inner surface of the BIC panel to diminish the influence of powder remaining in the BIC panel on the dust concentration in the box. Note that it was confirmed that this air filter does not influence the dust concentration measured by the dust monitors. The difference between the outside dust concentration  $C_o$  ( $\text{mg}/\text{m}^3$ ) and the inside dust concentration  $C_i$  ( $\text{mg}/\text{m}^3$ ) is considered to be due to the BIC panel. In the current paper, the filtering efficiency  $E_f$  (%) is defined by

$$E_f = \frac{C_o - C_i}{C_o} \times 100. \quad (1)$$

In the breathing DI system, the direction of airflow through BIC panels changes with a certain interval of time (e.g. 10 minutes). However, in this experiment, the direction of airflow through a BIC panel was not changed to accelerate the decrease of the filtering efficiency of the BIC panel.

Figure 2. Schematic of the experimental set-up to measure the filtering efficiency of a BIC panel.

The inside and outside dust concentrations as well as the temperature and relative humidity (RH) values were measured and averaged over every 10 minutes. For each parameter, 211 data were successively obtained. The average outside dust concentration for all the data was  $0.0135 \text{ mg/m}^3$  with a standard deviation of  $0.0084 \text{ mg/m}^3$  and the maximum is  $0.0350 \text{ mg/m}^3$ .  $E_f$  was 29.7 % on average with a standard deviation of 11.8 % and 61.5 % at the maximum. The relation between  $E_f$  and the number of measurement is given in Fig. 3a; the dependency of  $E_f$  on  $C_o$  is shown in Fig. 3b. Note that although in Fig. 3b there seems to be less number of data points, this means that some data show the same relation between  $E_f$  and  $C_o$ . The results show that the filtering efficiency did not decrease with time at least under the current study, although this is also supported by discussion on clogging in the last part of this section. It was also shown that the filtering efficiency is stably high when the outside dust concentration is high. This is probably because when the dust concentration is high, particles in the dust are large and thus easily captured by the BIC panel.

Figure 3. The dependency of the filtering efficiency  $E_f$  of the BIC panel on a) the number of measurement  $N$  and b) the outside dust concentration  $C_o$ .

In general, various factors affects the dust concentration (e.g. Csavina et al. 2014) that would eventually influence the filtering efficiency. In the current study, the relationships of  $E_f$  with the outside RH and humidity ratio are discussed as they would be considered to be one of the most important factors. Fig. 4. There is no correlation between  $E_f$  and the RH. However, only when the humidity ratio is high,  $E_f$  became stably high and there seems to be a positive

correlation between  $E_f$  and the humidity ratio. This is because particles in dust can swell when they absorb moisture and can be then captured by the pore structure of the panel more easily and because a wet surface of the pore structure can capture more dust.

Figure 4. The dependency of the filtering efficiency  $E_f$  of the BIC panel on a) the outside relative humidity and b) the outside humidity ratio.

Apart from air filtering, when a large amount of atmospheric dust accumulates in the BIC panel, the air permeability might be reduced which affects the performance of the DI system. The possibility of clogging of a BIC panel due to atmospheric dust was also estimated here tentatively assuming some input values and summarised in Table 1. The air permeability value of the BIC panel was taken from our own measurements. The result show that as the dust mass captured by the panel is very small, almost no clogging of the BIC panel would occur at least for 10 years. It should be noted that in the breathing DI system, the intake and exhaust of air through the panel are alternated periodically and thus the dust mass captured by the panel should be the half of the one given in Table 1 if the indoor air is clean.

Table 1. Estimate of the possibility of clogging of the BIC panel due to atmospheric dust

Input/Output	Parameter	Value	Unit
Input	Atmospheric dust concentration	0.02	mg/m <sup>3</sup>
	Air permeability	1.07	m/(h·Pa)
	Pressure difference between indoor and outdoor	20	Pa
	Service life	10	year
	Filtering efficiency	30	%
Output	Airflow rate	1.92	m <sup>3</sup> /h
	Airflow speed	5.93	m/s
	Dust mass captured by the panel	11.2	g/m <sup>2</sup>

#### 4. SORPTION AND DESORPTION OF FORMALDEHYDE

As one of drawbacks of the breathing DI system, a BIC panel can also sorb volatile organic compounds when the indoor air is exhausted through the BIC panel and then desorption of them to the inside might occur. According to Curling et al. (2012), the sorption and desorption of water and those of water plus formaldehyde were measured using the dynamic vapour sorption technique with a RH interval of 5 %. The results are given in Fig. 5a. The measured mass content of water plus formaldehyde was then subtracted by the measured water content to obtain the content of formaldehyde (Fig. 5b). Furthermore, the absorption/desorption rate was obtained by dividing the mass content increment/decrement for each RH step by the time used to obtain the equilibrium (Fig. 5c). The result means that after one cycle of absorption and desorption, most formaldehyde captured in the material is not desorbed. It was also shown that the desorption rate is lower than the absorption rate.

Figure 5. Measured sorption and desorption of water and formaldehyde by the BIC panel. a) sorption and desorption isotherm of water and water plus formaldehyde, b) the mass content of formaldehyde in the material, c) sorption and desorption rate of water and water plus formaldehyde.

## 5. FULL SCALE MEASUREMENTS AT A TEST HOUSE

Full scale measurements to confirm the thermal effectiveness of the breathing DI system were carried out at a two-storey test house (Fig. 6) located at Ibaraki prefecture, Japan. The test house has a gross floor area of 103 m<sup>2</sup> (1F: 52 m<sup>2</sup>; 2F: 51 m<sup>2</sup>), a total volume of approximately 300 m<sup>3</sup> and a high insulation performance with the area-weighted average U-value of 0.25 W/(m<sup>2</sup>K). At this test house, we measured the vertical temperature distribution (Fig. 6b) in an atrium space of the house with or without the breathing DI system. For three days (January 13-15, 2017) when the breathing DI system was operated with a time interval of 15 minutes for alternation of intake and exhaust of air, the ventilation rate was kept at 150 m<sup>3</sup>/h. For other three days (February 3-5, 2017) without the breathing DI system, three mechanical ventilation fans were always operated in two rest rooms and an undressing room to obtain a total ventilation rate of ~ 200 m<sup>3</sup>/h. Fig. 7 plots the indoor temperatures measured at different heights as well as the outdoor temperature measured near the test house. The results confirm the effectiveness of the breathing DI system, showing that with the breathing DI system, the indoor temperatures can be kept both higher and more uniform. Note that there

Figure 6. A two-storey test house equipped with the breathing DI system at Ibaraki prefecture, Japan. a) A photograph, b) Plan (1<sup>st</sup> floor).

Figure 6. Indoor temperatures measured at different heights in an atrium of the test house compared to the outdoor temperature. a) Breathing DI system, b) Normal mechanical ventilation.

was a heat source under the floor of the 1<sup>st</sup> floor, so the temperatures measured at 5 cm and 1.5 m were higher than those at  $\geq 3$  m.

## 6. CONCLUSIONS

In order to put the breathing DI system into practice in housing construction, we first experimentally studied the filtering efficiency and clogging of a BIC panel. This showed that approximately 30 % of the atmospheric dust can be captured by a BIC panel and no clogging would occur for at least 10 years. By measuring the sorption and desorption of formaldehyde by a BIC panel, we also showed that a BIC wall is effective to reduce gaseous state formaldehyde. Lastly, full scale experiments at the test house demonstrated that the breathing DI system can keep the indoor temperature higher and more uniform in winter.

### **ABSTRACT**

The rapid increase in space cooling and heating demand in recent years in the hot-summer and cold-winter (HSCW) zone in China (the most developed area in China) requires technology to be as efficient as possible, consuming the lowest amount of energy necessary. Heat recovery ventilation (HRV) system can meet this demand by lowering the building energy demand by pre-heating or pre-cooling. However, the climate in HSCW zone is humid and rainy all the year round, which may affect the energy performance of HRV system. The current research focuses on field measurements of the performance of HRV system in a test building located in east China to study the actual energy saving performance of the HRV system in the HSCW zone. The actual performance of the HRV system is measured. The experiment reveals that the system can save 14.5% of air-conditioning energy consumption in summer and 4.96% of air-conditioning energy consumption during rainy season. There is no significant energy saving effect in transition seasons. EnergyPlus is used to calculate the energy performance of the HRV system under different operating conditions. The simulation is compared with the test data. Both the measurements and simulation indicate that the use of HRV system can significantly reduce the energy consumption of the air-conditioned buildings in summer in HSCW zone.

### **KEYWORDS**

Heat recovery ventilation; Energy-saving; Field measurement

### **INTRODUCTION**

Improving indoor air quality and reducing building energy consumption have become an important area of research in architecture and related disciplines. Good indoor air quality is a guarantee for the health, comfort and productivity of occupants. The introduction of fresh air into room is one of the necessary conditions to improve indoor air quality <sup>[1]</sup>. However, the introduction of fresh air may result in a large fresh air cooling/heating load. There is a contradiction between the improvement of indoor air quality and the reduction of building energy consumption. Setting up a heat recovery system to exchange heat between fresh air and indoor exhaust air, and preheating or precooling the fresh air to reduce the heating or cooling load is an effective energy saving measure.

Many studies have been carried out to study the energy-saving effect of the heat recovery ventilation (HRV) system. For example, Roulet et al. <sup>[2]</sup> developed the evaluation method of heat recovery effect for different countries and regions based on energy gain method. However, the research on the energy-saving effect of HRV system for hot summer and cold winter zone in China mainly based on theoretical calculation or numerical simulation. Few experimental verifications have been carried out. Taking a library in Shanghai as an example,

Feng<sup>[3]</sup> calculated hourly energy recovery of HRV system and obtained energy-saving heat recovery modes and air conditioning modes for different conditions during the whole year.

The HSCW zone is one of the most developed areas in China, which has a hot and humid summer and a mild winter. Cooling is required through the summer season, but there is no central heating in winter. It is of great importance to verify the applicability of HRV system in summer in this area. Field measurements of the energy performance of HRV system in a test building located in east China has been carried out in this research. Results from experiments and numerical simulation have been compared and discussed in the paper.

## METHODS

### Evaluation method of heat recovery ventilation system

This paper selects HRV system with plate-type enthalpy exchanger as the research object. This exchanger is more suitable for the residential buildings and the HSCW zone.

#### •Heat transfer efficiency

The evaluation index system of heat recovery unit includes several important performance indexes, and the heat transfer efficiency <sup>[4]</sup> is one of them. The heat transfer efficiency includes three different types. The formula is shown in Table 1 as follows.

Table 1 Calculation formula of different heat transfer efficiency

Heat transfer efficiency	
Sensible heat recovery	$\eta_{ts} = \frac{m_s(t_2 - t_1)}{m_{min}(t_3 - t_1)}$
Latent heat recovery	$\eta_{ds} = \frac{m_s(d_2 - d_1)}{m_{min}(d_3 - d_1)}$
Enthalpy recovery	$\eta_{is} = \frac{m_s(h_2 - h_1)}{m_{min}(h_3 - h_1)}$

Where  $t$  is dry-bulb temperature (°C),  $d$  is moisture content (g/kg) and  $h$  is enthalpy (kJ/kg). Subscript  $s$  means fresh air; 1 means supply-in air; 2 means supply-out air; 3 means exhaust-in air; 4 means exhaust-out air.

Figure 1 Energy test principle diagram of ventilation system

#### •Energy-saving evaluation method

According to the above enthalpy transfer efficiency, the heat energy recovered from HRV system is related to the fresh air volume, the enthalpy efficiency of the device, the enthalpy difference of air and the density of fresh air<sup>[5]</sup> Calculation formula for heat recovery is as follows:

$$E = G\eta\rho(h_3 - h_1) \quad (1)$$

Where,  $E$  is the energy recovered by HRV system (kW),  $G$  is the fresh air volume (m<sup>3</sup>/s),  $\eta$  is the enthalpy efficiency of heat recovery unit,  $\rho$  is air density (kg/m<sup>3</sup>).

When HRV system is running, the resistance of the recovery system is increased and the energy consumption is increased. The energy consumption of HRV system is mainly produced by the fan, so the energy consumption energy of the fan is used as the energy consumption energy of HRV system. The formula is as follows:

$$W = \frac{(G_1 + G_2) \Delta p}{\eta_f} \quad (2)$$

Where,  $G_1$  is the supply-in air volume through HRV system ( $\text{m}^3/\text{s}$ ),  $G_2$  is the exhaust-out air volume through HRV system ( $\text{m}^3/\text{s}$ ),  $\Delta p$  the resistance of the air through HRV system (kPa),  $\eta_f$  is the fan efficiency. The energy consumption is converted to cooling / heating production

$$E' = W \cdot COP \quad (3)$$

$$W = \frac{(G_1 + G_2) \Delta p}{\eta_f} \quad (4)$$

When and only  $E' < E$  HRV system is energy-saving, and the amount of cold (heat) recovery is  $Q = E - E'$ .

### Experimental study

#### •The general information of the experiment site and the fresh air HRV system

The building used in the test is located in the Wujin District of Changzhou, Jiangsu province (HSCW). The test apartment consists of three main functional areas of the living room, the bedroom and the kitchen to simulate the ordinary residential space. The HRV system used in this test is plate-type HRV. The rated air volume is  $250\text{m}^3/\text{h}$ , and the power of the fan is  $80\text{W/h}$ . Heating and cooling of the experimental residential are applied by the VRF system. The rated cooling capacity is  $33500\text{W}$ . The rated heating capacity is  $37500\text{W}$ . The COP coefficient is  $6.0$ .

Figure 2 The test building

Figure 3 The plan of test apartment

#### •Experiment instrument and process

Main experimental instruments:

- (1) temperature and humidity recorder(testo-174H)  
Accuracy Temperature:  $\pm 0.5^\circ\text{C}$  ( $-20 \sim +70^\circ\text{C}$ );  
Accuracy Humidity:  $\pm 3\%$  RH ( $2\% \text{ RH} \sim 98\% \text{ RH}$ );
- (2) hot ball anemometer(TSI 9565-p): Accuracy:  $\pm 0.015\text{m/s}$  ( $0\text{m/s} \sim 30\text{m/s}$ ).

The experiment mainly includes two aspects: (1) to test the performance of the fresh air HRV system, which mainly includes air change rate, heat transfer efficiency, energy of the actual recovery etc.; (2) to measure the actual energy consumption of the test apartment, which includes energy consumption of all systems in the apartment. The heat gain or loss through the building envelope is also measured. Test process <sup>[6]~[8]</sup> is as follow:

- (1) start the HRV system / air conditioning preheating operation for 30min; keep the system running under the steady air volume.
- (2) fix the temperature and humidity recorder at a distance of 15cm from the air outlet and inlet; record the data every 5min;
- (3) use the hot ball anemometer to measure the air volume of the fresh air fan and record the wind speed of the cross section; calculate the air volume of the duct, and use the air volume hood to measure the air volume of the air conditioner;
- (4) Use power meter to test HRV system and air conditioning energy consumption separately;
- (5) keep the length of each working condition at the length of 2 hours.

## RESULTS

### •Experimental results

#### **Air conditioning + mechanical ventilation with fresh air bi-directional flow in summer**

HSCW zone is hot and humid in the summer, the daily average temperature is between 25-30°C, and the highest daily average temperature is over 30°C. The test condition is set as air conditioning temperature 26°C for cooling mode. The ventilation system keeps stable operation and the HRV system is on. The air enthalpy method is used to test the efficiency and energy consumption of summer air conditioning, and at the same time test the cooling load of the heat transfer, air infiltration and indoor heat source under the condition of air conditioning. The results are shown in Table 2 and 3.

Table 2 Test results of the ventilation system

Ventilation system	Temperature (°C)	Relative humidity (%)	Airflow (m³/h)	Enthalpy (kJ/kg)	Heat transfer efficiency
Exhaust-in	28.7	58.0	177.7	65.6	0.65(sensible heat)
Supply-in	35.4	63.0	166.3	95.2	0.52(latent heat)
Exhaust-out	33.3	57.5	175.1	86.1	0.55(enthalpy)
Supply-out	31.0	65.2	154.4	78.7	
Bedroom	26.6	48.7	/	/	
Living room	27.8	63.5	/	/	
Outdoor	35.0	58.0	/	/	

Table 3 Test results of the air conditioning

Air-conditioning	Temperature (℃)	Relative humidity (%)	Airflow (m³/h)	Enthalpy (kJ/kg)	COP
Bedroom（supply）	11.3	92.6	479.2	30.9	2.3
Bedroom（exhaust）	27.1	44.9	/	52.9	
Living room（supply）	22.6	87.2	/	60.9	
Living room（exhaust）	26.2	69.6	1545.0	64.4	
Energy consumption	5.8kwh=20880kJ				

#### **Dehumidification by cooling + mechanical ventilation with fresh air bi-directional flow in plum rain season.**

The plum rain season is a continuous phenomenon of rainy days in the middle and lower reaches of China's Yangtze River in June and July. In this period, the relative humidity is always over 90% during the whole month. Therefore, the dehumidification load of the air conditioner is huge. In the test, the condition of air conditioning is set as dehumidification mode, and the ventilation system is on. The results are shown in Table 4 and 5.

Table 4 Test results of the ventilation system

Ventilation system	Temperature (°C)	Relative humidity (%)	Airflow (m <sup>3</sup> /h)	Enthalpy (kJ/kg)	Heat transfer efficiency
Exhaust-in	23.4	64.9	175.0	53.3	0.62(sensible heat)
Supply-in	25.6	73.8	165.3	64.7	
Exhaust-out	25.4	67.2	177.1	60.5	0.33(latent heat)
Supply-out	24.2	67.2	152.4	56.7	
Bedroom	22.3	51.4	/	/	0.70(enthalpy)
Living room	22.4	72.	/	/	
Outdoor	23.3	97.0	/	/	

Table 5 Test results of the air conditioning

Air-conditioning	Temperature (℃)	Relative humidity (%)	Airflow (m³/h)	Enthalpy (kJ/kg)	COP
Bedroom (supply)	10.9	90.7	552.2	29.5	5.8
Bedroom (exhaust)	20.3	65.8	/	45.2	
Living room (supply)	16.9	96.0	/	46.3	
Living room (exhaust)	21.1	78.2	1604.6	55.0	
Energy consumption	3.1kwh=11268kJ				

### Simulation of energy consumption by EnergyPlus

Numerical simulation is also carried out in the study. The EnergyPlus model adopted in this paper is built strictly according to the actual size of the test apartment. The indoor air conditioning system is simulated by using the VRF system in EnergyPlus. The modelling of HRV is based on the sensible and latent heat exchange efficiency of the enthalpy exchanger. Air change rate in modelling condition is 0.5. The outdoor conditions for simulation is obtained from the weather station on site.

### Simulation results

Figure 5 Temperature change curve of bedroom in summer

Figure 6 Comparison of average heat flux density of enclosure structure in summer

According to the measured and simulated results, the calculated value and the measured value are in good agreement with the accurate setting of the heat transfer and outdoor weather conditions. The relative error between the measured temperature and the simulated value of bedroom is 0.4%, the relative error of envelope heat transfer is 7%, and the heat transfer error of envelope is related to the actual construction quality and accuracy of the structure. In order

to verify the accuracy of the model, a longer verification experiment was conducted during the transition period.

## CONCLUSION

The energy consumption of a residential building with HRV system in HSCW zone in China is measured experimentally. The energy saving effect of HRV system in the transitional season, summer season and plum rainy season is analysed(The accuracy of the instrument has a certain influence on the energy saving value.). The numerical model of a typical residential building with HRV system in HSCW zone is also established. The accuracy of the model is verified through the comparison of simulated and experimental results. This research draws the following conclusions:

- 1) In the summer of the HSCW zone, both indoor temperature and humidity are high, the room requires cooling and dehumidification by air conditioning system. Due to the big difference between the indoor and outdoor enthalpy, fresh air HRV system has a significant effect on the enthalpy recovery. The field measurements show that the HRV system can save energy 7059.68kJ within 2 hours and reduce 14.5% of the cooling load.
- 2) In the plum rain season, indoor air humidity is very high, which will cause large energy consumption for dehumidification. The fresh air HRV system has a great latent heat recovery effect. The experimental results show that the fresh air HRV system can save energy 3459.92kJ and reduce 4.96% of the dehumidification load within 2 hours.
- 3) Through the simulation results, it can be seen that the use of HRV system can significantly reduce the energy consumption of the air-conditioned buildings in summer. Compared with the natural ventilation, the energy consumption of the cooling system was reduced by 13.9% in summer after the introduction of the HRV system.
- 4) In hot summer and cold winter areas, air conditioning needs to be turned on in summer and winter, and the use of HRV system can save more energy.

## ACKNOWLEDGEMENT

The present study was financially supported by the national key project of the Ministry of Science and Technology of China on “Green Buildings and Building Industrialization” (Grant No. 2016YFC0700500), and the National Natural Science Foundation of China (Grant No. 51578278).

## Characterisation of the flexibility potential from space heating in French residential buildings

Jérôme Le Dréau<sup>1,\*</sup>, Johann Meulemans<sup>2</sup>

### ABSTRACT

Demand response (DR) at the building level (also named energy flexibility) will play an important role in facilitating energy systems based mostly or entirely on renewable energy sources. Flexibility is thus deemed necessary to control the energy consumption to match the actual energy generation from various renewable energy sources such as solar and wind power. However, there is lack of comprehensive knowledge about how much energy flexibility different building types and their usage may be able to offer to the present or future energy systems. In this study, the flexibility potential of space heating is characterised among the building stock in France. Five different typologies of buildings were chosen (post-1945, BR 1982, BR 2005, BR 2012 and BR 2020) with different levels of insulation, air-tightness and thermal mass. Building energy simulations were performed, with modulations (i.e. increase or decrease) of the space heating set-point during the heating season. From this study, the large influence of the envelope properties on the flexibility potential was highlighted: the storage efficiency for upward modulations and the rebound rates for downward modulations range from 40% up to 90% in poorly insulated and well-insulated buildings, respectively. This study describes a generic method and provides quantitative data to estimate the flexibility potential for demand response at the building level and to help designing future energy grids.

### KEYWORDS

Energy flexibility; Demand response; Space heating; Building stock; Building envelope

### INTRODUCTION

In order to decrease the environmental footprint of buildings, the European Union is encouraging the development of demand side management (DSM). These strategies consist in energy conservation measures to decrease the energy use of buildings on the long term and demand response (DR) to improve the operation of buildings taking into consideration the energy grids constraints. Demand response at the building level will play an important role in facilitating energy systems based mostly or entirely on renewable energy sources. Space heating, which accounts for 61% of the energy use in residential buildings in France (ADEME, 2013), can play an important role in providing flexibility to the energy grid. Recent studies in Denmark (Le Dréau and Heiselberg, 2016) and Belgium (Reynders et al., 2017) showed that the flexibility potential ranges from 50 up to 140 Wh/m<sup>2</sup><sub>floor</sub> for 4-hour modulations. Similarly, some field tests carried out in France (e.g., Modelec and Smart Electric Lyon projects) estimated this potential from 1 up to 3 kW per household (ADEME, 2016). However, these studies focussed on the type of control system and selected one or two building typologies to draw their conclusions. There is thus a lack of comprehensive knowledge about how much energy flexibility different building types and their usage may be able to offer to the present or future energy systems. The objective of this study is to evaluate the energy flexibility potential of single-family houses with respect to their thermal

characteristics, accounting for different types (i.e., upward or downward modulations) and durations of DR events. The objective of upward modulations is to fill the valleys, whereas the objective of downward modulations is to shed the peaks. The flexibility potential will be characterised by a virtual storage capacity as defined in previous studies (Le Dréau and Heiselberg, 2016; Reynders et al., 2018, 2017).

## METHODOLOGY & DESCRIPTION OF BUILDINGS

Five buildings were selected to perform modulations of the space heating and can be classified according to the year of construction and the building regulation: 50's (no building regulation), BR 1982 (first building regulation in France), BR 2005, BR 2012 and BR 2020 (extrapolated from the actual building regulation in France). These five classes of buildings represent a large share of the building stock of single-family houses in France (around 30% of the single-family houses have been built within these periods). The main thermal characteristics of these buildings can be found in Table 1. The level of insulation of the buildings increases with the building regulations and the airtightness decreases. All buildings are insulated from the inside since this is a common feature in France. The building built in the 50's relies only on natural ventilation to ensure a good indoor air quality, whereas other buildings are equipped with a mechanical extraction (with either an automatic or a hygrometric regulation). It should be noted that the building layout varies with the cases (3 different geometries with a floor area from 110 up to 140 m<sup>2</sup>). Realistic occupation and internal loads scenarios were defined, resulting in a total sensible heat load of around 5000 kWh/year (which corresponds to an average load of 4.8 W/m<sup>2</sup><sub>floor</sub>). Due to these different characteristics, the space heating needs of the simulated buildings range from 21 kWh/m<sup>2</sup><sub>floor</sub>.year up to 290 kWh/m<sup>2</sup><sub>floor</sub>.year in Nancy (continental climate).

This study focusses on the flexibility that can be gained by controlling the space heating energy use. The heating system consists of radiators located in each room and emitting heat both by radiation (30%) and convection (70%). Upward and downward modulations (i.e. by increasing/decreasing the operative temperature set-point from 21°C to 23°C/19°C) were investigated for durations between 1 and 12 hours. These modulations do not jeopardise the thermal comfort of the occupants (as defined in the standard EN 15251). The starting time of the modulations (noon) was chosen to match with the peak of production in an energy production system dominated by solar panels. The controller of the radiators is a “perfect” rule-based controller, which pre-calculates at each time-step the amount of heat to be injected

in the thermal zone to reach the set-point (taking into consideration the limitations of the heating system). Each building was modelled by 11 thermal zones using a Building Energy Simulation (BES) software (EnergyPlus 8.8). The simulation time-step was set to 2 minutes. Two different climatic zones in France were considered: Nancy (continental climate) and Nice (Mediterranean climate). The results obtained for both climates were quite similar, so only the results from Nancy will be presented here for the sake of brevity.

From the simulations, the heating power and operative temperature with and without modulation are compared. An example is given in Figure 1 (left), where an upward modulation for 2 hours (grey area) is performed in the building built according to the BR 2012. Three indicators are then derived from these simulations to characterise the virtual storage capacity of each building: the energy charged in or discharged from the thermal mass during the modulation ( $\Delta q_{\text{heating DR}}$ ), the energy change after the modulation ( $\Delta q_{\text{heating post-DR}}$ ) and the efficiency ( $\eta$ ) of the modulation. In case of an upward modulation, the efficiency is referred to as the storage efficiency. In case of a downward modulation, the efficiency is referred to as the rebound rate. The dimensionless power profiles were also plotted for the different days of the heating season (Figure 1, right) and a large variability can be observed.

$$\Delta q_{\text{heating DR}} = \int_{\text{start DR}}^{\text{end DR}} \Delta P_{\text{heating}} \cdot dt \quad [\text{Wh/m}^2_{\text{floor}}] \quad (1)$$

$$\Delta q_{\text{heating post-DR}} = \int_{\text{end DR}}^{\infty} \Delta P_{\text{heating}} \cdot dt \quad [\text{Wh/m}^2_{\text{floor}}] \quad (2)$$

$$\eta = \frac{-\Delta q_{\text{heating post-DR}}}{\Delta q_{\text{heating DR}}} \quad [-] \quad (3)$$

$$\overline{\Delta P_{\text{heating DR}}} = \frac{\int_{\text{start DR}}^{\text{end DR}} \Delta P_{\text{heating}} \cdot dt}{\int_{\text{start DR}}^{\text{end DR}} dt} \quad [\text{W/m}^2_{\text{floor}}] \quad (4)$$

Figure 1. Heating power (26<sup>th</sup> of January) and dimensionless power profile (200 days of the heating season) for the building BR 2012.

## RESULTS WITH SINGLE MODULATIONS

In a first part, single modulations were performed for each day of the heating season (resulting in more than 200 simulations for each building, each type and duration of modulation). By performing single modulations, the thermal mass has enough time to fully recover its initial state (which can last for several days) and interactions between different modulations can be dismissed.

### Upward modulations

Figure 2 shows the discharged energy (post-DR) and the storage efficiency for the different buildings and the different upward modulation durations. In order to show the variability of

the potential over the heating season, boxplots were used. The box shows the 25<sup>th</sup>, 50<sup>th</sup> and 75<sup>th</sup> percentiles, the whiskers extend up to 0.5 times the interquartile range and the dots represent outliers. A large number of outliers can be observed especially during the transition season, which can be explained by the large diversity in power profiles as shown in Figure 1 (right). In terms of energy, the longer the modulation, the larger the energy shifted, and the lower the storage efficiency. The influence of the building envelope can also be clearly observed: the higher the level of insulation, the higher the storage efficiency. In other words, the additional energy use when activating the building thermal mass varies much, from 50% losses in a 50s' building down to 10% losses for a BR2020 building (for a 6-hour modulation). It can also be observed that the BR 2020 building is able to store more heat during long modulation times due to the intermittent heating.

Figure 2. Heating energy post-DR (top) and storage efficiency for upward modulations (bottom).

### Downward modulations

In order to harvest flexibility from buildings, downward modulations can also be performed to shave the peaks or shift part of the load. Figure 3 represents the discharged energy (during the DR) and the rebound rate for the different buildings and the different modulation durations. The lower the insulation level, the higher the energy savings. However, these higher savings come at the cost of a lower operative temperature in the building: the temperature decreases quickly in poorly insulated houses due to their lower time constant (cf. Table 1). It can also be observed that the energy shifted with downward modulations is lower than the one shifted with upward modulations, especially in relatively well insulated buildings: intermittent heating is more pronounced for well-insulated buildings. The rebound rate was also evaluated (Figure 4, bottom). A rebound rate of 100% means that the savings achieved during the downward modulation have to be fully “paid back” (resulting in no energy savings). The rebound rate exhibits a large variability within the building stock, ranging from 43% up to 87%.

Figure 3. Heating energy DR (top) and storage efficiency for downward modulations (bottom).

## RESULTS WITH DAILY MODULATIONS

In order to test a possible control strategy, the flexibility of buildings is activated once a day, starting at noon. The objectives of these simulations are both to validate the flexibility potential observed in the previous section and investigate the influence of flexibility on the yearly heating needs (energy flexibility vs. energy savings).

Figure 4 represents the annual space heating needs with upward modulations. The decreased energy use after the modulation (i.e. discharged energy) is almost constant in the building stock (around  $12 \text{ kWh/m}^2_{\text{floor}} \cdot \text{year}$ ). However, the additional energy use by performing upward modulations differs and ranges from 4 up to 10% (2 up to  $13 \text{ kWh/m}^2_{\text{floor}} \cdot \text{year}$ ). Figure 5 shows the resulting total energy needs with daily downward modulations. The energy savings are relatively small, around 3-4%. It can be explained by the high rebound rates (Figure 3, bottom).

Figure 4. Annual heating need with a DR scenario (one upward modulation a day during 6 hours).

A good agreement can also be observed between the results of single and daily modulations in terms of efficiency and shifted energy. The results of single activations can thus be used by building designers to predict the flexibility potential. An example of the estimated charged energy is given below, for the BR2005 building and 6-hour upward modulations:

- from the single activations,  $59 \text{ Wh/m}^2 / 0.77 \times 180 \text{ DR event} \approx 13.8 \text{ kWh/m}^2 \cdot \text{year}$
- from the daily modulations,  $12.7 \text{ kWh/m}^2 \cdot \text{year}$

Figure 5. Annual heating need with a DR scenario (one downward modulation a day during 6 hours).

## CONCLUSIONS

The energy flexibility potential of the space heating system was evaluated based on building energy simulations. Both upward and downward modulations were performed in buildings with different levels of insulation. A better characterization of the link between energy flexibility and envelope properties was achieved. Upward modulations in poorly insulated buildings should be avoided, as it leads to large storage losses (around 50% in average). Downward modulations can be performed, but they will induce rapid changes in indoor climate, which can exceed the acceptable limit set by ASHRAE ( $1.1^\circ\text{C}/15 \text{ min}$ ). For relatively well-insulated buildings (built after the BR 2005), the efficiency and the stored energy did not change much and a good trade-off for flexibility was observed. If modulations are performed once a day for 6 hours, the decreased energy use as a consequence of the DR events amounts from 4 up to  $22 \text{ kWh/m}^2_{\text{floor}} \cdot \text{year}$ . This work also provides quantitative data to building designers to estimate the flexibility potential under a specific DR scenario and to help designing future energy grids.

## ACKNOWLEDGMENT

The authors would like to gratefully acknowledge IEA EBC Annex 67 - Energy Flexible Buildings for providing excellent research networking.

### **ABSTRACT**

Global sensitivity analysis associated with uncertainty analysis evaluates the robustness of a physical system and prioritises measurement and/or modelling efforts. The uncertainty analysis evaluates a confidence interval, whereas the sensitivity analysis quantifies the accountability of each uncertain input on the dispersion of the output.

These statistical methods are usually used to account for the variability of the static inputs, which are constant regarding the evolution of the system, for example the physical properties of the materials modelled. Dynamic inputs however, i.e. parameters that are variable over time, are rarely taken into account in the statistical analyses because of the difficulty managing correlations between the inputs in stochastic methods. Yet, the system's boundary conditions, such as meteorological input, are decisive for the evaluation of the behaviour of the building system.

This paper aims at quantifying the influence of six meteorological variables as well as 39 static inputs on the dynamic thermal behaviour of a net zero energy building. To do so, a method that stochastically generates consistent meteorological data is used and is adapted to the purpose of global sensitivity analysis. The results show a high dispersion of the cooling requirements, for which the direct solar radiation, the albedo and the window solar factor can be held accountable. Thus the variability of solar resources and their interaction with the building have the greatest impact on the performance of the building.

The variability of meteorological data needs to be considered to evaluate confidence intervals on energy performance. Furthermore, the impact of static parameters should not be overlooked, because their influence may remain significant. The considerable influence of the albedo and solar factor on the results of the present case study also shed light on the importance of assessing its value on site.

Global sensitivity analysis, Uncertainty analysis, Weather data, NZEB, solar gain

### **INTRODUCTION**

Performance guarantee is a major issue in the context of the Net Zero Energy Building design. It consists of assigning a confidence bound to the building performance in order to guarantee a consumption level during the building's operation stage. The main concern is the strong variability of energy consumption due to the variation of weather and occupancy (Wang et al. 2012). Studies emphasise that an adjustment variable must be developed from the building's actual operating condition (weather, occupants, system settings) (Ligier et al. 2017). This makes dynamic thermal simulation combined with statistical methods essential tools. Uncertainty analysis and sensitivity analysis (UASA) occur at different stages of the energy

performance guarantee process. By disturbing uncertain inputs, uncertainty analysis evaluates the confidence interval on the building performance so as to control the margin of error on the guarantee. In addition, sensitivity analysis identifies the most influential parameters on the variability in performance of the building modelled (Saltelli et al. 2008). This quest for the most influential parameter guides and/or warrants setting up a protocol for specific priority measures on the building delivered and/or the definition of the measurement and verification plan during the operation phase. This also allows one to identify the key elements in the pursuit of performance optimisation, while still in the design phase.

These statistical methods usually take into account the variability of the static inputs, which are constant regarding the evolution of the system, for example the physical properties of the materials modelled. Dynamic inputs, i.e. parameters that are variable over time, are rarely taken into account in the statistical analyses however, because of the difficulty managing correlations between the inputs in stochastic methods (Tian, 2013). Yet, the system's boundary conditions such as meteorological input, are decisive in evaluating the behaviour of the building system and therefore are one of the most important operating conditions for adjustment processes in the performance guarantee.

The purpose of the present study was to perform a UASA with dynamic and static inputs to illustrate the capabilities of this approach for the performance guarantee. The aim is to assign confidence bounds to model predictions by accounting for the natural variability of the weather inputs from year to year. This results in the characterisation of the robustness of the building performance, i.e. the stability of the performance predicted in an uncertain environment. Then we estimate the most influent input lead to measure and/or strategy to gain, respectively, confidence and/or performance. The study illustrates this on the cooling needs for July of a net zero energy single-family house with 39 static inputs and six weather variables.

## METHODS

### The building model

The detached house studied was built as part of the COMEPOS project, a French national program for the design, building, monitoring and feedback on 20 net zero energy single-family houses. The houses are occupied and located throughout France. The case study, in Figure 1, is situated in Strasbourg, which has a continental climate with hot summers and cold winters. The house is 137 m<sup>2</sup> on two levels. The airtightness is 0.4 m<sup>3</sup>/(h.m<sup>2</sup>) and the thermal resistance of the insulated exterior walls is 6 m<sup>2</sup>. K/W. Annual energy needs are 43.6 kWh/m<sup>2</sup> for heating and 11.5 kWh/m<sup>2</sup> for cooling with, respectively, set points at 19 °C and 25 °C. Details and validation of the EnergyPlus model are available in (Josse, 2017).

Figure 1: 3D representation of the case study house, west-south façade, east-south façade.

### The input variation for the UASA

To perform sensitivity and uncertainty analyses, a set of samples is generated based on the input variation defined. The variability definition of the input conditioned the results of the analysis. In this study the static and dynamic input uncertainty corresponds to the partial knowledge at the design stage.

A sampling-based method generates stochastic meteorological time series according to the typical meteorological EnergyPlus file. In this case study the Strasbourg IWEA (International Weather for Energy Calculations) is used and the generations are made for the month of July. The weather data set for UASA is built to be representative of the natural year-to-year variability of a summer month of July for Strasbourg. The sampling-based method is based on the procedure of Iman and Conover and maintains the statistical features of the meteorological time series (auto- and cross-correlations) (Goffart et al. 2017). The weather data sample generated allows the estimation of Sobol's indices (Sobol, 2001) of the first-order effect on the energy needs. The influence of each weather variable on the output variability can be quantified. The weather data set for the UASA is composed of six inputs: the dry bulb temperature, the relative humidity, the direct normal solar radiation, the diffuse horizontal solar radiation and the wind velocity and direction.

In the case of static inputs, the variability on the thermophysical properties of materials and windows are taken into account in the study as specific heat, conductivity, density in the case of materials and conductance and the solar factor for triple-glazing windows. Also considered in the study are airtightness, orientation, internal load of occupants for activity (90 W) and sleep (63 W), ventilation and ground reflectance. The variation of ground reflectance (albedo) is between 0.2 and 0.4, default values for asphalt and concrete, respectively. Both are potential exterior ground coating at the design phase. All variations are defined by uniform law and the range for each input is reported in Table 1.

Table 1: Variability of the static inputs

Input	Number of parameters	Range of the uniform law
Material properties (density, specific heat, conductivity)	31	$\pm 10\%$
Window properties (conductance, solar factor)	2	$\pm 10\%$
Orientation	1	$\pm 5^\circ$
Air-tightness	1	$\pm 20\%$
Ventilation	1	$\pm 10\%$
Internal load (occupants: activity and sleep)	2	$\pm 20\text{ W}$
Albedo (ground reflectance)	1	$\pm 0.1\text{ (33\%)}$

### Study protocol

According to the variability defined in Table 1 and the sampling-based method for weather data, coherent with natural weather variability for the month of July in Strasbourg, a set of 2000 values of the 39 static inputs and 2000 sequences of the six weather data variables was built and propagated into the EnergyPlus model of the single-family house. The 2000 simulations result in 2000 cooling need values, which are studied according to the 45-input variability in the next section.

## RESULTS

### Uncertainty analysis

First, we studied the output dispersion due to the propagation of the 45 uncertain inputs through the 2000 simulations. The cooling needs predicted for the month of July ranged from

1.30 to 5.31 kWh/m<sup>2</sup> with a mean of 3.07 kWh/m<sup>2</sup>. The 95 % confidence interval of the energy need in July was  $3.07 \pm 1.31$  kWh/m<sup>2</sup>, *i.e.* 43%. To extract the elements responsible for this variability from the 45 inputs, the sensitivity indices were computed.

### Sensitivity analysis

The Sobol sensitivity indices of the most influential inputs are gathered in Table 2. They represent the variance part of each influential uncertain input on the output variance. The sum of the indices is close to 1, indicating that interactions between inputs do not influence the overall output dispersion. Its variability is bound to the effect of each input separately.

This result underscores the importance of the solar aspects on the cooling needs and especially the impact of the natural variability of direct solar radiation (34%). Then the second and third most influential inputs are the albedo (24%) and the solar factor (22%), respectively, with the same order of magnitude. Finally, the outside temperature and the conductivity of the exterior wall insulation explain the rest of the output dispersion.

Table 2. Sensitivity indices of the most influential inputs.

Input	Nature	Sensitivity index
Direct solar radiation	Dynamic	34%
Albedo	Static	24%
Solar factor	Static	22%
Dry bulb temperature	Dynamic	10%
Ext. wall insulation conductivity	Static	8%

### Tendencies

It is possible to extract more information from the uncertainty and sensitivity analysis with the evolution of the output dispersion according to the variability of the most influential inputs. Figure 2 represents these tendencies for the albedo (a), the solar factor (b) and the monthly sum of the direct solar radiation (c). The shift of the average performance and the output uncertainty according to the value of an influential input can be visualised directly. For example, in Figure 2a), raising the albedo value to 0.2 from 0.4 results in a mean 45% increase in cooling needs. The same increase is observed in Figure 2b) with an increase in the solar factor to 0.44 from 0.54. The output dispersion in Figure 2a) and b) seems stable through the different albedo values and the solar factor.

Figure 2. Evolution of the 2000 output values according to a) the albedo, b) the solar factor, c) the sum of direct solar radiation for each sequence generated for UASA. The tendency is represented by a black line.

The direct solar radiation is a time series and because of this dynamic characteristic, the dependence between output variability and weather data variability is more difficult to characterise. Figure 2c) represents the behaviour of the building performance according to the sum of direct solar radiation of each sequence. The sum variability is about 45%. This may help to better understand the variability in the solar impact on the cooling behaviour of the house.

## **DISCUSSION**

The building performance uncertainty due to the natural variability in weather data and partial knowledge of the physical parameters of the building simulation is significant, with a variation of 43% at a 95% confidence bound. The sensitivity analysis quantifies the proportion of the influence of each input variability on the output variability: almost half of the output uncertainty is due to the variability of static parameters that determine solar radiation in the building: the ground reflectance and the window solar factor. The other part of output variability is explained by the natural weather variability of direct solar radiation (35%) and dry bulb air temperature (10%).

The interpretation takes into account the fact that the analysis results are conditioned by input variability: the solar radiation sum variability over stochastic sequences is about 45%, which explains 35% of the output dispersion; the albedo has 33% variability, which explains 24% of the output dispersion; and the solar factor has 10% variability, explaining 22% of the output dispersion. Thus, with variability at one-third of the variability of the albedo, the solar factor impacts the output variability equally, which must be the priority in characterising both the range of uncertainty and its nominal value.

The natural variability of direct solar radiation over the year cannot be reduced and is part of the operating uncertainty. More accurate in situ quantification of this entity might produce less bias in evaluating performance dependency in the guarantee process. Some of the input uncertainties may be reduced by expert knowledge by measuring the actual materials used and by the manufacturers' specifications. However, reducing uncertainties does not imply leaving them out. Indeed, the present study shows that ignoring uncertainty might result in underestimating the building performance variability and so may compromise the performance guaranteed.

## **CONCLUSIONS**

This case study illustrates the capability of the sensitivity and uncertainty analysis for building performance. It focuses on the necessity of taking into account the natural variability of weather data and especially direct solar radiation when evaluating the interval bounds of cooling needs. Identification of the most influential static parameter prioritises in situ measurements of the solar aspects and thus increases confidence in the building's predicted energy performance. Uncertainty must be characterised so that it can be taken into account in the performance guarantee procedure and the accurate confidence bound assessed.

The building performance simulation coupled with uncertainty and sensitivity analyses makes it possible to test a large number of configurations on the model to evaluate the response of the building and thus extract the dependencies of the most influential variables on consumption. The UASA with natural variability assigns more realistic confidence bounds to the building performance and characterises the building's behaviour according to the weather data input from year to year. This might contribute to the adjustment process.

Because of the importance of a building's solar characteristics, one should focus on the sun management components such as opening and closing the shutters. Optimal management can be carried out by the occupant or using an automatic strategy and may decrease the cooling needs significantly. However, the occupants' behaviour is complex and highly uncertain. With in-situ sociological studies and measurements, it should be possible to characterise and include the building's specific occupancy in the UASA statistical approach.

### ABSTRACT

Kyo-machiya, which is a traditional wooden dwelling in Kyoto, is generally equipped with a shallow well. The well water can be potentially utilized as a heat source with a geothermal heat-pump system without incurring a high drilling cost. Hereby, more energy saving in the traditional dwelling can be realized with the heat-pump system. However, an appropriate technique to utilize geothermal heat from a shallow well has not been established yet in Japan. To promote the geothermal use, we have continued an experiment to evaluate the practicability of a simple geothermal heat-pump system installed in a shallow well since the winter of 2013. In this study, the condition of the water flow in the well was examined using the computational fluid dynamics (CFD) technique, and the velocity of flow of the groundwater into the well was also estimated. We show that constant buoyancy was generated because of the temperature difference due to the heat-pump operation. Based on the results, a three-dimensional heat-transfer numerical analysis model, proposed in the previous study, was developed so that moisture transfer in the ground could be considered. Using the estimated buoyancy of the well water and the groundwater velocity, the calculated results seemed to reproduce the characteristic of the measured value. Furthermore, we show that the groundwater velocity has a large influence on the well water temperature.

### KEYWORDS

Geothermal Heat Pump, Kyo-machiya, Well, Groundwater, CFD

### INTRODUCTION

Geothermal heat is attractive as a stable energy source that is hardly affected by weather conditions and seasons. However, since the initial costs to utilize the geothermal heat such as those of drilling are very high, it is currently not widely used in Japanese dwellings (Nagano et al. 2006). Using geothermal heat, air conditioners can be operated without discharging cold air during winter. Additionally, the cooled ground can be used as a potentially cold heat source during summer. Since there are many unused shallow wells which were once used in a Kyo-machiya, a traditional wooden dwelling in Kyoto, energy saving may be realized by installing a ground-source heat pump (GSHP) system using the well water as the heat source, which will not involve a high initial cost. Therefore, the objective of this research is to spread the usage of GSHPs, which use the existing shallow wells in Japan, by providing basic information about the system and the efficient operational methods.

To promote the use of this system widely, it is necessary to evaluate the impact that this system has in real life and establish an optimum method whereby this system can be used. Hagihara et al. (2016) proposed a three-dimensional thermal model that can be used to predict the temperature change of the well water and showed the usefulness of the well water as a heat source. They also indicated that it is necessary for the well water to be restored to its original temperature for continuous heating. In their calculation, the water flow rate inside the well and

the inflow velocity of the groundwater into the well were estimated so that the calculation results agreed well with the measured results.

In this paper, we conducted a computational fluid dynamics (CFD) calculation to estimate the inflow velocity of the groundwater and the convective flow of the well water. Using the results, the heat and moisture transfer in and around the well during the heating operation was calculated by using the three-dimensional heat and moisture transfer model.

### Surveyed system and CFD Calculation

The surveyed heating system using well water is shown in Fig. 1 (a). The measured well is about 9 m deep from the ground surface and about 80 cm in diameter (Fig. 1 (b)). It is in the living room of a Kyo-machiya, Kyoto city. The GSHP system installed in this well has been operational since the winter of 2013. In this system, the heat-collecting pipe is in contact with the well water and antifreeze solution circulates in the pipe to exchange heat with well water. The well water temperature was measured at three different heights: 4500 mm (upper), 2500 mm (middle), and 500 mm (lower) from the bottom. Also, the depth of the well water, the heat-pump inlet/outlet temperatures of the antifreeze solution, and electricity consumption were measured.

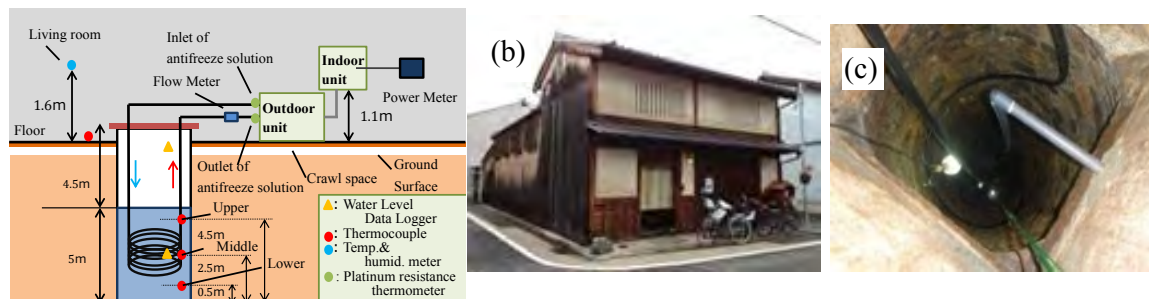

Fig.1 Surveyed system. (a) Schematics of measurement; (b) appearance of the Kyo-machiya; (c) well

### Outline of the calculation

To simulate the characteristics of the temperature distribution of the well water when the heat pump was operated, and to clarify the water flow inside the well, a CFD analysis was performed. The simulation model is shown in Fig. 1(c) and (d), and the CFD calculation conditions are listed in Table 1. The model simulates the positional relation between the well and the antifreeze solution, and although the shapes of the well and the heat-collecting pipe are cylindrical, the shapes of these elements are approximated for simplicity as a square pipe of a volume and surface area equal to that of the actual well and the heat-collecting pipe, respectively. Based on the visual inspection of the well, the arrangement of the heat-collecting pipe was modelled to be concentrated at an approximate height of 3 m from the bottom. The CFD analysis software "Flow Designer 2017" was used for calculation.

According to a well drilling expert, the peripheral wall of this type of well is generally clogged

with mortar to the deep part and water does not easily permeate through it. Therefore, in this calculation, the groundwater was assumed to flow in only through the region which is 0.5 m from the bottom, which is different from that assumed in the previous study, (Hagihara et al. 2016) where the groundwater flows in through all parts of the well wall.

According to the literature (Fukukawa, 1969), several velocities of the groundwater were used to analyze the influence on the well water temperature by them. Only the results in case of a velocity of 2m/day, which agreed well with the measured results, were examined here. The remaining boundary surfaces were insulated.

The measured result during 07:30–13:00 h on December 22, 2015, which was the first day of the usage of heat pump during the winter, was used to verify the calculation.

## Results and discussion

Fig. 3 (a) shows the comparison between the calculated and the measured temperatures, and Figs. 3 (b) and (c) show the water flow during and after the heating operation, respectively.

The points of the antifreeze solution that were obtained from the measurement and calculation were different. The point obtained from the measurement was located in the living room, whereas the point obtained from the calculation was located in the well water because of the limited calculation domain. Therefore, both the temperatures may not be in agreement after the termination of the operation.

The calculated temperatures agree well with the measured results; thus, it can be said that the

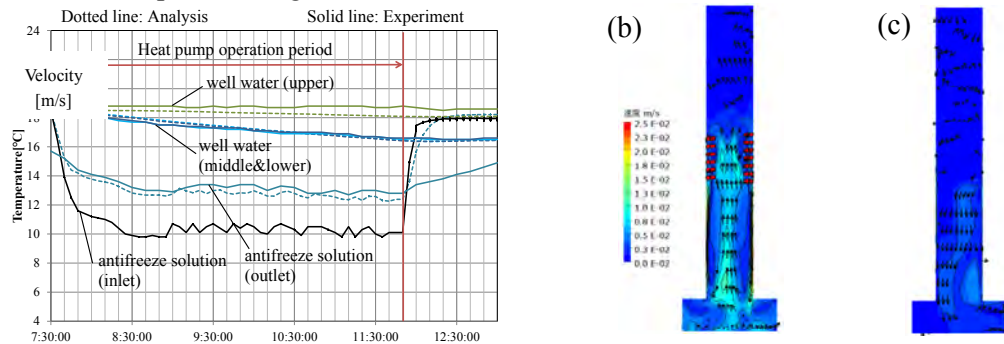

Fig. 3 Results of the CFD calculation. (a) Comparison of the calculated and measured temperatures. (b)(c) Water flow in the well: (b) 1 hour after the operation started and (c) 1 hour after the operation terminated.

inflow velocity of the groundwater and the location of the inflow inlet are accurately assumed. Fig. 3 (b) shows that water moves upward at about 0.01 m/s after commencing the heating operation. Since this upward flow did not occur after the heating was stopped, as shown in Fig. 3 (c), this water circulation was caused by the temperature difference between the inside and outside of the well. Judging from this result, the buoyant flow was taken into consideration in the three-dimensional heat and moisture analysis in the next section.

## CALCULATION OF HEAT AND MOISTURE TRANSFER

### Outline of calculation

A simulation model, as shown in Fig. 3, was proposed. The calculation area comprised soil, air, and water. The period considered for the calculation was from January 1, 2013 to January 16, 2014 (380 days), and the heating operation period was from December 27, 2013 to January 16, 2014 (20 days).

Therefore, on all sides of the calculation domain, the boundary temperature at a depth of more than 5 m was assumed to be 17.5°C, which was the annual average outdoor air temperature of Kyoto city (JMA 2014). The boundary temperature from the ground surface to a depth of 5 m was also approximated using the linear distribution by considering the results of one-dimensional thermal calculation. On the upper side of the calculation domain, three different values were used as the thermal boundary conditions: the temperature of the living room of the house ( $T_{\text{room}}$ ); temperature of the crawl space ( $T_{\text{U}}$ ); and temperature of the outside air ( $T_{\text{o}}$ ). The inlet temperature ( $T_{\text{in}}$ ) and the rate of flow of the antifreeze solution were also used as the boundary conditions.

The thermal conductance between the antifreeze solution and the well water as well as between the antifreeze solution and the well air are depicted in Fig. 3 as KS. Considering that the heat-collecting pipe was arranged in a bundle mainly in the middle height of the well, the thermal conductance was assumed to differ depending on the height.

Fig. 4 Schematic of the simulation model: (a) x-z section; (b) y-z section; and (c) x-y plan

The equations (1)–(4) are the heat balance equations of the soil, well water, air in the well, and antifreeze solution proposed by Matsumoto et al. (1995); the basic equation of the groundwater flow is given by equation (5). The air in the well was dealt with as one mass. In the heat balance equation of the well water, both conductive and convective heat transfer were considered. From the results of the CFD analysis, it was assumed that the groundwater flow occurs by ground gradient, and the convective term by the groundwater flow is added to the heat balance equation. Table 2 shows the ground gradient coefficient and the liquid water conductivity related to the water chemical potential gradient. Also, from the results of the CFD analysis, it was assumed that a buoyant water flow of about 0.01 m/s occurs when the water temperature of the upper mesh is higher than that of the lower cell. In the calculation, two velocities of groundwater flow

were considered; as assumed in the CFD analysis, one is 2 m/day, and the other is two times larger. The boundary conditions between the well water and well air, and the well water and the antifreeze solution are given by equations (6) and (7).

$$c_s \rho_s \frac{\partial T_s}{\partial t} = \nabla \left[ \left( \lambda_s + r \lambda'_s \right) \nabla T + r \lambda'_s \mu_g \nabla \mu \right] - c_w J_g \nabla T_s \quad (1)$$

$$c_w \rho_w \frac{\partial T_w}{\partial t} = \nabla (\lambda_w \nabla T_w) - c_w J_{buo} \frac{\partial T_w}{\partial z} - c_w J_c \frac{\partial T_w}{\partial x} - c_w J_c \frac{\partial T_w}{\partial y} \quad (2)$$

$$c_a \rho_a \frac{\partial T_a}{\partial t} = - \sum \frac{K_a S_a}{V_a} (T_a - T_b) - \sum \alpha_i A_i (T_a - T_i) \quad (3)$$

$$c_b \rho_b \frac{\partial T_b}{\partial t} = \nabla (\lambda_b \nabla T_b) - c_b J_{bx} \frac{\partial T_b}{\partial x} - c_b J_{by} \frac{\partial T_b}{\partial y} - c_b J_{bz} \frac{\partial T_b}{\partial z} \quad (4)$$

$$J_{gi} = - \lambda'_{i\mu} \left( \frac{\partial \mu}{\partial i} - n_i g \right) \quad (i = x, y, z) \quad (5)$$

$$- \lambda_w \frac{\partial T_w}{\partial z} = \alpha_a (T_a - T_w) \quad (6) \quad - \lambda_w \frac{\partial T_w}{\partial n} = K_w (T_b - T_w), - \lambda_b \frac{\partial T_b}{\partial n} = K_w (T_w - T_b) \quad (7)$$

Table 2 Moisture conductivity and ground gradient coefficient use in equation (5) ( $Z \geq 8.5$  m)

direction	$n$	$\lambda'_{\mu}$ [kg/ms(J/kg)]
x	0.017	$1.5 \times 10^{-4} - 3.0 \times 10^{-4}$
y	0	0.0
z	0.999711	0.0

The material properties used are listed in Table 3. The density, specific heat, thermal conductivity, and moisture conductivity of the soil are assumed to change depending on its temperature and water content.

Table 3 Material properties used in the calculation

Material	$c$ [J/kg·K]	$\lambda$ [W/m·K]	$\rho$ [kg/m <sup>3</sup> ]
Water	4,200	0.6	998
Air	1,005	(Heat transfer coefficient: 0.023[W/m <sup>2</sup> K])	1.248
Antifreeze solution	4,100	0.5	1,020

Using these equations and conditions, the temperatures of the antifreeze solution and the well water were calculated. In the simulation, the space was discretized by using the central difference method and the time using forward difference. However, the heat balance equation of the antifreeze solution was discretized using the upwind difference method. The time increments were set as 0.15 s during the heating operation and 15 s in other cases.

## Results and discussion

Figs. 5 (a) and 6 (b) compare the calculated temperatures of the well water with the measured results when the groundwater velocity was assumed to be 2 and 4 m/day, respectively. Figure 5 (c) compares the heat gain. In both cases (Figs. 5 (a) and 5 (b)), the measured tendency, i.e., that the water temperature in the upper region was higher than that in the middle and lower regions, was reproduced under the condition that the groundwater flows in only through the lower region of the well, which is different from that assumed in the previous study. Furthermore, it is likely that the groundwater velocity may be larger than that assumed in the CFD analysis since the result in (b) agrees with the measured result better than that from (a). Fig. 5 (c) shows that the heat gain is by 30% larger in the case of a groundwater velocity of 4 m/day. Thus, it can be said that the influence of the groundwater inflow on the well temperature

is very large.

However, shortly after beginning the calculation, the calculated well water temperature rapidly decreased as compared to the measured temperature, and the calculated upper temperature remained lower than the measured temperature. This may have occurred because the factors related to temperature recovery, such as infiltration of the ground water from the upper well wall, may not have been properly taken into consideration. To accurately evaluate the ground temperature and the water level of the well, it may be necessary to incorporate the aforementioned factors into the calculation model.

Fig. 5 Comparison of the calculated and measured results.

(a) Temperature (groundwater velocity of 2 m/day); (b) temperature (groundwater velocity of 4 m/day); (c) heat gain

(in Fig. 5(c), the measured heat gains are discretely distributed because they are calculated based on the measured temperatures in the units of 0.1°C)

## CONCLUSION

In this study, the heat flow associated with water flow in and around the well with a heat-pump heating system was investigated by CFD analysis. It was shown that the water velocity due to the buoyancy amounted to about 0.01 m/s when the heating system was operated. Furthermore, previously proposed thermal model was extended to a heat and moisture transfer model based on the results of the CFD analysis, which show that the buoyancy and groundwater flow exist partially. The calculated results by the extended model agree well with the measured results that the water temperature in the upper region is higher than those in the middle and lower regions. It is also shown that the velocity of the groundwater has considerable impact on the well water temperature.

## ACKNOWLEDGEMENT

The authors would like to thank the Kyo-machiya residents for their generous cooperation while setting up and using the heat pump.

## Offsetting Peak Residential Cooling Loads Using a Medium Temperature Chiller and Sensible Cold Thermal Storage

Christopher Baldwin<sup>1\*</sup> and Cynthia A. Cruickshank<sup>1</sup>

<sup>1</sup>Carleton University, Ottawa, Ontario, Canada

*\*Corresponding email: christopher.baldwin@carleton.ca*

### ABSTRACT

Space cooling places a significant peak load on the electrical grid during hot, sunny afternoons. With the introduction of time-of-use billing, space cooling during these periods has become very expensive. To reduce utility costs and shift peak loads, the use of a medium temperature chiller coupled with a sensible cold thermal storage system was investigated. Optimal configurations were found for seven cities located within each of the seven ASHRAE climate zones and an analysis on the energy consumption and annual utility costs are presented. It was found that in all locations, peak loads from air-conditioning could be reduced or eliminated, and that when the cooling load was great enough, or the peak utility rate was sufficiently greater than the off-peak period, annual utility costs savings, approaching 30% in some areas, could be realized.

### KEYWORDS

Cold Thermal Storage, Demand Side Management, Residential Air-Conditioning, Peak Loading, Time-of-Use Billing

### INTRODUCTION

As global temperatures increase with global warming, the demand for space cooling has seen a significant increase. This coupled with the increase in residential floor space, has caused a spike in air conditioning use, and consequently the amount of energy consumed for space cooling. Both the United States and Canada have seen an increase in energy consumed for space cooling in excess of 50% in the last 25 years, while total residential consumption has only increased 2% and 5% in the United States and Canada respectively (NRCan-OEE, 2013; U.S. EIA, 2018).

This demand for space cooling is greatest during afternoon and early evening, when daily temperatures and solar radiation are at their peak. Since electrical grids are sized to the anticipated peak load, an increase in generation and transmission capacity is required to meet these increasing loads. In order to address the required increase in grid capacity (which is also extremely expensive), utility providers are implementing measures to control when electricity is being used and to shift consumption from peak to off-peak periods. Of these, the most common strategy is implementing time-of-use billing. Electricity rates during hours of the day, when electricity demand is at its greatest, is more expensive than electricity during low demand or off-peak periods.

One approach for a utility customer to reduce the higher cost associated with time-of-use billing is lowering the air conditioning set-point, or turning off the unit entirely. This can impact the desired comfort of the occupant and is not always possible, particularly for elderly occupants. An alternative solution is to couple an air conditioning unit with cold thermal storage, allowing the air conditioner to run during off peak periods, and storing the cooling potential for use during peak periods.

In a previous study, Baldwin and Cruickshank (2016) explored this possibility using a standard liquid-to-liquid heat pump coupled to a cold thermal storage system. This was studied for Ottawa, Canada and in this study, it was found that peak loads from air conditioning can be eliminated if adequate storage is installed in the system. That being said, a significant increase in off-peak power was observed. This was caused by the substantial drop in performance of the heat pump when storing cooling potential at low temperatures, as well as the relatively low total cooling load of a residential building located in Ottawa. As a result, an increase in the annual electricity cost was observed.

This paper builds on the previous study, and looks at using a medium temperature chiller coupled with a sensible, cold thermal storage system using a 50/50 (by volume) water/glycol solution as the sensible storage medium. Medium temperature chillers are designed to operate with evaporator temperatures between 0°C and -25°C. By utilizing a chiller designed for lower temperatures, it was hypothesized that chiller performance would not degrade as storage temperatures near or below freezing are utilized. Additionally, multiple locations throughout all of ASHRAE's major climate zones are utilized to determine the impact of load on the potential for offsetting peak electrical loads as a result of air conditioning.

## METHODS

To determine the potential of shifting electrical consumption to off-peak periods, a city in each ASHRAE climate zone was selected. Cities were selected where the major electrical provider either used only time-of-use billing or provided it as an option for customers who wished to opt-in to the program. The selected cities and the utility rates are provided in Table 1. All utility rates are as of March 2017 and are shown in local currency.

Table 1: Selected cities and the associated utility rate

Location	ASHRAE Climate Zone	Peak Rate* (\$/kWh)	Mid-Peak Rate* (\$/kWh)	Off-Peak Rate* (\$/kWh)
Miami, Florida	1	0.19165	N/A	0.0331
Phoenix, Arizona	2	0.1020-0.2226	N/A	0.0711-0.0741

Boston, Massachusetts	5	0.1973	N/A	0.0920
Toronto, Ontario	6	0.1564	0.1194	0.0894
Sudbury, Ontario	7	0.1504	0.1134	0.0834

\* (FPL, 2018; SRP, 2018; LADWP, 2018; PGE, 2018; NG - ME, 2018; THC, 2018; GSU, 2018)

A model was developed in TRNSYS, and consisted of a two-storey house with a fully conditioned basement. The house had a total above grade floor area of 220 m<sup>2</sup> and a volume of 835 m<sup>3</sup>. The house was also modelled to the current Ontario building code, with an above grade wall RSI value of 4.5 m<sup>2</sup>K/W, and with windows on all 4 sides of the building, with an overall window to wall ration of 30%. A detailed description of the model is described in Baldwin and Cruickshank (2016).

For this study, baseline simulations to determine annual energy consumption using traditional heating and cooling methods were first run. In these models, space heating and cooling loads were met using a standard heat pump with a performance map developed by Baldwin and Cruickshank (2016). The domestic hot water demand was met using an instantaneous electric

water heater. Baseline results and annual utility costs for space heating, cooling and domestic hot water were then determined for each location.

Once the baseline energy consumption was determined, the medium temperature chiller and cold thermal storage were integrated into the house model. A performance map for the medium temperature chiller was experimentally determined at steady-state. A total of 315 tests were performed. A number of simulations were then performed to determine the optimal storage volume and tank set-point for each location. Using these results, an analysis was conducted to determine the feasibility in each of the chosen locations. The results of these simulations are shown and discussed in the next sections.

## **BASELINE ENERGY RESULTS**

Baseline energy consumption and the resulting annual energy costs were calculated for each of the seven locations. Annual energy consumption was calculated first by end use (i.e., hot water, space heating, space cooling), neglecting any appliance, plug or lighting loads. A second baseline analysis was conducted on the time of day the energy is used, breaking down the peak, mid-peak and off-peak periods as defined by the local utility, as well as the utility costs for each period of the day. The results of two analysis are shown in Figure 1.

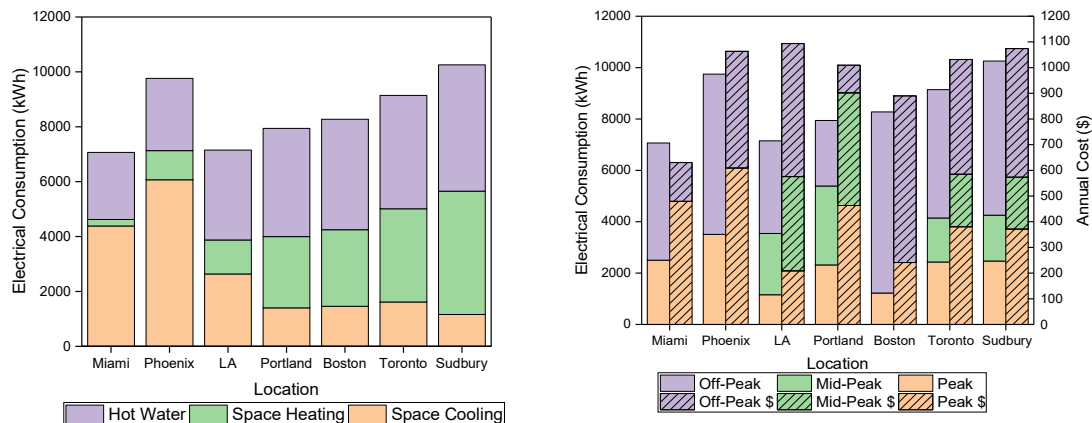

Figure 1: Energy consumption by: end use (left), time of day and annual utility costs (right)

From these results, it can be seen that as the ASHRAE climate zone number increases (going left to right on each graph), the proportion of heating to cooling of the building increases. It can also be noted that in all locations, the peak and mid-peak costs were disproportionately higher than the amount of energy used during the same period. Additionally, in general, the higher the percentage of the building load that is attributed to space cooling, the greater the percentage of utility costs as a result of energy used during peak periods.

## **OPTIMAL SET-POINT AND TANK VOLUME**

Once the energy baseline was determined for each locale, a parametric study was undertaken to determine the optimal tank size and tank set-point for each location. The tank was controlled using the average tank temperature as the control variable and two set-points were implemented. The first was the tank set-point during peak and mid-peak periods, which was kept constant through all simulations at 15°C, and the second was the tank set-point during off-peak periods, which was varied through the simulations to determine the optimal value. During the study, the tank volume was varied from 0.25 m<sup>3</sup> to 3 m<sup>3</sup>, in 0.25 m<sup>3</sup> increments, while the off-peak tank set-point was varied from -10°C to 5°C, in 5°C increments. As such, a total of 48 simulations were completed for each locale. The annual utility costs were then calculated for each

simulation, and the results were plotted as a 3-dimensional surface plot, interpolating between the individual points, was developed for each city. The annual utility cost was the variable of interest, with the goal of minimizing the annual utility costs for the dwelling. Two examples for these plots for Phoenix and Portland are shown in Figure 2.

Figure 2: Example simulation results for Phoenix and Portland varying the off-peak set-point and tank volume

From this series of graphs, it can be seen that the optimal configuration for any given locations is dependent on both the cooling loads of the building, the ratio between peak and off-peak utility costs, and the total energy consumption. In all cases, it was concluded that it is paramount to find the correct storage capacity, as if not enough storage is integrated into the system, the amount of peak energy that is off-set is minimal, increasing the annual energy costs. On the other hand, it is seen that a second spike in energy costs occur in most locations if too much storage is integrated into the system, as the chiller must constantly operate at lower temperatures, near the set-point of the storage tank, without realizing the stored cooling potential. This decrease in operating temperature resulted in a significant drop in chiller performance, and consequently an increase in electrical energy required. Additionally, a trend towards higher set-point temperatures seeing lower annual costs was observed, as again, the performance of the chiller decreases with the lower operating temperatures. In contrast however, the higher the set-point temperature, the larger the tank volume typically required, and as such, more space and a higher initial capital cost is required.

Taking the results from each location, the optimal tank size and tank set-point was determined for each of the seven locations. When results from multiple configurations provided the same, or very similar results, the configuration in which the tank size was smallest was selected to reduce the required volume within the system. The optimal configuration in which annual energy costs are minimized for each location, and a comparison of cost compared to baseline for each of the locations is shown in Table 2. Further, a comparison of when energy is used between baseline and optimized configurations is shown in Figure 3.

Table 2: Optimal configuration and electrical costs per location

Location	Optimal Tank Volume (m <sup>3</sup> )	Optimal Set-Point (°C)	Annual Energy Cost (\$)	Baseline Energy Cost (\$)	Difference (%)
Miami	1.50	0	446.39	630.44	-29.19%
Phoenix	1.75	5	937.65	1063.40	-11.83%
Los Angeles	0.50	5	1083.40	1093.78	-0.95%
Portland	2.00	0	963.93	1009.48	-4.51%
Boston	1.50	5	954.81	890.11	7.27%
Toronto	1.25	0	1046.52	1031.52	1.45%
Sudbury	1.00	5	1175.67	1074.24	9.44%

Figure 3: Comparison between baseline and optimal energy consumption and utility costs

## DISCUSSION

Based on these results, a number of trends were observed. The first is the potential is greatest for offsetting significant peak loads in regions where building loads are dominated by cooling loads. In Northern climates a substantial reduction in peak loads can be obtained, however the economic benefits are not there when compared to southern climates. Even though climate appeared to be the most significant factor in determining the feasibility, the ratio between utility rates between peak and off-peak periods influenced the optimal configuration of the system. This can be seen in particular in the results for Los Angeles, where the small difference in peak to off-peak rates creates little economical benefits even though a high cooling load exists. When the ratio is high (peak to off-peak), it was beneficial to increase the storage capacity to offset as much of the peak load as possible, even if the increase in off-peak consumption is disproportionately large.

Although benefits were observed in most locations, additional benefits could be realized if heat recovery on the condenser side of the chiller was utilized, for one of, or both domestic hot water production or space heating. This could be in the form of a small hot water tank which is preheated using the waste heat from the chiller, or a direct heat exchanger between the condenser loop to the hot water inlet, warming up the water before it enters the on-demand heater.

In all locations, although the peak load is reduced, an increase in the overall annual energy consumption is also observed as a result of the decreased performance of the chiller in charging the thermal storage. Although the assumption is being made in the paper that it is always beneficial to switch consumption to off-peak periods, a more detailed analysis of each locations energy grid and specifically the generation methods used to produce power is required. If the

location has a clean generation base using sources such as hydro or nuclear that can't be turned off, that there is benefit to switching, however, if a location's electricity is met using fossils fuels (e.g., coal, natural gas), the increased power consumption would significantly increase the greenhouse gases released to generate the required electricity.

Finally, although many locations have seen an annual economic benefit, the benefits in terms of actual costs are quite small, in some cases only a few dollars. If a detailed life cycle economic analysis was completed, the system under today's economic conditions would not be profitable over the life of the system. A significant increase in both the absolute cost of electricity, as well as the ratio between peak to off-peak periods would need to occur to improve the economics of the system.

## CONCLUSIONS

This paper has shown that using a medium temperature chiller coupled with cold thermal storage has the potential to reduce, and in some cases, eliminate the electrical consumption required for air-conditioning during peak utility periods. It was found that in southern climates, and those with a large ratio between peak and off-peak utility rates, significant savings can be realized on an annual basis. This paper shows there is significant potential, however before these systems see widespread implementation, significant research is still required to improve performance and further optimize the control strategy and configuration.

## **Prosumer Cluster of Single-Family Houses under the Danish Net Metering Policy**

Marijana Larma<sup>\*</sup>, Rongling Li and Carsten Rode

Department of Civil Engineering, Technical University of Denmark, Denmark

*\*Corresponding email: marila@byg.dtu.dk*

### **ABSTRACT**

In the energy sector, prosumers are typically houses with rooftop PV. With the drastically falling prices of PV panels, the number of installations is rising. Prosumers can have negative impacts, on power grids especially in the distribution grid. In order to mitigate this effect, and for the own benefit of the prosumers, they can function as groups sharing their resources. A literature overview is given focusing on studies that deal with this issue from the prosumer perspective, showing that many optimization studies focus on maximizing economical benefits and others on self-consumption or related indicators by means of energy management strategies and market models, most often hourly based. A case study is presented in the context of the current Danish net-metering scheme. The results show that savings for prosumers and increase of total self-consumption can be achieved by redistributing energy within the building cluster with rule-based control.

### **KEYWORDS**

Energy prosumer, PV, net-metering, single-family house, building cluster

### **INTRODUCTION**

Prosuming buildings are buildings that both “produce” and “consume” energy (Schleicher-Tappeser, 2012). Typically the term prosumer in the energy sector refers to a house with rooftop photovoltaic (PV) panels ([www.energy.gov](http://www.energy.gov)). An estimate of 25-35% of the global cumulative installed PV capacity is at the residential level (Couture et al., 2014). Because of the high electricity tariff, PV has reached grid-parity in Denmark, like in most other European countries (Schleicher-Tappeser, 2012). In order to support renewable energy, some countries have implemented net-metering schemes for residential prosumers. This means that the surplus energy can be stored in the grid within a set period. In Denmark the net metering is on an hourly basis ([www.iea.org](http://www.iea.org)). Electricity production at the residential level can have a negative impact on the grid, especially at the local scale, amongst others by causing overvoltage in some cases (Vallée et al., 2013). In order to mitigate this, it has been suggested to increase the self-consumption (Luthander et al., 2015). The hypothesis of this study is that the impact on the grid can be decreased and the economical benefit of the users can be increased by forming groups of single-family house prosumers. A case study is carried out in the context of Danish hourly based net metering, based on a literature review.

### **LITERATURE REVIEW OF PROSUMER CLUSTERS**

For the present literature search, a systematic search for documents containing the terms “prosumer” and “energy” on Web of Science and Scopus was done. Papers were selected based on the following two rules:

Table 1. – Studies of prosumer clusters						Technologies		
Objective function	KPI	reference	Time Step	Simulation Time	Method	PV	ES	other
case study	self-consumption	Bellekom et al., 2017	5 minutes	24 hours	5 scenarios combining residential storage and peer-to-peer exchange	x	x	
maximize self-consumption	profit	Broering and Madlener, 2017	15 minutes	1 month	3 scenarios in the German context varying grid-use and feed-in tariffs	x		battery cloud

1) included Q1 and Q2 journal papers focusing on groups of residential grid-connected prosumers of electricity from renewable energy sources and 2) -excluded the papers that focus on design of trading models, clustering method, demand response models, social science, politics or business, or has a more general viewpoint. An overview is given in Table 1. As can be seen, in the recent years, the number of optimization studies about energy prosumers has been growing rapidly. The objective function in most of these studies is either an economical indicator related to the interest of each prosumer or the prosumer cluster, or a grid-related indicator like maximizing the self-consumption or local consumption. These two objectives are correlated and studies that choose one often pick the other as a key performance indicator. In most studies, the focus is on the operational costs, as opposed to investments. It is difficult to compare the efficiency of the employed methods directly, as different system setups are used. The time step of the simulation is commonly one hour and the simulation time 24 hours. Also, the consumption profiles used are often generic ones, scaled down from national domestic consumption. Based on the above literature study, both economic benefits and self-consumption were chosen as indicators for this study. A one minute based time step is used with the simulation run for one year, in order to gain a helicopter view of the prosumer cluster.

## METHODS

### Consumption profiles and PV electricity generation

The energy consumption in one minute resolution for 2015 was generated with the open source generator “CREST Demand Model” provided by McKenna & Thomson (2016). Three single family houses of the same building type and each with four residents but with different orientations were considered. The house type was defined by “building index 1” in the CREST Demand Model, which is a detached house of 136 m<sup>2</sup>.

The PV production was simulated with TRNSYS. For the weather file, a Meteonorm generated typical meteorological year for Copenhagen Taastrup was used. The Parameters for the PV panel were taken from the datasheet for REC ([www.recgroup.com](http://www.recgroup.com)), for a panel with a nominal power of 300W. The model for PV production was validated by comparing the efficiency of the Panel in the simulation against the efficiency stated by the manufacturer.

### Setup for simulation scenarios

The three single family houses were oriented towards east, south and west, respectively (see figure 1). The slope of the roofs with the PV panels installed was set to 55°, which is close to the latitude of Copenhagen, as recommended for all-year round PV systems with a fixed slope (Agrawal & Tiwari, 2009; Phadke, 2010). Each house was simulated with 10 PV-modules of 1.67 m<sup>2</sup>, and a total PV installation of 16.7 m<sup>2</sup> aperture area. Two scenarios were considered: 1) base case scenario, in which each house is operated separately, and 2) cluster scenario, in which a common controller is used to redistribute energy flows from houses with excess production to houses with energy deficiency. This flow redistribution was performed in each simulation step.

Figure 1. – Houses with orientations

### Control algorithm for energy flow redistribution

Rule-based control was used for the flow redistribution. If any house has production at a given time, covering one's own demand is prioritized. After subtracting the energy use from the respective productions in a time step, the net energy flows are assessed and if there is simultaneous surplus and deficit, the surplus is then sent to the house with energy deficit. The prioritization is based on the absolute value of surplus or deficit, meaning electricity is first sent to/from the one with the larger deficit/surplus.

The indicators for the evaluation are self-consumption and electricity cost savings. Self-consumption is defined as the ratio of the momentary consumption of the power produced on-site (Luthander et al., 2015). It was calculated according to the following equations:

$$E_{SC}^{time\ step} = \min(E_{prod}^{time\ step}; E_{cons}^{time\ step}) \quad (1)$$

$$SC = \frac{E_{SC}^y}{E_{prod}^y} \quad (2)$$

Where  $E_{SC}^{time\ step}$  is the self-consumed energy in each time step,  $E_{prod}^{time\ step}$  is the energy produced and  $E_{cons}^{time\ step}$  is the energy consumed in each time step.  $SC$  is the self-consumption ratio,  $E_{SC}^y$  is the yearly total self-consumed energy and  $E_{prod}^y$  the yearly total energy produced on-site. In the second scenario, the effective self-consumption  $SC_{eff}$  (or local consumption), for each house was based on the effective consumption (or local consumption of the energy produced by that house) ( $E_{ec,i}^{time\ step}$ ), calculated as in equation (3), and the on-site production of each house, as in the base case scenario.

$$E_{ec,i}^{time\ step} = E_{cons,i}^{time\ step} + flow_{i\_}^{time\ step} \quad (3)$$

$$SC_{eff} = \frac{E_{ec,i}^y}{E_{prod,i}^y} \quad (4)$$

Where  $flow_{i\_}^{time\ step}$  represents the total redirected flow from the given house  $i$  to other houses. The Danish Net-metering scheme is hour-based (iea.org), making it one of the most restrictive carryover provisions. This was taken into account when modelling the cash flow. When the net hourly energy was positive, it was multiplied with the feed-in tariff of 0.07 €. When it was negative it was multiplied with the retail electricity price of 0.31 €. Due to this difference, there is incentive to self-consume as much of the produced electricity as possible, in order to make the PV installation more profitable.

## RESULTS

### Self-consumption in the building cluster

Table 2. shows the self-consumption and its relative increase after clustering the three buildings and redirecting the surplus flows. The total self-consumption (or local consumption) is based on the total instantaneous production and the total instantaneous consumption.

Table 2. Self-consumption ratio (%)

	Separate scenario	Clustered scenario	Increased, %
House 1	40.56	54.41	34.2
House 2	36.91	51.07	38.4
House 3	44.14	57.61	30.5
Total	40.15	52.93	31.8

### Electricity cost and savings

The calculated yearly electricity cost for each house, and in total, are presented in Table 3. For reference, the electricity cost without installed PV panels is shown in the third column. Based on this reference the savings were calculated for both the base case scenario and the clustered scenario. These can be seen in Table 4. The increase in savings of the clustered scenario is calculated in comparison with the separate scenario. The yearly electricity cost is reduced after clustering, with the increase in self-consumption. This is because the retail price of electricity from the grid is higher than the feed-in tariff for surplus electricity sent to the grid.

Table 3. Yearly electricity cost (€)				Table 4. Savings compared to baseline case (€)			
	Baseline case (no PV)	Separate scenario	Clustered scenario		Separate scenario	Clustered scenario	Increased, %
House 1	1597	1190	1121	House 1	407	476	17%
House 2	1551	1138	1017	House 2	413	535	30%
House 3	1661	1236	1138	House 3	425	523	23%
total	4809	3564	3276	Total	1245	1534	23%

## DISCUSSIONS

In order to represent the grid-impact and the instantaneous self-consumption more accurately, in this study a time step of 1 minute was used, simulated over a year. The case setup was a simple example to give an indication of the effect on the correlation of the savings with the grid-impact reduction for the given tariff scheme. In this case study, it was assumed that the three houses freely share their surplus energy with rule-based control. The increase in self-consumption was slightly higher than the increase in electricity cost savings. The difference in savings is expected to be more pronounced with no net-metering. In this study the houses had a similar production and shared their surplus production freely and it was not necessary to consider the local trading dynamics. For a more general case, a remuneration has to be agreed upon, with a price between the feed-in tariff and the retail price. Additional wiring and controller costs for the local redistribution should be considered for making a more comprehensive economical analysis that also includes investment costs, for example by calculating the Net Present Value (NPV). This calculation was out of scope for this study. Some technologies for smart grids that enable local energy management are still in early stages and are expected to become more affordable in the future.

## CONCLUSIONS

A literature overview was presented, focusing on studies about groups of prosuming buildings with PVs. It was found that most previous studies were on an hourly basis with a 24 hour time-frame. In those studies, both impact on grids and economic gains for users were often investigated. A case study of three prosumer houses was conducted under Danish hourly net metering conditions. Simulations were run for one year to investigate the effect of energy distribution within this building cluster. In the clustered scenario, self-consumption ratio increased 32% in total, indicating a decrease of the impact on the grid. Electricity cost savings with respect to the baseline case with no local production were calculated for both scenarios. In the clustered scenario, the savings increased 23% compared to the separated scenario. It is in line with the expectations that the savings increased when the self-consumption increased, as

the electricity retail price is higher than the feed-in tariff. The control in the current study is rule-based. In further research MPC for buildings will be considered with flexible electric load.

### **ABSTRACT**

Exergy analysis is an important tool to fully appreciate the usability of energy at different levels and has been widely applied in the building system analysis domain. It has become more useful as low temperature heating and high temperature cooling began to attract more attention both in Europe and the United States. Using low-grade energy to supply for these systems have, in return, led to an increase in awareness of low exergy (LowEx) system designs. The possibility of modeling the last missing link in the system that is to delivery thermal comfort, the human body, have therefore become a topic that increasingly draws the attention of many more researchers. Due to the complexity of these human body exergy models, it is very rare for these models to be linked back to building systems and produce an exergy efficiency for occupants' thermal comfort. Attempting to fill in the blanks of overall system exergy efficiency on delivery occupant thermal comfort, we have developed a visualization algorithm that could visually assess the exergy efficiency in comfort delivery. Using the ExFlow tool, it is much clearer and easier to determine the relationship of how much primary energy input is eventually converted to the energy that is used to condition for the occupants' comfort.

### **KEYWORDS**

exergy analysis; thermal comfort; energy delivery; visualization

### **INTRODUCTION**

The efficiency of systems to maintain a certain built environment is very often categorized by their energy efficiencies. How much primary energy input or levelized costs is necessary to deliver to the end of the chain where the users' demands are met. A common tool used to visualize this process is the Sankey diagrams (or occasionally referred to as the flow charts), where the total input and outputs can be visualized. Exergy analysis has gained popularity among many researchers as an addition to the existing analysis method during the last 20 years due to its capability of gauging not only the amount of energy, but also the usability of the energy.

With the growing popularity of systems that utilizes the low grade heat, or otherwise known as the low exergy (LowEx), exergy analysis has begun to receive a growing amount of attention from researchers. While the heat demand from the occupants stays the same, the same amount of exergy can be delivered with water warmed up by waste heat of a nearby factory than that heated with a gas boiler. Similar concepts of heat harvesting at stages of processing to be reused have been extensively used in chemical plants. This is particularly true for the domestic systems where the required water temperature rarely exceeds 75°C, but

are often supplied by primary energy sources that has high exergy and experience large amount of heat loss during distribution.

Acknowledging the magnitude of the question at hand, a tool named ExFlow was developed dedicated to visualize the exergy flow through a building systems' energy supply chain towards the occupants' thermal comfort. Basing off existing methods of calculating steady-state exergy consumption during the energy delivery for occupants, this tool specializes on visualizing both the exergies that are 'consumed' and the exergies that are used provide thermal comfort. Applying the ExFlow tool to three different types of building systems, a parametric study of an office study focusing mainly on its exergetic performance of components and thermal comfort is presented in this paper.

## METHODS

Performing steady-state exergy analysis on a office building, we simulated the energy and exergy delivery chains for an office building, as was presented in Annex 37 for the heating case. Using simplified building geometry and thermal properties as inputs, the heat losses, heat demand and the amount of primary energy necessary to produce the heat necessary to maintain the room air condition can be calculated. Simplified system components assumptions were made including their inlet/outlet and operation temperatures as well as their individual efficiencies and required auxiliary energy consumptions. These parameters were then combined with the calculated energy consumption and heat losses along the energy delivery chain so that the exergy delivery chain can be determined.

Volume, net floor area and indoor air temperatures as well as the area and thermal transmittance information of the envelope were used to generate basic estimation of the transmission heat losses. The ventilation heat losses is then determined through the designated air exchange rate and heat exchanger efficiencies. The solar heat gain is then calculated by assigning a window-wall ratio and pre-determined solar radiation rate per area. Internal heat gains were then obtained by using the number of occupants while the specific internal heat gains from equipments were obtained using equipment density per floor area. Same applied to lighting energy consumption and total ventilation power necessary. Subtracting the total heat gain from the heat loss, we then obtain the total building heating demand.

Splitting the energy delivery process into six distinctive stages, namely primary energy input, generation from primary energy input, distribution system from the generation system, emission system and room air towards envelope. The fundamental calculation behind the visualization algorithm of ExFLOW calculates the energy and exergy available at every stage of the delivery.

Previous investigations towards increasing the acknowledgement of the exergy consumption during the energy delivery process includes the I Schmidt, 2007), "Low Exergy Systems for Heating and Cooling of Buildings", Annex 49 , "Low Exergy Systems for High-Performance Buildings and Communities" (Angelotti & Caputo, 2007) and Annex 64, "LowEx Communities" (Schmidt, 2014). Annex 37, in particular, devised an excel tool that calculates steady-state flow of the energy as well as exergy when energy is being delivered to specific building cases. As a general rule of thumb, the exergy was calculated by multiplying the energy necessary with quality factors. These factors vary from 1.0 for electrical energy and mechanical energy, to 0.9 for fossil fuels and 0.06 for thermal energy at 40 degree Celsius. To determine the thermal exergies that are associated with different sources, their quality

factors can be written as the following Equation 1, where  $T_j$  and  $T_i$  are respectively the temperatures of the temperatures of the temperature generated and the temperature necessary at input.

$$F_p = 1 - \frac{T_j}{T_i} \quad (1)$$

As we are able to determine quantitatively both the energy and the exergies during the energy and exergy delivery to households, it is important to associate the resulting parameters with the human body exergy consumption models. Since the air temperature and the envelope temperatures were considered homogeneous per the original assumptions for the model, it is possible to be introduced into the human body exergy consumption models constructed by previous researchers. Among the three existing major human body exergy consumption hubs (Shukuya, Prek and Mady), the results were comparable as most resulted in a 4~5 W/m<sup>2</sup> for an adult man weighing 80 kg and 1.8 m<sup>2</sup> surface area of the body where the air temperature sits at about 21°C. This points to a total of 7~9 W for a single occupant, and with an assumed number of occupants at 13 for the entire building, this points to a 91~117 W for the entire building. Since the analysis is steady-state, it is reasonable to assume that the human body exergy consumption will remain constant as the other parameters of the building that is being simulated (Shukuya et al., 2010).

Specifically relating to the case study that we are examining within the scope of this paper, we are simulating an office building with the an overall volume of 6882.35 m<sup>3</sup> and 2202.35 net floor area. For the indoor environment, we will be assuming indoor temperature was to maintain at 21°C while the outdoor temperature (or reference temperature for the calculation of exergy) remains at 0°C, we can simulate the energy and exergy required at every single level of the energy delivery (Sakulpipatsin & Schmidt, 2003).

To better understand the performance of ExFLOW as a tool to visualize both the energy and the exergy flow, three different variations of said building is considered and qualitatively compared between. We will be focusing mostly on how the generation level and the distribution level performance differences could have led to different scenarios of energy and exergy deliveries towards the end-goal, the human thermal comfort. More specifically, we would like to examine the possible implications in deploying larger surfaces for heat exchange (floor heating/radiators) vs. air-based heating and cooling as well as harvesting the primary energy generation/conversion systems through either standard boiler or taking in heat directly from district heating networks. These systems and their different parameters can be found in the following Table 1.

Table 1. Cases investigated with different building system combinations

Combination	Emission System	Generation System	Sup/Ret T (°C).	Generation Effi.
1	Floor Heating	District Heating w/ Waste Heat Recov.	35/30	0.89
2	Floor Heating	Standard Boiler	35/30	0.8
3	Air Heating/Cooling	Standard Boiler	35/25	0.8
4	Radiator	District Heating	70/60	0.89

It is important to point out that there are many other sources of primary energy input that would allow a significant decrease in primary energy input as the renewable energy sources essentially makes up the necessary primary energy input - such as various heat pump with

different sources, i.e. ground-sourced, air-sourced, etc. We will not be including any of these studies within the scope of this paper due to its length limitation.

## RESULTS

Using the ExFLOW tool, it is possible to generate both the energy flow diagrams and exergy flow diagrams qualitatively with quantitative hover information as is shown in Figure 1. Qualitatively speaking, generating an energy flow diagram that includes the waste heat that is generated at different stages is the same with exergy consumption modeled in exergy analysis.

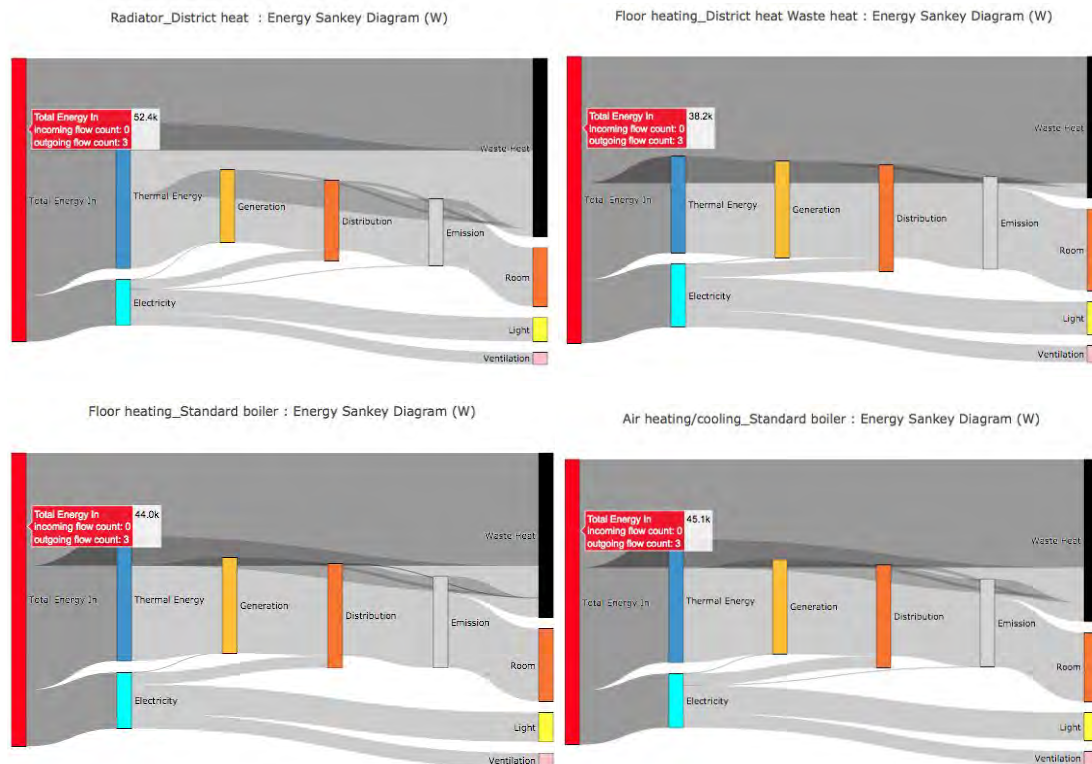

Figure 1. Energy Flow Sankey Diagrams generated by ExFLOW with four different combinations of energy generation and emission systems.

It is not very difficult to observe the discrepancy between the amount of waste heat is not quantitatively equivalent of that of exergy consumed. This is mostly because the amount of waste heat were in fact harvested at different levels of usability - or in other words, different amount of exergy. The total amount of waste heat as is shown in Figure 1 is, therefore, not representative of how much of which could have been harvested for secondary or further utilization.

Another interesting observation from the results generated by ExFLOW is its capabilities of showing how little amount of exergy is actually necessary at the end of the delivery. While the entire exergy/energy delivery chain is dedicated to provide for comfortable indoor conditions for the occupants, much of that is not dedicated to the comfort of the occupants, but rather conditioning the air indoor as is mandated by the design guidelines with respect to the supply and return temperature of the generation/distribution/emission systems.

## DISCUSSIONS

The results from the ExFLOW tool brings ample of room for discussing its current and future room of applications. Looking at the similarities and discrepancies between the results of energy and exergy flow diagrams as shown in Figure 1 and Figure 2, the energy and exergy consumption concepts led to a very different understanding of the viability of various systems.

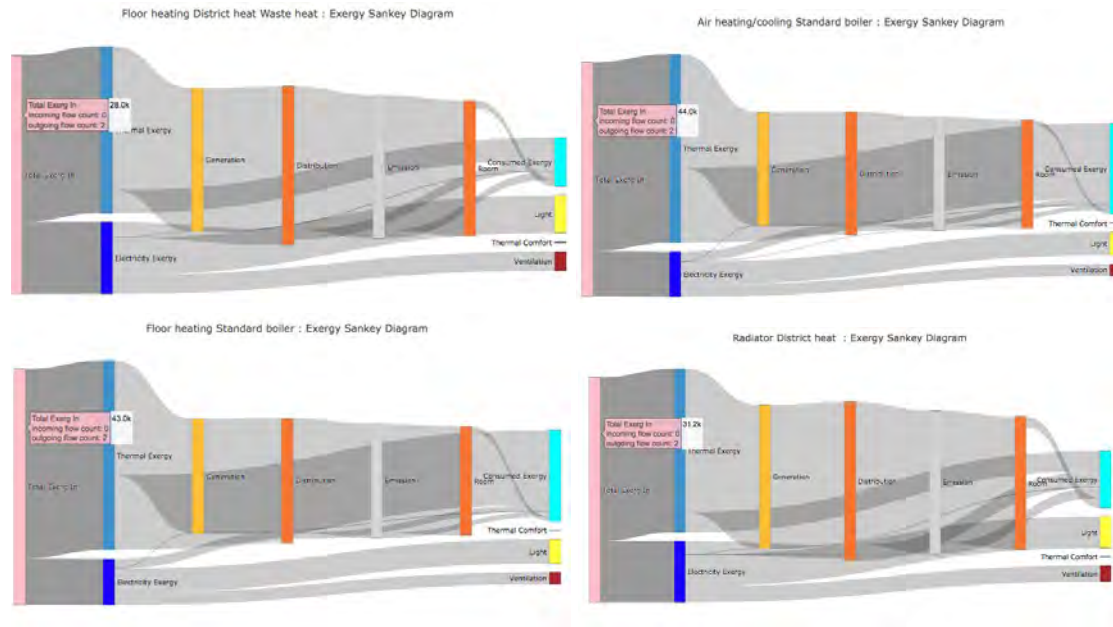

Figure 2. Exergy Flow Sankey Diagrams generated by ExFLOW with four different combinations of exergy generation and emission systems.

Combination of the floor heating system as emission system and district heating with waste heat harvesting was found to be the most energy and exergy efficient system of all four combinations. This is to be expected since their necessary supply temperatures are much lower and can benefit from generation system with a much smaller exergy input. The energy input then increases for the floor heating and standard boiler combination, further for air heating/cooling and standard boiler, and the largest for the combination of radiator and district heating combination. For the exergy side, this changes as the radiator plus district heating was found to require exergy input that was slightly larger than that of floor heating with district heating. This demand increases dramatically for floor heating and standard boiler combination, while the air heating and cooling was the least exergy-efficient combination of all four combinations.

Comparing the final exergy consumption at the human body reveals some even more interesting findings, where we can observe the final stage of exergy consumption being split into four categories, exergy consumed by system components, exergy consumed by the human body to maintain thermal comfort, and exergy required to maintain proper lighting and healthy ventilation. The energy that is necessary to maintain thermal comfort appears to be much smaller than that of the other three, while the light and ventilation exergy consumption remains the same since they are not subject to any change by any input parameters. This brings up a very interesting research question, as to whether we have positioned our energy assets in appropriate locations to achieve the maximized system efficiency. More importantly,

can we design systems that can deliver the same amount of comfort to the occupants without resulting with the same amount of exergy that is consumed by the transformation and distribution.

## CONCLUSIONS

We developed a visualization tool for the energy and exergy flow to deliver satisfying indoor environment to occupants. Understanding the challenges of avoiding the stove-piped disciplines in understanding the overall system design, we compared four different combination of systems that could be used for a specific building with ExFLOW and quantitatively and qualitatively compared the results obtained from ExFLOW. Since exergy flows are by definition describes the quality of the energy flows, we were able to quantitatively understand the amount of exergy that are being consumed by the processes and compared against the necessary exergy consumption of a hypothetical human to understand the overall scope of comfort delivery.

### ABSTRACT

Microgrid combined cooling, heating and power energy systems are under intensive investigation owing to expansion of renewable energy generation and development of advanced technologies in distributed energy generation. Multi-generation systems serve as one of the core parts in any microgrid energy systems. This review paper presents the summary of state-of-the-art technologies in these multi-generation systems. The first part introduces the energy structure based on energy sources and the latest renewable energy harvesting technologies for solar, biomass and geothermal energy. In the second part, prime movers, including small-scale ones used in a microgrid energy system, are summarized. The third part shows the expanded microgrid system configurations mainly for desalination. The fourth part describes the control and operation strategies for complex multi-generation systems. In the first three parts, insufficient investigation or research gaps are also pointed out. Overall, this paper systematically summarizes recent progress in microgrid multi-generation system, and suggest future researches for designing and optimizing a microgrid energy system.

### KEYWORDS

Microgrid, CCHP, Renewable Energy, Multi-generation, Prime Mover

### INTRODUCTION

Combined cooling, heating and power (CCHP) microgrid system can increase energy efficiency by recovering waste heat and eliminating transmission and distribution losses as compared with separate individual systems. And it will naturally decrease the operation cost and greenhouse gas (GHG) emission because of the energy input saving. In addition, microgrid systems are more reliable than centralized power plants from natural and man-made disasters since renewable energy serves as a localized energy source in most of the systems (Ebrahimi, 2014). A conventional CCHP microgrid system can be divided into four sub-components as shown in Figure 1: energy source (top), energy conversion technologies (middle left), energy demands (middle right) and storage systems (bottom). Different from traditional energy sources, more renewable energy including wind, solar, geothermal and biomass have been utilized in microgrid systems. The upstream of microgrid system will highly influence the system configuration and technologies applied.

### RENEWABLE ENERGY SOURCES

Available renewable energy applied in CCHP systems has expanded from solar to biomass, geothermal and wind energy. Solar PVs and thermal collectors are two methods used for solar energy powered CCHP, in which solar thermal part can be integrated into the system as heat source of various energy conversion components due to its flexible temperature range. Solar thermal energy is always serving as a heat source for ORC, ABC or direct heating in CCHP. Wang et al. (2016) show that the solar thermal integrated CCHP system is more energy efficient but less exergy efficiency than the solar PV integrated system. However, due to the

intermittent and daytime-occur-only characteristics, CCHP systems powered by solar energy are sensitive to weather variation in its performance and cost change in its payback. Thus, accurate demand predictions and reliable control strategies are needed for efficient and effective solar integrated CCHP systems. While most of the research works considered parameters of solar PV as constant, Arsalis et al. (2018) provided detailed solar PV model experimentally validated in a CCHP system. Biomass as an alternative to natural gas has garnered researcher's attractions as it can produce more stable power than solar. In terms of structure, the biomass integrated CCHP system is similar to conventional one except that the fossil fuel is replaced by gasification subsystem. The increment of components and coupling within subsystems increases system complexity. Exergoeconomic analysis is the mainstream of biomass based system. Wang and Mao (2015) show that the biomass price greatly influence the product unit cost and the exergy cost of cooling water is the most sensitive among all the demand. However, the comparison of environmental and energy benefits between biomass powered CCHP system and conventional one has not been investigated sufficiently. Maraver et al. (2013) adopted ORC or Stirling engine to biomass-based CCHP system and found it is more favorable than stand-alone generation system in terms of the environmental aspect under small cooling-to-heating ratio. Nonetheless, the comparison is only limited to heat powered subsystems and other engines like gas turbines or internal combustion engines have been ignored. Similar to solar thermal energy, geothermal energy can be used to generate electricity. Figure 2 shows how geothermal energy is used in CCHP system. Kalina cycle is more utilized than ORC in system when geothermal is the only thermal source since the thermal efficiency is relatively low (Sun et al., 2017). ORC was used more often when solar thermal energy exists. The ground source heat pump is the most intensive investigation. Other researches were about supercritical CO<sub>2</sub> cycle power cycle, two-stage ORC cycle, combined with LNG gasification process. The utilization characteristics of geothermal in CCHP system is due to the lower temperature range. However, the pressure recovery of ground water has not been explored.

### PRIME MOVERS

Wu and Wang (2006) showed the characteristics, performance as well as economic information of main prime movers (PM), including steam turbine (ST), gas turbine (GT), microturbine (MT), internal combustion engine (ICE), Stirling engine (SE) and fuel cell (FC), utilized in CCHP microgrid system. The selection of prime mover in CCHP microgrid system varies based on the energy source, energy, environment and economic (3E) criteria. Wang et al. (2008) use multi-criteria (3E+society) to evaluate different PMs based trigeneration system and found gas turbine plus LiBr ABC is the best and SOFC based one is the worst. Ebrahimi and Keshavarz (2012) expanded this method to different climate regions. The results showed that the best to worst PMs are ICE, SE, separated system and MT, and climate difference has

little influence for selection. However, there are only limited hierarchy criteria in the second layer, which would limit the application of this method. Khorasaninejad et al. (2016) combined several other fuzzy approaches to the second layers criteria for selection of PMs in ORC based CCHP system. This work found PV panel is the best PM and GT is the worst when every primary criterion (3E+society) are segmented into 16 to 5 sub-criteria. Roman and Alvey (2016) provided following hybrid load operation-based selection method among ICE, MT and phosphoric acid FC. However, the selection is only one layer, so it can only provide the selection in each sub-criteria. Moreover, selection of PMs in these papers is based on some fixed configurations and no consideration of operation strategies for different PMs. The truth is that different PMs have their own optimal subsystem configuration and operation strategies, there is no work based on this premise. In addition, PMs can be driven by renewable energy, there is little concern about the influence of renewable energy on selection. For small size microgrid, FC, MT and SE are the main PMs in microgrid system based on the capacity range. Solid oxide fuel cell (SOFC) and proton exchange membrane (PEMFC) are the most common FC that are used in CCHP system, which can be seen from the distribution of published paper in Figure 3. Overall, FC based CCHP system has earned more attention recently. In system design and analysis, most of the research focused on energy saving potential and economic feasibility through parametric study. As for optimization, most of the work tried to solve multi-objective optimization through 3E criteria. Due to the research intensity and complex experiment setup, there is not much review work and test verification in this subtopic. The electricity to heat ratio for FC is relatively larger than conventional large-capacity PM, so it is sometimes insufficient to provide thermal cooling energy for ABC, however, the electric cooling can be designed in CCHP system, so there is need of comparison for FC based CCHP in which cooling is provided by ABC and EC.

Researchers have integrated MT integrated CCHP system based on cogeneration system since 2000. Figure 4 shows the research paper distribution from 2001 to 2018, in which 'others' includes dedicated investigation of MT and dynamic system modeling. Early stage research concerned about the system thermodynamic analysis, simple operation strategies and it always comes along with new system designs. Sugiarta et al. (2009) started to adopt 3E analysis in MT based CCHP system but no optimization analysis was provided until recent. Since MT is impaired under the variable ambient condition, so efficient and accurate system control is important for 3E benefits. However, there is not much work specified on control of MT based CCHP system. At last, limited research about combined cooling and power system is a special design in which heating demand is negligible compared with other two.

SE based system has not been explored much in recent research work. Limited investigators designed SE as supplementary PM in CCHP system to further improve energy efficiency of whole system (Ansarinassab and Mehrpooya, 2018). Other research chooses SE as main PM are all about system design and sizing. Kaldehi et al. (2017) designed a solar driven SE trigeneration system and mainly focused on the SE modeling and verification in different climate regions. However, when the authors tried to analysis the system performance, the thermal load was calculated based on ASHRAE standard, which is a fixed value and not reflects the actual demand. Thus it would not well suit for following electricity/thermal (FTL/FEL) load control strategies. Moghadam et al. (2013) use 3E criteria to optimize SE size under FTL/FEL. Nonetheless, auxiliary device or power is needed under these following strategies, so there is still some space for improvement of energy efficiency. Karami and Sayyaadi (2015) applied fuzzy-AHP decision-making method to choose the best optimization objective for different cities. However, the fuzzy-AHP method is subjective and depends on researchers' experience, so objective method should be considered. Harrod James et al. (2010) provided a sizing method for SE in CCHP through parametric study, however, the optimization is single objective which is not sufficient for SE design and selection. Moreover,

in the PM selection research mentioned above, SE is sometimes considered less competitive compared with other PMs when considering the capital cost. Overall, SE shows its developing potential in CCHP system and there is a need for more investigation of SE based CCHP, especially in related to the economic analysis.

Figure 3. Research trend of fuel cell.

Figure 4. Research trend of microturbine.

## SYSTEM CONFIGURATIONS

Desalination is an additional function that has been enriched in CCHP microgrid systems, especially for shipboard application. The system efficiency can be further improved. Shu et al. (2013) developed a fresh water producing CCHP system based on shipboard ICE. Mohammadi and Mehrpooya (2017) designed a desalination integrated CCHP system, which can provide 46.8 kW power, 451 kW heating, 52 kW cooling and 0.79 kg/s potable water, and optimal operational parameters were decided based on the sensitive analysis. Sadeghi et al. (2017) designed a novel multi-generation system for producing power, cooling and fresh water by adopting ejector and humidification /dehumidification desalination technology. The optimal exergy efficiency can reach 17%. Najafi et al. (2014) presented 3E modeling of a solid oxide fuel cell–gas turbine (SOFC–GT) hybrid system integrated with a multi-stage flash (MSF) desalination unit. The optimal design leads to an exergetic efficiency of 46.7% and 9 years payback period. However, the practical water demands have not been reflected in these researches. Besides, the most of these systems are not CCHP based and seldom provide optimal control strategies.

## CONTROL AND OPTIMIZATION

The CCHP system optimization problems are always attributed to the multi-objective problem since almost all the investigations consider not only energy savings but also payback time and greenhouse gas emission reduction. The most common optimization algorithms used in CCHP system are genetic algorithm (GA) (Zhang et al., 2018), particle swarm optimization algorithm (PSO) (Luo and Fong, 2017a) and differential evolution algorithm (DEA) (Yao et al., 2017). The optimization of system control strategy has a great impact on system operation performance. The control strategies have gone from fixed pattern like following thermal load and following electricity load (Fumo et al., 2011) to model predictive control (Rossi et al., 2016) and discrepancy consideration (Luo and Fong, 2017b).

## CONCLUSIONS

This review paper summarizes recent progress of CCHP microgrid systems from energy source, prime mover, system configuration, system control and optimization points of view. First, other renewable energy such as biomass and geothermal have been considered in microgrid systems in addition to conventional available distributed energy sources such as solar thermal and PV. Exergoeconomic analysis is the mainstream in biomass powered systems, and energy and environmental effects should be investigated more as

compared with other conventional energy sources. There exists research gap for pressure recovery in geothermal powered microgrid system. Second, research works related to MT, SE and FC are summarized in this paper. Current selection of prime movers is based on fixed system configuration which is not designed for various PMs. In addition, renewable energy should be considered when selecting PMs. FC, MT, and SE based small-scale CCHP microgrid systems focus on thermodynamic analysis and optimization through 3E criteria. There is a lack of experimental validation. Third, a microgrid system has expanded its function to desalination for further improving energy efficiency. However, the system becomes more complex and is not clear whether water demand is met when integrated with CCHP system. Last, the control and optimization work on the microgrid CCHP system has contributed to improving the performance. The control has upgraded from simple strategies to comprehensive and real-time ones.

### **ABSTRACT**

This work investigates the effects of future climate uncertainties in calculating the heating and cooling demand of buildings and estimating potentials for renewable energy generation (solar PV and wind). The building stock of Lund in Sweden is considered for energy simulations and for future climate, the most recent outputs of RCA4, which is the 4<sup>th</sup> generation of the Rossby Centre regional climate model (RCM), is used considering several two representative concentration pathways (RCPs) and four global climate models (GCMs). Simulations and assessment are performed for three 30-year time periods, from 2010 until 2099. Through comparing distributions of data sets, it is found that the uncertainty induced by climate models affects the estimation of renewable energy generation more than those induced by time periods. Changes in the heating demand due to climate change and uncertainties are surprisingly low while it is very large for cooling demand. This can be because of having a good quality for buildings on the average, however this should be more investigated for other cities in Sweden.

### **KEYWORDS**

Climate change; regional climate model; Future climate uncertainties; energy demand in urban areas; renewable energy generation;

### **INTRODUCTION**

By the advances in climate simulation and numerical modelling, it is possible to make better estimating the probable future conditions, which helps a lot in energy and infrastructure planning. A large amount of work exists on assessing the impacts of climate change on buildings as the main energy users, considering different types of buildings, their characteristics and their thermal comfort, retrofitting and energy saving potentials (e.g. (de Wilde and Coley 2012) (Nik 2012)). More than the energy demand, climate change may also alter generation out of renewable sources such as wind, hydropower and solar energy (Nik 2016).

The common approach in the impact assessment for engineering applications is introducing future weather files into building simulations. One of the big difference is the source and type of the future weather file. The origin of most of the available future weather files (in any temporal and spatial resolutions) which are used for energy simulations, are global climate models (GCMs) – also known as the general circulation models –which simulate climatic conditions under different initial and boundary conditions. GCMs simulate future climatic conditions for the spatial scale of 100-300km<sup>2</sup> which is coarse for the purpose of impact

assessment. Therefore, GCM data are downscaled by the means of statistical (such as morphing) or dynamic downscaling techniques. The latter is performed through using regional climate models (RCMs), which provide weather data with suitable temporal (down to 15 minutes) and spatial resolutions (down to 2.5km<sup>2</sup>) for direct use in building and energy simulations. It is not possible to rely on short time spans in the impact assessment of climate change the considered span should be 20 to 30 years. Moreover, there are different uncertainties which affect simulated climate data, such as the selected GCM, RCM, emissions scenario (which is not used anymore by IPCC) or representative concentration pathways (RCPs) and the spatial resolution (Nik, Sasic Kalagasidis, and Kjellström 2012). This means that a valid assessment should consider several future climate scenarios. Therefore, one important challenge is dealing with large data sets and uncertainties ((Nik, Sasic Kalagasidis, and Kjellström 2012) (Nik 2010)). Uncertainties due to climate change have been considered in several works (e.g. (Nik 2010)).

This work investigates the impacts of climate change on the energy demand of buildings and the renewable energy generation out of solar PVs and wind turbines. In this respect, the building stock in Lund is modelled for six different climate scenarios. The same scenarios are used for estimating the potentials of renewable generation. More information about the climate models and energy calculations are provided under the methodology section and results discussed afterwards.

## **METHODOLOGY**

This section briefly describes the energy and climate models and some of the equations which are used for renewable generation calculations. Since most of the theory part have been discussed in previously published works, the reader is referred to the major references. For all the calculations, hourly weather data sets from six climate scenarios have been used for three 30-year periods of 2010-2039, 2040-2069 and 2070-2099.

### **Climate models and future weather data sets**

The weather data sets are synthesized version of RCA4 (Samuelsson et al. 2015), the 4<sup>th</sup> generation of the RCM by the Rossby Centre at Swedish Meteorological Hydrological Institute, with the spatial resolution of 12.5km resolution and the temporal resolution down to 15 minutes. RCA4 downscaled four GCMs: CNRM-CM5, ICHEC-EC-EARTH, IPSL-CM5A-MR and MPI-ESM-LR. The first two GCMs are forced by two Representative Concentration Pathways (RCPs), RCP4.5 and RCP8.5, and the other GCMs are forced only by RCP8.5. This gives six different climate scenarios for Lund. RCPs are four greenhouse gas concentration trajectories adopted by the IPCC for its fifth Assessment Report (AR5) in 2014. All the RCM weather data were synthesized in Matlab before being used in energy simulations. For more details the reader is referred to (Nik 2016) and (Nik 2010).

### **Energy demand simulation**

The residential building stock in Lund, Sweden is modelled in Simulink/Matlab. Lund is one the major cities in southern Sweden with the area of 25.75 km<sup>2</sup> and the population of around 88790. The building stock of Lund is statistically represented by 52 buildings using the data sets by the the Swedish National Board of Housing, Building and Planning (Boverket), which is the major information source for the energy performance of buildings in Sweden and has been used previously in several works (e.g. (Nik 2012) (Nik and Sasic Kalagasidis 2013) (Nik et al. 2016)). Figure 1 shows distributions of the U-values, heated floor areas and window areas of the buildings. For more details about modelling and assessing the future energy

performance of the building stock the reader is referred to (Nik 2012) and (Nik and Sasic Kalagasidis 2013).

Figure 1. Distribution of the U values, heated floor areas and window areas of the building stock in Lund (figure is from (Nik 2012)).

### Calculating the potentials for renewable generation

For comparing the effects of climate data uncertainties is estimating the solar energy potentials, the generated power from unit surface area (1 m<sup>2</sup>) is calculated according to relation (1) (Zervas et al. 2008):

$$P = A(0.128G_T - 0.239 \times 10^{-3}T_a) \quad (1)$$

where,  $P$  is the generated electrical power [W],  $A$  is the aperture surface area of PV module [m<sup>2</sup>],  $G_T$  is solar radiation flux (irradiance) on module plane [W/m<sup>2</sup>] and  $T_a$  is the ambient temperature [K].

Wind power generation is calculated according to relation (2) (Perera et al. 2012):

$$\bar{P}_w(t) = \begin{cases} P_w = 0 & V < V_{ci} \\ P_w = aV^3 - bP_r & V_{ci} < V < V_r \\ P_w = P_r & V_r < V < V_{co} \\ P_w = 0 & V_{co} < V \end{cases} \quad (2)$$

where  $\bar{P}_w$  is the power output from wind turbine [kW/m<sup>2</sup>],  $V$  is the wind speed at hub level [m/s] which is assumed 60 m,  $V_r$ ,  $V_{ci}$  and  $V_{co}$  are respectively rated wind speed, cut in wind speed, cut off speed [m/s],  $P_r$  is rated power of the wind turbine [kW] which is assumed as 20.  $a$  and  $b$  are calculated as  $a = P_r/(V_r^3 - V_{ci}^3)$  and  $b = V_{ci}^3/(V_r^3 - V_{ci}^3)$ .

## RESULTS

Distributions for the heating and cooling demand of the building stock in Lund are shown in Figure 2 during 2070-2099. Differences due to climate change and its uncertainties are calculated in Table 1 and Table 2. Differences are visible and considerable in cooling demand; it can be even above 200% during 2070-2099 (depends on the climate scenario, e.g. 215% for ICHEC-rcp45 during 2070-2099) and depending on the selected climate scenario, differences (for one time period) can be also more than 200% (e.g. 234% for CNRM-rcp45 during 2010-2039 in Table 2). For Lund, which the cooling demand is much smaller than heating demand, differences between scenarios and time periods are quite negligible. This is in the contrary of the previous results using RCA3 (the older version of the RCM) which GCMs were forced by emissions scenarios defined by SRES IPCC (for more details, the reader is referred to (Nik 2012)(Nik and Sasic Kalagasidis 2013)).

Impacts of climate change and its uncertainties on estimating the renewable energy potentials are presented in the following; Figure 3 and Table 3 show results for solar PV power generation and Figure 4 and Table 4 for wind turbine. Differences due to selection of the climate scenario are visible for both the renewable sources, affecting solar PV generation up to 20% (e.g. for ICHEC-rcp45 during 2070-2099 in Table 3) and wind power up to 22% (e.g. CNRM-rcp45 during 2070-2099 in Table 4). According to all the scenarios, potentials for PV power generation will be less in future while for wind power, some scenarios predict higher potentials and some less. In general, differences due to time period (climate change) are

smaller – which is around 8% at the maximum – than those induced by the selection climate scenario (climate uncertainty) – which is around 20% at the maximum. It is important to consider that these results can be highly dependent on the location and the considered time scale. In this work, all the calculations were done in the hourly time scale, however the relative differences have been calculated based on the annual production. These differences can vary if the time scale changes for example to seasonal.

## CONCLUSION AND DISCUSSION

According to the results, differences induced by climate change and its uncertainties in the cooling demand of buildings are very large, while there are negligible for heating demand of the building stock. The latter is contrary to the calculations using the older version of the climate model and should be investigated in more detail. Effects of climate change and uncertainties are visible in the renewable energy calculations, inducing differences up to 20% due to climate uncertainties and up to 8% due to climate change. In general, scenario point to less potential for renewable generation from solar PVs while for the wind turbine, numbers do not change considerably.

### ABSTRACT

Urban districts develop in a dynamic manner over multi-year horizons with new buildings being added and changes being made to existing buildings (*e.g.* retrofits). Nevertheless, optimization models used to design urban district energy systems (DES) commonly consider a single, “typical” year for the design. This practice, however, does not allow for energy design decisions to be made in multiple phases in order to reflect a district’s development phases. This paper addresses this issue and presents a novel optimization model that allows the multi-stage optimal design of urban DES. The model identifies the cost-optimal technology investment decisions across a horizon that spans multiple years, while also calculating the energy system’s optimal operating patterns in order to meet the district’s energy demands. The evolution of the district’s energy demands and aspects like the evolution of technology costs and energy carrier prices are considered in the model. The model is applied to a new urban district in Zurich, Switzerland, for which 5 development stages are considered with new buildings of various types constructed in each phase. A multi-stage DES design plan is developed for the period 2021-2050, which includes large energy technology investments for each new development phase, but also smaller ones in the intermediate years between 2021 and 2050. The model specifies the amount of energy generated by each technology installed in each year, as well as the contribution of renewable energy in covering the district’s energy demands.

### INTRODUCTION

District energy systems (DES), incorporating multiple efficient energy technologies and locally available renewable sources, have the potential to sustainably transform the energy supply of existing and new urban districts. Designing DES is commonly performed using mathematical optimization models. These models aim to identify the optimal set of technologies that need to be installed in a DES, their capacities, and their operating patterns in order to cover the building energy demands and optimize a specific criterion (*e.g.* total system costs, CO<sub>2</sub> emissions etc.).

In these models, the DES design investment is typically assumed to occur in one stage, at the beginning of the project, without the possibility of further investments in later stages. Moreover, the design is usually performed for a “snapshot” in time, which corresponds either to the district’s current state or to the final state of a district. Multiple studies have presented such DES design models (see *e.g.* (Orehounig et al., 2015; Weber and Shah, 2011)).

This DES design paradigm, however, fails to consider the dynamic character of existing and new urban districts, which dynamically develop as buildings are getting retrofitted and/or new buildings are being added. Energy planning for urban districts should instead be able to account

for the developments in an urban district and involve multiple investment phases. This would allow the energy system plan to not only reflect the changes in the district, but also to take advantage of future investment opportunities *e.g.* due to reducing technology costs.

Therefore, this paper presents an optimization model, which enables the multi-stage design of urban DES. More specifically, the model outputs a multi-year investment plan for the DES design and calculates the system's optimal operation for each year. Additionally, the model is able to perform these tasks taking into account the evolution of a district's characteristics, as well as, the evolution of other external factors like energy prices and technology costs.

### FORMULATION OF A MULTI-STAGE OPTIMAL DES DESIGN MODEL

In this section, the formulation of the multi-stage DES design model is presented. In order to be able to make DES design decisions in multiple stages, the model's horizon needs to include multiple years  $y = \{1 \dots \mathcal{Y}\}$ . Each year  $y$  is then represented with a set of days  $d = \{1 \dots \mathcal{D}\}$ , which are in turn represented with 24 hourly time steps  $t = \{1 \dots 24\}$ .

The developments considered in the model's multi-year horizon are: (i) the district's heating and electricity demands, (ii) the solar radiation availability, (iii) the energy carrier prices, (iv) the electrical grid's carbon factor (due to grid mix changes), and (v) the future technology costs.

The set of candidate energy generation and storage technologies for the DES are given in Fig. 1 and include a gas and a biomass boiler, a CHP engine, a ground-source heat pump (GSHP), PV panels, a thermal storage and batteries for the storage of electricity. Note that the connection to the electrical grid is maintained and accounted as a "generation technology" in the model.

Figure 1. Candidate energy generation and storage technologies for the synthesis of a DES

The model aims to minimize the total DES cost,  $TC$ , over the modeled horizon.  $TC$  is expressed as the sum of the discounted annual costs ( $AC_y$ ), which include an investment ( $Inv_y$ ) and an operating expenditure ( $Op_y$ ). All the relevant cost metrics are given in Eq. (1)-(3) (bold symbols indicate model variables).

$$TC = \sum_y (AC_y) \cdot (1 + DR)^{y-1} = \sum_y (Inv_y + Op_y) \cdot (1 + DR)^{y-1} \quad (1)$$

$$Inv_y = FC_{i,y} \cdot d_{i,y} + LC_{i,y} \cdot ncap_{i,y} + (L_y^{net} - L_{y-1}^{net}) \cdot LC_{net,y}, \quad \forall y \quad (2)$$

$$Op_y = \sum_{j,d,t} (P_{j,y,d,t} \cdot OC_{j,y}) - \sum_{d,t} (L_{y,d,t}^{exp} \cdot FiT_y), \quad \forall y \quad (3)$$

In all terms of Eq. (1)-(3), the indices  $y$ ,  $d$ , and  $t$  signify that a term is indexed per year, day, and/or time, respectively. In Eq. (1),  $DR$  is the discount rate used for future expenditures. In Eq. (2),  $FC_{i,y}$  and  $LC_{i,y}$  are the fixed and the capacity-dependent costs of technology  $i$ ,  $d_{i,y}$  is a binary variable denoting the installation of technology  $i$ , while  $ncap_{i,y}$  is the newly installed capacity of technology  $i$ .  $L_y^{net}$  is the length of the thermal network and  $LC_{net,y}$  is the investment cost per  $m$  of network. These two variables form the *design decisions* of the model. In Eq. (3),  $P_{i,y,d,t}$  is

the input energy flow to energy generation technology  $j$ ,  $OC_{j,y}$  is the price per kWh of the energy carrier used by generation technology  $j$ ,  $L_{y,d,t}^{exp}$  represents exported electricity to the grid, and  $FiT_y$  is the feed-in tariff for exported electricity. The variables  $P_{j,y,d,t}$  and  $L_{y,d,t}^{exp}$  are indexed per  $y$ ,  $d$ , and  $t$  to calculate the system's operation for each year, day, and time step considered.

The carbon emissions,  $Carb_y$ , resulting from the system's operation in year  $y$  are defined in Eq. (4), in which  $C_{j,y}$  is the emission factor [gCO<sub>2</sub>/kWh] of the carrier used in technology  $i$ .

$$Carb_y = \sum_{j,d,t} (P_{j,y,d,t} \cdot C_{j,y}), \quad \forall y \quad (4)$$

An additional variable is needed in the model to track the total capacity of technology  $i$  in each year considering not only the introduction of new capacity, which is represented by  $ncap_{i,y}$ , but also the retirement of capacity that has reached the end of its lifetime. This variable is noted as  $tcap_{i,y}$  and is defined in Eq. (5), in which  $life_i$  represents the lifetime of technology  $i$  in years.

$$tcap_{i,y} = \sum_{\max(0, y-life_i+1)}^y ncap_{i,y}, \quad \forall y \quad (5)$$

An additional important set of model constraints are needed to ensure that the DES covers the district's energy demands in each time step. Eq. (6) expresses the energy balances for the heating and electricity demands of the district.

$$P_{j,y,d,t} \times \Theta_j + Q_{l,y,d,t}^{dis} - Q_{l,y,d,t}^{ch} = \eta_{net}^{dem} \cdot L_{y,d,t}^{dem} (+L_{y,d,t}^{exp}), \quad \forall y, d, t, dem \in \{Heat, Elec\} \quad (6)$$

In Eq. (6),  $\Theta_j$  is a matrix of conversion efficiencies for each generation technology,  $Q_{l,y,d,t}^{dis}$  and  $Q_{l,y,d,t}^{ch}$  represent the charging/discharging flows from storage of type  $l$ ,  $L_{y,d,t}^{dem}$  are the district's heating/electricity demands,  $\eta_{net}^{dem}$  is the efficiency of the thermal/electrical network connecting the DES to the buildings, while  $L_{y,d,t}^{exp}$  is only included in the electricity demand balance.

Additional constraints are included in the model to express the energy balance for the storage technologies, non-violation of capacities and charging/discharging rates, and other technical and operational constraints. These constraints have similar formulation to the constraints included in previous models that performed one-stage DES design. The difference, though, is that these constraints must also be indexed per year  $y$  instead of just per day  $d$  and time step  $t$ .

## CASE STUDY

The developed model can be applied for both existing districts and new developments. In this paper, a hypothetical new urban district in Zurich, Switzerland is taken. New buildings of various types are added to the district every five years from 2021 to 2040. The analysis horizon is taken as 2021-2050 in order to analyze the DES operation for ten years after the district's construction is complete. The evolution of the district's building stock is shown in Fig. 2.

A centralized DES is envisioned for the district that will generate and distribute energy to the buildings using local thermal and electrical networks. The DES's location and thermal network are also shown in Fig. 2. Each new building of the district is assumed to be built with the newest standards defining U-values for the building envelope parts. The hourly heating and electricity demands and solar radiation patterns for each building and year are calculated using the software EnergyPlus. Future climate projections are sourced from the CORDEX project (Giorgi et al. 2009). The resulting annual district energy demands are shown in Fig. 3.

The evolution of energy carrier prices and the grid's emission factor are taken according to the New Energy Policy (NEP) scenario in the Swiss Energy Strategy 2050 (Prognos, 2012) and are shown in Fig. 3. The  $FiT$  is taken as 9 Rp./kWh for 2021 and is assumed to be linearly phased out until 2050. The evolution of technology prices is described using the approach of Gahrooei et al. (2006). The cost of technology  $i$  in year  $y$ ,  $C_{i,y}$ , is described as:  $C_{i,y} = C_{i,0}e^{-\gamma_i y}$ , where  $C_{i,0}$  is the price in 2021 and  $\gamma_i$  determines how fast future costs are reduced (this equation is applied to both  $FC_{i,y}$  and  $LC_{i,y}$ ). Base costs for year 2021 are taken from (Mavromatidis, 2017). A  $\gamma_i$  value equal to 0.01 is then used for the thermal storage and district heating network pipes, 0.02 for the GSHP and gas and biomass boilers, and 0.03 for PV panels and batteries.

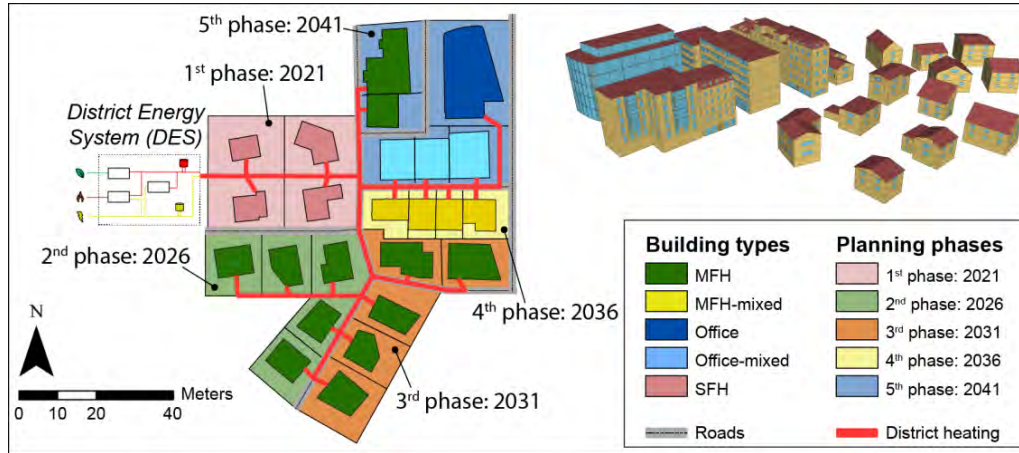

Figure 2. Evolution of urban district from 2021-2040

Figure 3. a. Evolution of district energy demands and total floor area, b. Evolution of energy carrier prices and the grid's emission factor

## RESULTS

The first set of model results shown in Fig. 4a pertain to each year's operating and investment expenditures for the optimal DES design. The energy plan involves investments in primarily 5 stages, matching each development phase of the district. However, smaller investments are also necessary during the horizon (*e.g.* in year 2029). On the other hand, expenditure for the system's operation is necessary in each year and its evolution reflects the evolution of the district's energy demands and of the energy prices, leading to gradually increased costs in the future.

Fig. 4b presents the evolution of the system's CO<sub>2</sub> emissions along the modeled horizon. Initially, the emissions exceed the 10 tCO<sub>2</sub> per year during each year of the district's first phase. Then, during the second phase, the emissions reduce significantly only to increase again during

2031-2040. Finally, during the district's final phase after 2041, the emissions show a sharp increase. Despite the grid's CO<sub>2</sub> factor getting lower from 2041 on (see Fig. 3b), the district's increased floor area (see Fig. 3a) and the resulting increase in the total energy demands (see Fig. 2) offset this benefit and lead to higher CO<sub>2</sub> levels. Nevertheless, the CO<sub>2</sub> emissions per total floor area for the district remain at the same levels as the previous years.

Figure 4. a. Investment and operating cost expenditures per year, b. CO<sub>2</sub> emissions per year

The evolution of the system's composition in terms of the energy generation and storage technologies and their capacities is shown in Fig. 5. On the generation side, the DES in the first phase consists of only a gas boiler of small capacity. A GSHP is first introduced in year 2026 and then in year 2036, while additional gas boilers are introduced in 2031, and, finally, a much larger boiler is added in year 2041. The evolution of the PV capacity is also shown in the figure with the first panels installed in 2026 and the maximum capacity being reached 2041. The figure also shows the generation capacity reduction when a device reaches the end of its lifetime (see e.g. year 2046 when the GSHP from year 2026 is retired). On the storage side, thermal storage capacity is added in two phases – in year 2026 and then in year 2036, reaching eventually a total capacity of approx. 560 kWh. Finally, in 2046 some storage capacity is retired and replaced in the final year of the modeled horizon.

Figure 5. Total installed capacity for energy generation (a) and storage (b) technologies

The installed capacities, however, do not necessarily reflect the utilization of each technology. Thus, Fig. 6 shows the total annual heat and electricity supplied by the different technologies. During the first phase of the district, the heat demands are only covered by the gas boiler. After year 2026, though, the GSHP emerges as the main heat supply technology, and the utilization of the gas boiler remains low until 2040 and is only increased after 2041. These patterns can also explain the system's emissions in Fig. 4. Initially, when the system relies mostly on gas, the emissions are high. During the period 2026-2040 the emissions remain low as the GSHP is mainly used. Finally, from 2041 onwards the emissions increase due to both higher gas consumption, but also due to higher district energy demands.

On the electricity side, grid electricity is the primary source for covering the district's electricity demands, as well as the electricity needed by the GSHP. In the first 5 years, it is the only source

of electricity; however, as more PV capacity is installed after 2026, the contribution of PV electricity increases and reaches 28% of the total electricity supply in 2050.

Figure 6. Heat (a) and electricity supply (b) by technology

## CONCLUSIONS

In this paper, a model for the optimal multi-stage design of urban DES is presented and applied to a hypothetical urban district in Switzerland. The model is able to identify optimal energy technology investments and their timing along a multi-year horizon. Moreover, it calculates the system's optimal operation in each year and quantifies the contribution of each technology in meeting a district's energy demands.

The model's formulation is very flexible, as it can accommodate any number and type of energy technologies and be applied in urban districts of different scales. Moreover, the model can also be valuable for urban planning. Currently, urban DES are typically designed only after the district's development is finalized. By integrating the model in the urban planning process, the concurrent design of a district and its energy system can be performed, leading to potentially better solutions.

As future work, additional aspects like the efficiency improvements of energy technologies will be introduced. Additionally, the issue of uncertainty is very important, as predicting accurately the long-term evolution of energy demands, prices etc. can be very difficult. By introducing uncertainty considerations in the model, more robust DES strategies can be obtained.

### ABSTRACT

Performance of a novel gas-driven, electricity-producing heating, ventilation, and air conditioning (HVAC) system with no vapor compression and no hydrofluorocarbon (HFC) refrigerant shall be discussed in the paper. The prototype was evaluated at ORNL under a Small Business Voucher (SBV) Cooperative Research and Development (CRADA) program. The target market is commercial buildings in the United States. The goal is to mitigate or eliminate grid-power for building air conditioning, coincident peak demand and associated spinning reserves, aiding in flattening of the “duck curve”. The technical goal is to transform the common packaged rooftop unit into a cost-effective distributed energy resource, opening a new range of small applications and broad markets for micro-combined cycle cooling, heating, and power with integral thermal energy storage. The test results indicate the prototype would be competitive with natural gas distributed power plants with average electrical production ranging from 45% to 60% natural gas to electricity conversion efficiency. The technology has a Primary Energy Savings Potential of 4.4 Quads, higher than any other air conditioning and heating technology.

**KEYWORDS:** Fuel Cell, Distributed Generation, Heating, Cooling, Dehumidification

### INTRODUCTION

The first integrated electricity-producing heating, ventilation, dehumidification, and air conditioning (HVAC) system using a non-vapor compression cycle (VCC), packaged rooftop unit that also produces base-load electricity was evaluated<sup>1</sup>. For convenience throughout this document we will call this integrated system Electricity-Production HVAC or EP-HVAC. The EP-HVAC unit represents a distributed energy resource with energy storage that eliminates the tremendous peak electricity demand associated with commonly used electricity-powered vapor compression air conditioning systems.

The objective is to enable the proliferation of renewable resources into the electric grid, reduce greenhouse gas emissions, eliminate the use of refrigerants used for air conditioning, and provide significant cost savings for utilities and ratepayers. This technology eliminates grid-powered electricity for building air conditioning, coincident peak demand and associated spinning reserves, aiding in the flattening of the “duck curve.” The technology is scalable from 2 to 20 tons and is applicable to 98% of US commercial buildings.

The results of the evaluation indicated that the technology, as tested would be competitive with natural gas distributed powerplants with average electrical power efficiency ranging from 45% to 60%. Test results indicate that the technology has a Primary Energy Savings Potential of  $1.3 \times 10^{12}$  kWh (4.4 Quads); higher than any other air conditioning and heating technology.

<sup>1</sup> Natural Gas Powered HVAC System for Commercial and Residential Buildings, ORNL/TM-2017/211, CRADA/NFE-16-016126, <https://resolution.ornl.gov/pub/preview/74419>

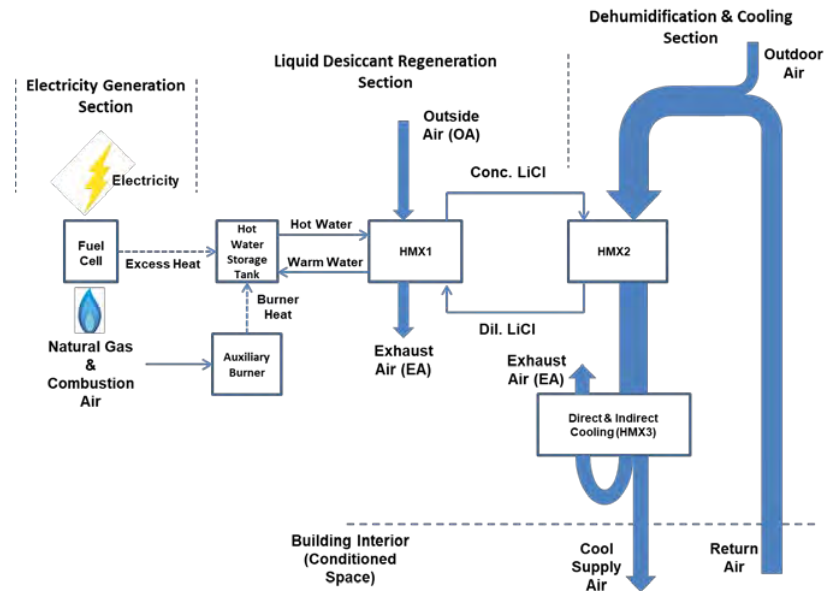

The project goal was to test and evaluate the performance metrics of a unit that provided 5 kW cooling capacity and generates electricity from burning natural gas using a commercially available solid oxide fuel cell (SOFC).

## TECHNOLOGY DESCRIPTION

### Principle of operation of the prototype:

A simplified description of the prototype is shown in Figure 1 and consists of three main sections: natural gas driven fuel cell for producing electricity; liquid desiccant regeneration; and dehumidification and air conditioning.

**Figure 1 Schematic of the prototype EP-HVAC with three discrete sections: electricity Generation; LD regeneration; and Cooling and Dehumidification.**

The prototype operates using a fuel cell and a burner to transform natural gas into electricity and heat. The heat generated is used to increase the concentration of a LiCl solution to 42% (mass fraction). This process occurs within a heat and mass exchanger (HMX) for liquid desiccant regeneration (HMX1). The concentrated LiCl is stored in a tank. When air conditioning is required, the concentrated LiCl is used to dehumidify process air (PA) within a dehumidifier (HMX2). PA for this prototype system is generally composed of a mixture of 30%–40% outdoor air (OA) with the remainder being return air (RA). The HMX2 is composed of a series of plates designed so that PA and high concentration LiCl flow on one surface. The LiCl is separated from the PA by a selectively permeable membrane that enables the interaction of water (in vapor form) with the air but prevents the flow of LiCl into the air. Because the liquid desiccant is at a high concentration, it will remove water from the air to reach water vapor pressure equilibrium with the air. This process, if adiabatic, would be isenthalpic dehumidification, resulting in a significant temperature increase of the process air. To mitigate this temperature rise, OA flows on the opposite side of the HMX2 plates, in cross-flow to the PA. The plate prevents both streams from mixing but enables heat transfer between the two flows. Water is also flown on the surface of the OA side of the plate. The OA in HMX2 absorbs the water, and this evaporation process (as well as sensible heat exchange with the air) cools the liquid desiccant dehumidification process on the other side of the plate. Consequently, the PA leaving HMX2 has a humidity that corresponds to a design dew point temperature, and a dry bulb temperature that is sometimes higher than the inlet air temperature but far lower than it would be if the dehumidification was isenthalpic (the exit temperature can be slightly lower

than inlet temperature if the outdoor conditions are very dry, which yields high-powered evaporative cooling).

To reduce the temperature of the PA down to supply air (SA) conditions, the stream is subjected to dew point-style indirect evaporative cooling (IEC) in a heat and mass exchanger (HMX3). HMX3 is composed of a series of plates. The entire PA flows over the plate's surface. However, at the exit of the plate approximately 30%–40% of the PA is redirected to flow counter to the bulk PA flow through HMX3, on the opposite side of the plates as the bulk PA flow. On this side of the plate water is flown, causing the redirected flow to cool to its wet bulb temperature. The redirected air flow leaves at close to 100% relative humidity (RH) and is exhausted. This reverse flow both cools the bulk flow, and is derived from the bulk flow, which means the lowest temperature achievable is the incoming air's dew point temperature, instead of its wet bulb temperature. At the outlet end of HMX3 plates, where a portion of the flow reverses its path, the exhaust air will indirectly cool the bulk air toward the exhaust air's wet bulb temperature. The cooler bulk air now has a lower wet bulb temperature, and it subsequently becomes the next batch of exhaust air, lowering the achievable temperature further. This continues until it cannot continue further, which (in theory) is when the dry bulb temperature of the bulk air equals the wet bulb temperature of the exhaust air, which, since they are the same stream, occurs when the bulk process air is exiting at its dew point. The bulk PA exiting HMX3 is the supply air (SA) to the building.

#### **A more effective cooling process:**

The air conditioning/dehumidification process is referred to as enhanced liquid desiccant air conditioning (ELD-AC). ELD-AC typically removes the latent heat duty of the air prior to cooling it down to as near the theoretical limit of the dew point temperature as possible. Compared to conventional VCC, the ELD-AC process is more energy efficient.

The ELD-AC process removes the more energy intensive latent first, followed by sensible indirect evaporative cooling using water extracted from the air. The change in enthalpy is typically roughly 30% lower than vapor compression (Figure 2). Most VCC systems introduce air into the space at near 100% RH and at a temperature much lower than for human comfort. VCC systems rely on heat from occupants and from building equipment (and sometimes supply their own reheat) to heat the air up to a comfortable temperature. Consequently, the prevailing method of air conditioning, VCC, is energy intensive.

In contrast, the ELD-AC dehumidification process is achieved through diffusion of water vapor from humid air across a semipermeable membrane into a flowing concentrated liquid desiccant. Liquids cannot penetrate the membrane, keeping the desiccant isolated from the conditioned air stream. This process of dehumidification is actively cooled using outside air so that it does not increase the DA temperature (however, even if it did, this would not increase the overall maximum enthalpy change, as long as the dehumidification process remains close to being isothermal). Air dehumidification, due to latent loads, is energy intensive and its removal by the above technique is more efficient than a VCC process. After removal of sufficient latent loads, further cooling in the ELD-AC process is achieved with indirect evaporative cooling.

## **RESULTS**

The evaluation consisted of 29 data sets with varying conditions in the outdoor air chamber (Figure 3 and **Error! Reference source not found.**). The test showed a 1st law efficiency that ranged from 0.6 to 1.2. The average 1st law efficiency for all runs was 0.9, with a standard deviation of  $\pm 0.15$ . Supply air temperature varied from 15.4°C to 19.4°C, with an average SA temperature of 17.3°C and a standard deviation of  $\pm 0.9^\circ\text{C}$ . SA average RH was 55%, and it ranged from 48% to 62%. Note that the 1st law efficiency in this case can be greater than 1 because the heat of water vaporization is not included in this calculation.

The first law efficiency is defined in Eq.(1) as,

$$\eta_{1st\ Law} = \frac{C+E}{F} \quad (1)$$

$C$  is the air cooling is instantaneous steady state rate of enthalpy removed from air, corrected to eliminate liquid desiccant energy storage effects;  $E$  is the electrical power produced by the system; and  $F$  is the rate of chemical energy of the fuel provided to the system during a day. In this report,  $F$  is calculated using the lower heating value of the fuel.

**Figure 2** Difference in air conditioning and dehumidification processes between conventional vapor compression cycle (VCC) and the enhanced liquid desiccant evaporative cooling air conditioner (ELD/AC) cycle.

The testing was conducted at constant simulated outdoor and indoor air conditions. In other words, it did not take into account the daily varying requirements for air conditioning, which might have resulted in the air conditioning not being operated while the fuel cell continued to provide electrical power and regenerating liquid desiccant for later use. Under these test conditions, the heat supplied by the fuel cell was not sufficient to provide the heat required to sustain the air conditioning process, since these isolated tests could not rely on storage from daily continuous regeneration. For this reason, the supplemental natural gas burner was used to supply the extra heat required. Fuel cell performance was very predictable and repeatable. On average the fuel cell electrochemical efficiency was 47% (lower heating value based) with a combined heat and power efficiency of 90%, when producing 2.5 kW<sub>e</sub>. Certain tests were performed without the fuel cell (burner only), in which case, for consistency, the expected power output and total natural gas input were calculated via the stable observed fuel cell electrical and combined heat and power efficiencies and included in the 1st law efficiency.

To provide a more insightful and comparative evaluation of the performance of the EP-HVAC, we define a distributed power efficiency ( $\eta_{DG}$ ), as shown in Equation (2), where  $\dot{E}$  is the electrical power produced by the fuel cell system as a function of time,  $\dot{C}$  is the rate of cooling provided by the system as a function of time,  $COP_{VCC}$  is the coefficient of performance of an equivalent vapor compression system,  $\dot{F}_{FC}$  is the rate of fuel energy consumed by the fuel cell system as a function of time on a lower heating value basis, and  $\dot{F}_B$  is the rate of fuel energy consumed by the auxiliary burner as a function of time on a lower heating value basis. Note that  $\dot{F}_B$  is only required when the fuel cell is unable to produce enough excess heat to drive the air conditioning process. The heat required to run the air conditioning process can be calculated using the quantified  $\eta_{1st\ Law}$  in Equation 1.  $\tau$  is the operating time period under which the efficiency is calculated, and  $t$  is time. Equation 2 converts the air cooling produced into an

electrical equivalent output of the system. This efficiency definition enables the comparison of the EP-HVAC with a power plant that is providing both electrical power to the building and to run an air conditioning unit with equivalent output performance as the EP-HVAC.

$$\eta_{DG} = \frac{\int_0^\tau \dot{E} dt + \int_0^\tau \frac{\dot{c}}{COP_{VCC}} dt}{\int_0^\tau \dot{F}_{FC} dt + \int_0^\tau \dot{F}_B dt} \quad (2)$$

**Figure 3.** Psychrometric chart showing summary of outdoor air test points and  $\eta_{1st\ Law}$  achieved (represented by point color and referenced to color bar on left) with the prototype unit. Comfort zone region is shown in dashed line polygon.

For illustration and simplicity, we have evaluated  $\eta_{DG}$  assuming the outdoor and indoor air conditions do not change during a day and that the air conditioning portion of the system operates in on/off operation (as most air conditioners do). Given this, a duty cycle can be defined as a ratio of the time the system spent cooling (air conditioner on) and the time the system produced electrical power. Also, for simplicity, we maintained the fuel cell power output constant during the day.

The tested conditions had two extremes: hot and humid (H&H), and hot and dry (H&D) conditions. These conditions are summarized in Table 1. Using the collected data and the simplifying assumptions previously described, where the power to cooling capacity ratio of the EP-HVAC is 1kW/RT, and a  $COP_{VCC}$  of 4.1 (EER = 14), which would correspond to a very high efficiency vapor compression cycle system,  $\eta_{DG}$  as a function of duty cycle was evaluated and the result is shown in Figure .

The results indicate that initially,  $\eta_{DG}$  increases as duty cycle increases, as the excess heat generated by the fuel cell is more than the heat required to drive the increasing air conditioning loads. In this regime, the excess heat from the fuel cell is better utilized and efficiency increases. As the duty cycle increases further, the fuel cell excess heat becomes insufficient to drive the cooling load, leading to increasing use of the auxiliary burner. This increases fuel consumption and decreases  $\eta_{DG}$ . For both H&H and H&D cases  $\eta_{DG}$  is higher than most distributed generation systems, ranging between 65% and 52% for the H&D case, and between 59% and 37% for the H&H case.

**Table 1. Hot and Humid (H&H), and Hot and Dry (H&D) conditions tested**

Hot and Humid Conditions			
First Law Efficiency:	90%	DG Efficiency Range:	37% to 57%
	Dry Bulb Temp. (°C)	Relative Humidity (%)	
Outdoor Air	31.8	72%	
Return Air	25.2	56%	
Hot and Dry Conditions			
First Law Efficiency	126%	DG Efficiency Range:	52% to 65%
	Dry Bulb Temp. (°C)	Relative Humidity (%)	
Outdoor Air	37.4	30%	
Return Air	25.5	55%	

**Figure 4. Distributed power efficiency of tested EP-HVAC as a function of duty cycle for constant return air and outdoor air conditions H&H and H&D. The  $COP_{VCC}$  is 4.1 and fuel cell power to air conditioner cooling capacity is 1kW/RT.**

## DISCUSSIONS

The EP-HVAC tested was the first prototype of its kind tested under varying outdoor air conditions. While the performance of the system measured in terms of  $\eta_{1sr\ Law}$  is generally high, with improvements to the design it could be significantly higher.

EP-HVAC is an enhanced power generator and the most relevant comparative performance indicator is  $\eta_{DG}$ . The analysis of  $\eta_{DG}$  presented is sensitive to the assumptions made. In particular,  $COP_{VCC}$  and the power to cooling ratio.  $COP_{VCC}$  depends on outdoor air conditions and humidity, an effect that is not captured in the results presented. A  $COP_{VCC}$  of 4.1, the value used in our analysis, corresponds to the peak value found in the literature for high efficiency roof-top units.

Fuel cell electrical efficiency and CHP efficiency also play an important role and affect the optimization of the power to cooling design point in different weather conditions.

Further work is needed to complete a full evaluation of the EP-HVAC. This includes improving design of the system to reduce size and increase  $\eta_{1sr\ Law}$  in all weather conditions. Additionally, there is a lot of room for system optimization for a particular building and weather conditions. To explore this, further dynamic, yearlong, location specific models should be developed.

## CONCLUSIONS

The building and testing of this 1<sup>st</sup> EP-HVAC demonstrates that this is a technology with enormous potential to reduce energy consumption associated with electricity generation and powering air conditioners in buildings.

## Optimization of Electric Vehicle Charging in a Fully (Nearly) Electric Campus Energy System

### ABSTRACT

The goal of this work is to build a set of computational tools to aid decision making for the modelling and operations of integrated urban energy systems that actively interact with the power grid of the future. District heating and cooling networks incorporating heat recovery and large-scale thermal storage, such as the Stanford campus system, dramatically reduce energy waste and greenhouse gas emissions. They have historically played a small, but important role at a local level. Here we explore the potential for other co-benefits, including the provision of load following services to the electrical grid, carbon emissions reductions or demand charge management. We formulate and solve the problem of optimally scheduling daily operations for different energy assets under a demand-charge-based tariff, given available historical data. We also explore the interaction and interdependence of an electrified thermal energy network with actively managed power sources and sinks that concurrently draw from the same electrical distribution feeder. At Stanford University, large-scale electric vehicle charging, on-site photovoltaic generation and controllable building loads could each separately represent up to 5 MW, or 15% of the aggregate annual peak power consumption in the very near future. We co-optimize financial savings from peak power reductions and shifting consumption to lower price periods and assess the flexibility of both the different components and the integrated energy system as a whole. We find that thermal storage, especially complemented with electric vehicle charging, can play the role that is often proposed for electrochemical storage for demand charge management applications and quantitatively evaluate potential revenue generators for an integrated urban energy system. Although there is little value to smart charging strategies for low penetrations of electric vehicles, they are needed to avoid significant increases in costs once penetration reaches a certain threshold – in the Stanford case, 750-1,000 vehicles, or 25% of the vehicle commuter population.

### KEYWORDS

District energy system, electric vehicle charging, thermal energy storage, integrated urban energy.

### INTRODUCTION

More than half of the world's population currently lives in urban areas (54% in 2014), and this fraction is expected to increase to 66% by 2050 (UN DESA, 2014). Increasingly, buildings and the urban environment are becoming a nexus for different energy networks across sectors such as electricity, heat and transportation (Keirstead et al., 2012). These networks will be denser, more complex and interdependent. Heat, electricity and transportation also account for two thirds of global carbon dioxide emissions from fuel combustion, which makes the urban environment a battleground for climate change mitigation efforts. A viable pathway to addressing climate change goals is to electrify the heat and transportation sectors while decarbonizing electricity generation. Along this pathway come serious challenges however: the demand for electricity is likely to rise significantly beyond the capacity of current infrastructure,

and current options for decarbonized electricity sources largely depend on the wind and sun, so they are more variable and less controllable than the traditional thermal power generation sources that constitute the backbone of current power grids (Apt, 2015). Unmanaged, the electrification of heat and transport represent a threat to the power system. On the other hand, exploiting the inherent flexibility in these sectors could also ease the integration of larger shares of renewable generation through demand side management (Callaway & Hiskens, 2010). Enhanced sensors and actuator controls are available to manage the interactions and energy flows between the heat, electrical and transportation networks (O'Malley et al., 2016).

District energy systems have historically played a small, but important role at a local level (Rezaie & Rosen, 2012). It is expected and desirable that they will play a larger one in future sustainable energy systems (Lund et al., 2014). In particular, the optimization of district electric heating and cooling systems offers a way of incorporating large thermal storage in power systems at the transmission and distribution levels as a major flexibility asset, while increasing the value of investments by broadening the services they can provide to an ever-expanding area (de Chalendar et al., 2017). Plug-in Electric Vehicles (PEVs) are expected to represent an increasing share of electric load in power systems in the near future, which is why a significant amount of recent work has focused on studying their impact on the grid (Richardson, 2013). Given the capital cost of chargers, it is likely that workplace charging will play a large role in future transportation networks. Whereas uncontrolled charging will present a risk if not managed adequately, when connected to the grid, the batteries of PEVs represent a potential storage asset for the system operator.

The Stanford Energy Systems Innovations project is a prime case study for this work. A schematic for the campus energy system is shown in Figure 1. The main energy requirements are those of the buildings, that consume cooling, heating and power. The heating and cooling needs are met through hot and chilled water distribution networks that are supplied by the onsite Central Energy Facility (CEF). The bulk of the thermal needs are met through electric heat pumps that leverage heat recovery and are backed by thermal storage tanks. These replaced the gas-fired co-generation plant that was decommissioned in 2015. Stanford University is a perfect example of a continually evolving urban environment: large-scale electric vehicle charging, on-site photovoltaic generation and controllable building loads could each separately represent up to 5 MW, or 15% of the aggregate annual peak power consumption in the very near future.

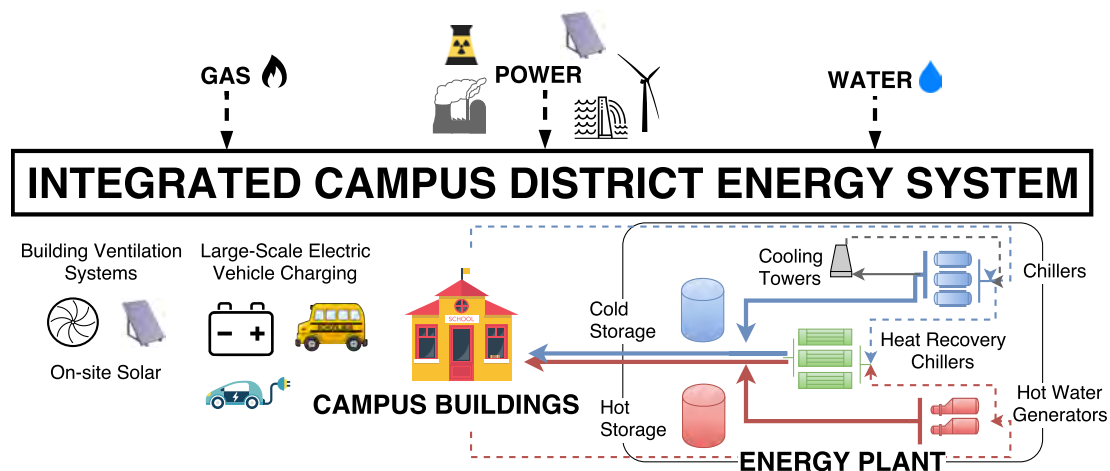

Figure 1. Schematic for an integrated campus district energy system.

The problem we are considering here is that of the optimal management of an integrated energy system in an urban environment. Since infrastructure investments in systems such as these are typically capital intensive and intended to last for many decades, ensuring that they are designed

in a way that they are not only flexible to short-term operating conditions but also longer-term evolution trends is critical to recovering invested value. In this paper we build on a previous model of the Stanford energy system to further explore the interdependence of the heat, electricity and transportation sectors at the urban energy system level. We assess the impact of different penetrations of electric vehicle charging on the campus distribution system and quantitatively determine the value of different PEV charging strategies.

## METHODS

We consider an integrated urban energy system that meets its thermal needs through electric heat pumps backed by thermal storage. We call the operations scheduling problem that of determining the hourly operations at the CEF such that energy demands and technological constraints are met at minimum cost. This problem is formulated for the 8,760 hours in a year as a Linear Program (LP) with  $\sim 130,000$  variables and  $\sim 170,000$  linear constraints in de Chalendar et al. (2017). The objective function of this program is the campus aggregate energy bill, *i.e.* we consider financial savings in the context of a demand-charge-based system, where a time-varying, hourly price is paid for energy (measured in kWh), and a monthly price is paid for the peak power consumption (measured in kW). The decision variables of the program are the hourly power injections to the different machines at the CEF. At every time step, the campus heating and cooling loads must be met, as well as various operating constraints, *e.g.* available capacities and ramp rates. The machines available to contribute to the hot and chilled water streams are electric heat recovery chillers, electric chillers, and gas-fired boilers.

To model future interactions of the Stanford ecosystem with large-scale PEV charging, we now build a module to represent the population of PEVs on campus. This model also has an hourly resolution and tracks the energy and power flows associated with the different vehicles connected to campus chargers. The vehicles are characterized by the parameters in Table 1: they are present only for a portion of the day (arrival and departure times); their batteries have different technical characteristics (capacity and charge rate); the energy in their battery packs, or State of Charge (SoC), is different when they arrive in the morning; and finally they have different requirements for SoC levels when they leave the campus at the end of the day. We assume that when the drivers plug in to the campus chargers, they specify a minimum SoC for the end of the day and the time at which they leave, and then hand over control to the campus operator as to when the charging actually occurs. The dynamics of the SoC of the batteries in the vehicles is governed by the following equation during the hours when it is controlled by the system operator:

$$S_{t+1} = S_t + P_t^c \delta t \eta^c - \frac{P_t^d \delta t}{\eta^d} \quad (1)$$

where  $S_t$  is the SoC at time  $t$ , and  $P_t^c$  and  $P_t^d$  are the power charged and discharged during the time step of length  $\delta t$  at efficiencies of  $\eta^c$  and  $\eta^d$ , respectively. The power that is charged and discharged at every hour from the vehicle batteries are decision variables for the optimization program and represent bidirectional charging. During the hours where the vehicles are not connected to the campus chargers, we impose the constraint  $S_t = 0$ . The PEV module that was just described is tied to the main optimization program described in de Chalendar et al. (2017) through the total hourly electrical energy consumed by the PEV population, which is added to the aggregate campus consumption. A small penalty is also added to the objective to account for battery degradation (and prevent excessive charge/discharge cycles).

The storage dynamics represented by equation (1) hold for each of the vehicles that connects to the campus, and for small numbers of vehicles, each individual vehicle is tracked by the program. For large populations of PEVs however, the problem quickly becomes numerically intractable, and it is no longer reasonable to track every vehicle separately. Instead, we assume that the vehicles can be clustered into a set of commuter archetypes. Each archetype corresponds

to one set of parameters as defined by Table 1 (16 archetypes can be modelled here). For each archetype, a weight and the number of connected vehicles is used to scale the technical characteristics of the battery, such that all vehicles of a given archetype are grouped together as one large equivalent vehicle, and the 16 equivalent vehicles present the same technical characteristics to the distribution system as the full PEV fleet.

Table 1. Parameters for commuter archetypes in PEV model. We use  $\eta^c = \eta^d = 90\%$ , which corresponds to a round-trip efficiency of 81%. Arrival and departure times for each archetype are uniformly drawn from [6,7,8,9] AM and [5,6,7,8,9] PM.

Parameter	Value 1	Value 2
Storage capacity (kWh)	20	60
Charge/Discharge rate (kW)	4	20
Arrival state of charge (%)	20	70
Departure state of charge (%)	80	100

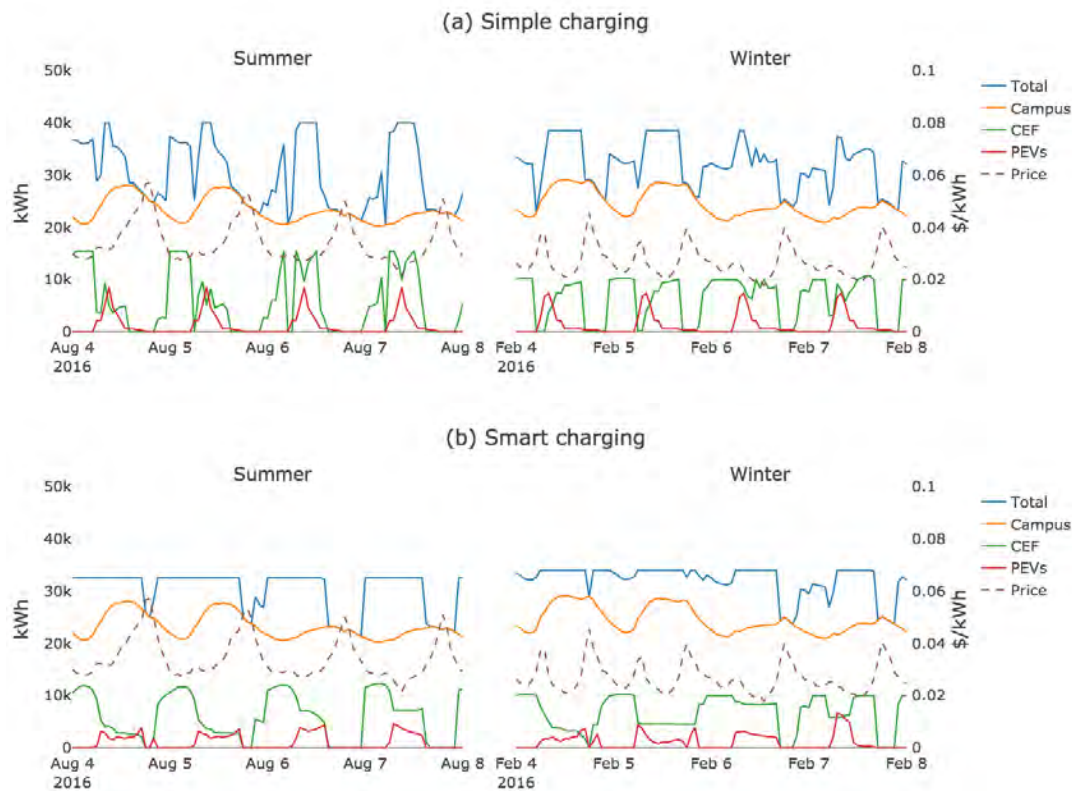

Figure 2. Typical summer and winter operations schedules for two charging strategies for 2,000 vehicles (~60% of campus commuter vehicles): (a) simple charging, where vehicles charge as soon as possible, and (b) smart charging, where the optimization program chooses when to charge the vehicles. The schedules report the energy (kWh) consumed by each component of the energy system during each hour.

## RESULTS

To assess the impact of large-scale PEV charging on the Stanford energy system, we compute optimal operating schedules for the CEF with two operating modes for PEV charging: (i) “simple” charging where the PEVs charge as fast as possible when they arrive, until they reach their departure SoC level; and (ii) “smart” charging where the charging is handled by the optimization program. Real 2016 data is used for campus thermal and electrical loads. Figure 2 shows typical summer and winter operations schedules for the two charging strategies, for 2,000

vehicles. The (controllable) CEF, respectively PEV load, is represented in green, respectively red, while the (uncontrollable) background campus load is represented in orange, and the aggregate university load is represented in blue. In the top graphs where simple charging is adopted, the system operator does not control charging, so that the uncontrollable load consists of both building and PEV loads and presents a peak in the morning. By contrast, the smart charging strategy spreads charging throughout the day to avoid raising peak power demand and to target low price periods. The program is able to distribute charging throughout the day whether it is a summer, winter, weekend or week day and chooses never to use the Vehicle-to-Grid (V2G) capability: the discharge variable  $P_t^d$  is zero for every timestep. We also compare the financial and grid benefits at different PEV penetration levels from the considered charging strategies in Figure 3. We compute the average cost of charging the vehicles as the campus electric bill increase divided by the number of vehicles for Figure 3a, and the peak monthly power demand for Figure 3b. Data for Figures 3a and 3b are normalized to one for 100 vehicles. The results in Figure 3 show that although there is little benefit in smart charging strategies for low penetrations of PEVs, not applying them becomes extremely detrimental when penetrations rise above a critical threshold (here 750-1,000 PEVs for all months except March).

Figure 3. Comparing the benefits of charging strategies at different PEV penetration levels (from 0 to 160% of the current commuter population): (a) normalized average charging costs and (b) normalized average monthly peak load. Average charging costs are computed as the increase in total campus costs from introducing PEVs, divided by the number of PEVs. In figure (a) charging costs are normalized to one for 100 vehicles, and similarly in figure (b), peak load is normalized to one for 100 vehicles. Solid lines represent smart charging, dashed lines represent simple charging.

## DISCUSSION AND CONCLUSIONS

In the application presented here, multiple controllable electric loads interact, which means that different energy assets may be competing to generate the same value stream for the campus. Peak-shaving in particular is usually found to present substantial economic benefits for facilities such as the Stanford energy system. In a different setting where PEVs are the only controllable load, it could be expected that energy costs would decrease as PEV penetration increases, if the car batteries were used to provide electricity to the campus during peak demand (*e.g.* V2G). Since the CEF already possesses a very cheap way of shifting loads (by exploiting thermal energy storage) however, there is little added value left from peak shaving when PEV penetration increases. Here, the real value from smart charging lies in avoiding increased peak power charges when PEV penetration rises. As highlighted by Figure 3a, if smart charging is not adopted, the cost of charging will increase dramatically with penetration levels and peak demand will increase almost linearly, whereas charging costs can be kept almost constant through smart charging. We emphasize that only one value stream from PEV smart charging is considered here. Other more complex revenue streams may hold additional value, for instance to mitigate short-term power variations in local solar generation or to participate in frequency

response. The penetration threshold at which smart charging strategies start showing real value corresponds to a fleet of PEVs that can draw 15-20% of peak power demand, and 25% of the commuters are driving EVs<sup>1</sup>, which demonstrates that significant interactions between the transportation and electricity sectors is not very far away. Injecting real data on PEV commuter patterns would bring even more value to this analysis to confirm these conclusions by more precisely segmenting vehicles in realistic customer archetypes. Additionally, coarser reduced-order-modeling of the PEV population may become necessary in order to increase the number of energy assets that can be managed by our optimization program. With 16 commuter archetypes, the size of the monthly optimization program jumps from 12,000 to 48,000 decision variables when adding the PEV module, which makes runtimes slower.

The results presented here have strong implications for policymakers and decision makers. They highlight how urban energy systems will become increasingly integrated across the transportation, heat and power sectors. This integration can bring real value but also presents corresponding risks if not properly managed. Given the high infrastructure costs associated with investments in urban environments, especial care should be taken in planning, in particular to consider the new energy networks that they will interact with.

## ACKNOWLEDGEMENTS

Funding for this research was supported by the Global Climate and Energy Project and a Precourt State Grid Corporation of China Graduate Student Fellowship. The authors thank Joe Stagner, Executive Director of Sustainability and Energy Management Department at Stanford University, for providing energy load data for this study.

### **ABSTRACT**

Surface as well as air temperatures are due to the urban heat island effect higher in urban compared to their surrounding rural areas. These increased temperatures have a strong impact on the building energy performance in urban environments and thermal comfort as well as health of inhabitants of these environments. At smaller scales, local heat islands are formed within urban environments, which have the same negative impacts. In this study, we investigate the influence of local heat islands on the space cooling demand of buildings. Commonly, climate information from one weather station is used for building performance simulations within a whole city. This climate information cannot take local hot spots into account, what can lead to inaccurate space cooling demand predictions. Here, we model the local urban climate with CFD (Computational Fluid Dynamics) simulations. With CFD also the local convective heat transfer coefficients (CHTC) for the building surfaces can be predicted. These local CHTC can strongly vary locally due to differences in local wind speeds. The commonly used coefficients are mostly based on measurements at facades of stand-alone buildings, where the local wind speeds are higher compared to urban areas. This study shows a dependency of the space cooling demands on the local urban climate. Space cooling demands are higher in areas with high local temperatures, where the wind-driven ventilation is decreased. Additionally to the higher local temperatures also the local CHTC are lower leading to lower heat losses from the buildings. It can be concluded that it is important to account for the local microclimate to accurately predict the space cooling demand of buildings in urban environments.

Urban climate, CFD, Building Energy Simulations, Space Cooling Demand, Local Urban Heat Island

### **INTRODUCTION**

In the past decades, cities have been continuously growing and today about 54% of the world population lives in urban areas, a ratio that will increase to about 66% by 2050 (United Nations, 2015). Urban areas experience the urban heat island (UHI) effect, characterized by higher air temperatures compared to the surrounding rural environment (Oke, 1987). The UHI is expected to further increase due to the continuous growth of our cities, leading to even harsher urban climates in future. In addition to the UHI effect at city scale, local hot spots can be found in cities. Certain city quarters, neighbourhoods or zones between individual buildings may show much higher air temperatures compared to neighbouring urban areas, referred to as local heat islands (Allegrini and Carmeliet, 2017). These local hot spots are mainly due to lower wind speeds caused by wind sheltering. The intensity of these local heat islands depends on factors like building density, lack of shadowing by buildings and trees, type of building materials, lack of water bodies, vegetation or parks and deficiency of wind

flows to ventilate and remove heat. The local urban climate may highly influence the energy demand for buildings, especially the space cooling demand during hot periods. Most of the building energy simulation models, which are used to predict energy demands of buildings, were originally developed for stand-alone buildings (Hensen, 2011). For buildings in urban environments the building energy demand can be quite different to buildings in rural areas. The important impact of the local urban climate on the energy demand of buildings has been shown in a number of studies (e.g. Bouyer et al. 2011) with different approaches and levels of detail.

There exist a large number of numerical urban climate models, which predict the urban climate with different spatial resolutions and levels of accuracy. In this study a detailed urban microclimate model developed by Kubilay et al. (2017) is used to simulate the local urban heat islands in a small urban neighbourhood. This is a fully-integrated urban climate model, which solves for wind flow and for the transport of heat and moisture in the air and building materials. The predicted local air temperatures and local convective heat transfer coefficients for a period of 24 hours during a generic heat-wave event are used as inputs to building energy simulations (BES), which predict the space cooling demands. This study is conducted for the climate of Zürich (Switzerland).

## **NUMERICAL MODEL AND SIMULATION**

An offline coupling between a CFD and a BES model is used to predict the impact of the local urban climate on the space cooling demands of a building in an urban neighbourhood. First the urban climate model based on CFD is conducted to predict the local urban climate for a time period of 24 hours. In a second step the local air temperatures around the studied building is used as an input parameter for the BES. The local air temperature is determined as the mean temperature in the air volume surrounding the building with a maximum distance of 0.3 m. For the convective heat transfer coefficients (CHTC) the correlations by McAdams (1954) are used (default correlations for the used BES model). For this study, for each building surface the local wind speed (mean over the façade or roof area) is used in the CHTC correlation instead of the wind speed from the climate file. With this offline coupling approach, we can account for the local microclimate, when simulating the space cooling demand of a building.

For the microclimate simulation the urban microclimate model by Kubilay et al. (2017) is used. This model solves the steady Reynolds-averaged Navier-Stokes (RANS) equations iteratively with the unsteady heat and moisture transfer in the building materials. The model includes long and shortwave radiation exchange between the urban (building and street) surfaces. The urban climate model is implemented in OpenFOAM 2.4 and a standard k- $\epsilon$  turbulence model is used. The building materials are modelled as porous domains and the heat and moisture transport equations are solved. The long and shortwave radiation is modelled based on a radiosity approach. For more details on the urban climate model, we refer to Kubilay et al. (2017).

For the Building Energy Simulation (BES), the program CitySim (Kämpf, 2009) is used. CitySim is a simulation tool which models the energy fluxes in a city, with a size ranging from a small neighbourhood to an entire city. In CitySim detailed radiation models for solar and longwave radiation are implemented that can account for the radiation exchange between neighbouring buildings, the ground and environment. The heat flow through the walls is determined with a model based on the analogy with an electrical circuit (resistor-capacitor network). CitySim uses an hourly timestep, which cannot be changed. CitySim also includes HVAC and energy conversion system models. CitySim determines the heat balances for all building materials and for the ground (e.g. street) materials.

In this study, urban microclimates for six different urban morphologies are studied and their impacts on the space cooling demands of the middle building (Fig. 1). All buildings are 10 m high and the lengths of the buildings are between 10 m and 50 m.

Figure 1. The layout and orientation of the urban morphologies under investigation.

All buildings are modelled as office buildings with corresponding occupancies and internal gains (SIA 2006). Ventilation and infiltration are considered. The glazing (G-value: 0.7, U-value:  $1.1 \text{ W/m}^2\text{K}$ ) fraction of the buildings is 40 % and all façades have a solar reflectance of 0.4. The walls have a U-value of  $0.5 \text{ W/m}^2\text{K}$  (with inner insulation); the roofs have a U-value of  $0.23 \text{ W/m}^2\text{K}$  and the floors a U-value of  $0.44 \text{ W/m}^2\text{K}$ . The walls are made out of brick and the same material properties are used for the BES and urban climate simulations. External shading devices are used to protect the buildings from solar gains.

The simulations are conducted for the city of Zürich on June 21<sup>st</sup>. A generic heat-wave situation with ambient temperatures between  $20^\circ\text{C}$  and  $33^\circ\text{C}$  is assumed. Fig. 2 shows the variations of the ambient temperature during the day.

Figure 2. Daily variation of the ambient temperature.

The wind direction is assumed to be  $270^\circ$  for the whole 24 hours. At the inlet of the computational domain vertical profiles of the mean horizontal wind speed, the turbulent kinetic energy and the turbulence dissipation are imposed for a reference wind speed of 5 m/s at 10 m height. These profiles represent a neutral atmospheric boundary layer, where the turbulence originates only from friction and shear (Richards and Hoxey, 1993). The mesh, the computational domain size and the solution algorithm are in agreement with best practice guidelines (e.g. Franke et al. 2011).

Both the CFD as well as the BES are simulated for a number of 24 hour cycles until the results for the same hour of the day are the same for at least two consecutive cycles.

For each urban morphology four different BES are conducted. The first simulation is conducted with the default CHTCs used in CitySim and the ambient temperatures from the

weather file (shown in Fig. 2). A second simulation is conducted using the local air temperatures from CFD (with the default CHTCs). In the third simulation the local CHTC are used (with the ambient temperatures from the weather file) and finally the local CHTCs and local air temperatures are used for the simulations. Therefore it is possible to evaluate the impact of the different input parameters on the predicted space cooling demands.

## RESULTS

### Microclimate

First the predicted local microclimate is analysed, before the impact on the space cooling demands is studied. In Fig. 3, the local heat island intensities (temperature difference between the local temperature and the ambient temperature) for the warmest hour of the day are presented. The temperatures are locally 2 °C and more above the ambient temperature. This local temperature increase has an impact on the space cooling demands. Strong differences can be found for the different urban morphologies. Lower local heat island intensities (LHI) can be found for less dense morphologies and morphologies with open flow paths in wind direction. Fig. 4 shows the LHI shows during the coldest hour of the day. Here the LHI are lower, but the hot spots can be found in similar locations.

Figure 3. Local heat island intensities (LHI) at 2 m above the ground for an hour with an ambient temperature of 33 °C.

Figure 4. Local heat island intensities (LHI) at 2 m above the ground for an hour with an ambient temperature of 20 °C.

### Space cooling demands

The differences in the local microclimate (discussed above) have an important impact on the energy performance of buildings in urban areas. The microclimate simulations show that the daily mean local heat island intensities in the air volume close to the studied building (used for the BES as input) are between 0.4 °C and 1.4 °C. The maximum local heat island intensities in this air volume are up to 2.7 °C. In Figure 5, the daily space cooling demands for the different urban morphologies are compared. For each morphology the space cooling demands are determined with the default settings of CitySim (“Base Case”), using the local air temperatures (“Local temperatures”), using the local CHTC (“Local CHTC”) or using local values for temperatures and CHTC (“Local temperatures and CHTC”). The results show that predicted space cooling demands of the same building can vary up to 20 % depending on the local microclimate and on the degree of detail that the microclimate is modelled in the BES. The urban morphology has first of all an impact on the radiation exchange between the buildings, what causes the differences between the different base cases. Urban morphologies also lead to different wind patterns and local air temperatures, what increases the space cooling demands in urban areas. The contribution of these two effects have a similar magnitude for the here studied cases. The combined effect of the local heat islands and the decreased wind speeds is approximately the sum of the individual effects.

Figure 5. Normalized space cooling demands for different morphologies and microclimate boundary conditions (in percentage). Results are normalized by the case with the lowest daily space cooling demands (45.5 kJ/m<sup>2</sup>).

### DISCUSSIONS

The results of this study show a clear impact of the local microclimate on the space cooling demand of buildings in urban environments. Additional studies are needed to get more general conclusions, since the results here are limited to a (realistic) case study. Here the study is only conducted for one climate with the focus on a generic heat-wave. Also only one type of building was studied, but not all building types have the same sensitivity to the local climate. Additionally a number of simplifications were made here. The wind speed and wind direction are constant during the studied 24 hours and generic building configurations are used. Finally, the coupling between the CFD and BES can still be improved. With the models used in this study, the spatial resolution of energy fluxes and the temperatures of the building facades are significantly higher for the CFD compared to the BES.

### CONCLUSIONS

In this study the impact of the local urban microclimate on the space cooling demand of a building during a heat-wave is investigated. A very detailed local urban climate model based

on CFD is used to predict the local microclimate for six different urban morphologies. The urban climate simulations show local hot spots between buildings with temperatures, which are more than 2 °C higher compared to the ambient air temperatures. The local heat island intensities are found to be larger during the day compared to the night. The BES show that the local hot spots lead to increased space cooling demands of an office building of 5-13 %. The lower wind speeds in the urban areas cause a further space cooling demand increase of 3-6 %. Finally, the radiation exchange with the neighboring buildings also has an impact on the space cooling demands of the studied building.

This study shows that it is important to not only account for the urban heat island effect in BES, but also considering the local heat islands that exist within the urban heat islands.

### **ABSTRACT**

In the United States, 41% of produced energy is consumed by the building sector, i.e. residential and commercial buildings (Building Energy Data Book, Buildings Sector, US Department of Energy, Office of Energy Efficiency and Renewable Energy, Building Technologies Office, 2012. n.d.). The anticipation is that Home Energy Management Systems (HEMS) will support energy efficiency gains through control of the devices in an optimal fashion. New opportunities are offering the ability to integrate grid type controls and the most suitable way to perform these controls is through a multi-agent system (MAS). In this paper, approaches on supporting a HEMS and MAS integration are discussed.

### **INTRODUCTION**

Home Energy Management Systems (HEMS) today are consumer electronic devices that provide a home owner the option to monitor and control different end-use devices such as heating, ventilation, and air-conditioning (HVAC) systems, water heaters, and lighting to name a few, to support energy efficiency. For the most part, these systems have primarily focused on simple scheduling, control, and linkages (methods) such as IFFT (if this then that) that allow one device or application's output to trigger another. However, these systems are seeing rapid evolvement into a vision of smart homes that can support the smart grid with load and resource flexibility (Karlin et al. 2015). This evolvement is spawning potential grid supporting use cases that support the adoption of home owner HVAC, water heaters, energy storage, and photovoltaic (PV).

Significant research regarding HEMS has been actively pursued with several open-source and proprietary HEMS available (Lobaccaro, Carlucci, and Lofstrom 2016)(Aman, Simmhan, and Prasanna 2013)(Asare-Bediako, Kling, and Ribeiro 2012)(Helia Zandi, Teja Kuruganti, Edward Vineyard 2017). These HEMS typically support a specific suite of devices and methods from partnered vendors with communication protocols such as Wi-Fi, ZigBee (ZigBee. Retrieved from <http://www.zigbee.org/> n.d.), and Z-Wave (Z-Wave. Retrieved from <http://www.z-wave.com/> n.d.). As a result, interoperability across these devices is a key challenge as each of these devices has unique protocols, interfaces, and control functionality.

Hence, control flexibility from grid to devices through a HEMS has been a difficult proposition.

Multi-agent system (MAS) architectures have been proven as means to provide the necessary infrastructure for HEMS to achieve control goals (Asare-Bediako, Kling, and Ribeiro 2013). A MAS consists of agents that can communicate, and coordinate behaviour based on the overall system goals and status of other agents. By this transformation, the hardware and software components represented by agents can be grouped to collaborate to satisfy a main objective such as minimizing energy cost within the bounds of comfort. By utilizing a MAS architecture, the control strategies are distributed between agents that facilitates increased flexibility, less complexity, and better performance. In this paper, a general framework for integrating HEMS into a MAS using two general interfacing approaches is presented. This allows for a rapid development of new use options for load management and control to support the electric grid, which is also discussed.

## METHODS

In this paper, the focus is not specifically on the development of an agent-based system, but on the integration of this type of system with a HEMS. Hence, an open-source distributed agent based platform, VOLTTRON<sup>TM</sup>, was used and will be referenced here forth in tandem with MAS (Haack et al. 2013). Also in this paper, a Home Assistants (HASS), which is an open-source home automation platform is chosen to represent the HEMS (Home Assistant n.d.). However, the architecture developed supports any general MAS and HEMS integration.

The first approach to adopting a MAS into HEMS is the potential utilization of a RESTful API (application programming interface) developed by the HEMS manufacturer as shown in Figure 1. This type of interface often exists in the cloud with direct access control and cyber security measures such as bearer tokens leading to a more seamless integration (Fielding 2000). For adopting the MAS, an agent (represented as HASS driver) is needed to communicate with the HEMS API and receive information about the devices for publishing on a local message bus for sharing with other agents. The agent also can send actuation commands to the devices using the HEMS API. An example is shown in Figure 1, and explanations is provided in Table I and Table II. While vendors may support the utilization of these APIs, these can be proprietary often reducing the ability to integrate with a MAS.

In the case where an API is not supported, the adoption can be performed by using a MQTT machine-to-machine communication protocol. In this case, a MQTT broker is needed as a communication median, represented by mosquito (an open-source broker (Mosquitto Broker n.d.)) in Figure 1. The broker provides the interface between a HEMS and MAS. An agent performing MQTT communications is required to bridge the data from the MQTT stream to a message bus. Also, a MQTT client is needed to publish the information about the devices supported by the HEMS to the broker. This client can also receive actuation commands from the HEMS MQTT Agent. An example along with description is provided in Table I and Table II.

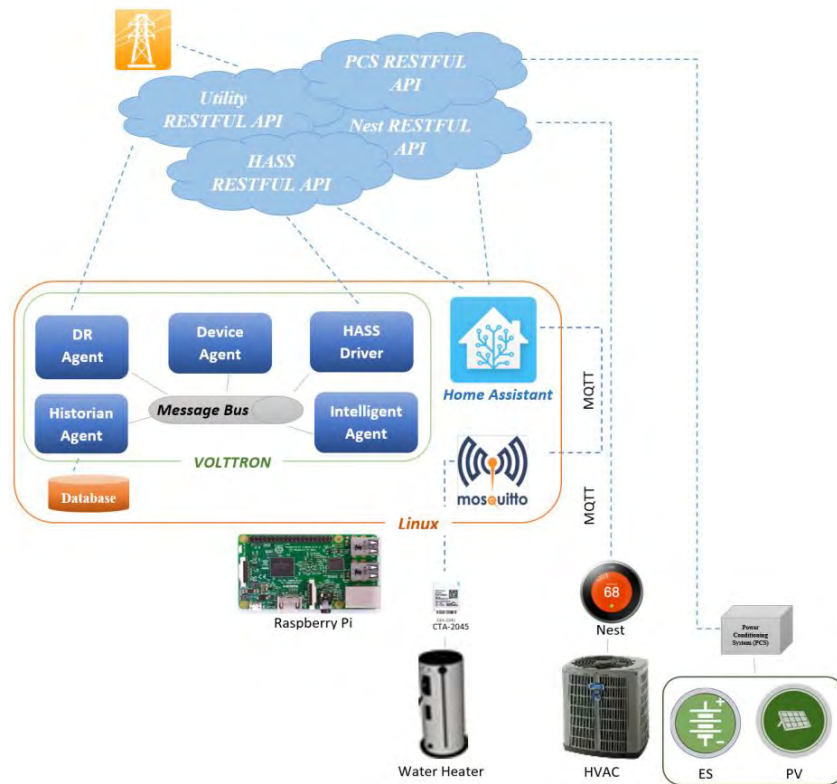

Figure 1- Integrating Home- Assistant with VOLTTRON USING RESTful API

VOLTTRON MQTT agent subscribes to HASS messages on the broker and publishes them on message bus for decision making</li> <li>4. MQTT Agent sends control messages to the broker</li> </ol>	<ol style="list-style-type: none"> <li>1. Home Assistant provides RESTful API.</li> <li>2. MAS HASS Agent extracts device and provides control requests</li> <li>3. HASS Agent publishes messages on VOLTTRON message bus for decision making</li> </ol>

## IMPLEMENTATION

In this section, the hardware and software components used in the system for the transformation are described. The code used for this integration is also openly available on github (Zandi n.d.). The software is installed on a Unix based Raspberry Pi (Raspberry Pi n.d.). Different agents are implemented and running using VOLTTRON as a platform such as Device Agent, Historian Agent, etc. Each of these agents provides various services and can coordinate its decision based on other agents. Device Agent is responsible for monitoring and controlling devices running different communication protocol such as Wi-Fi, CTA- 2045 (CTA- 2045 n.d.), etc. An intelligent agent is responsible for goal-based scheduling and notifying appropriate devices. DR agent is responsible for communicating with the utility and Historian Agent is responsible for data storage and retrieval. Each agent can publish information on the message bus or subscribe to specific topics of its interests published by others (See Figure 1).

The HEMS location is dependent on the mechanism used for the transformation. If the HEMS Restful API is used for the integration, then the HEMS can be located anywhere. If the transformation is done using a local MQTT broker, the HEMS should be connected to the same router as the VOLTTRON. Also, the MQTT broker used for the transformation should also be connected to the same router as other software pieces. The result of the HASS-VOLTTRON integration can be seen in Figure 2.

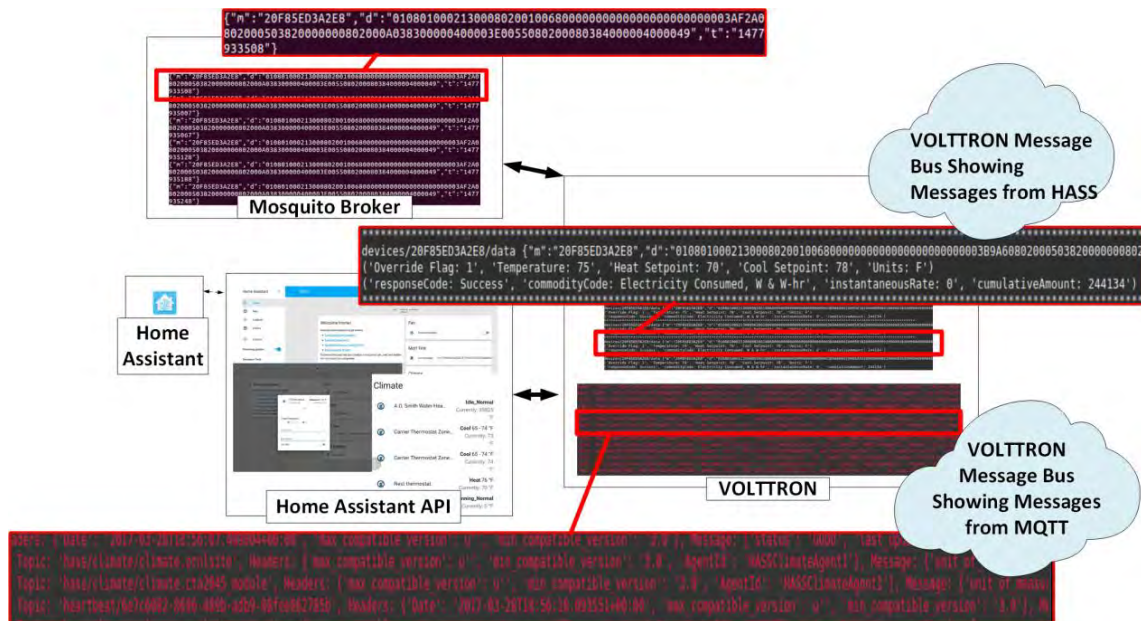

Figure 2- HEMS-VOLTTRON integration information flow

## FUTURISTIC USE CASES

While there are a number of opportunities to utilize loads to support traditional demand response load shedding requests, these are already often imbedded in a HEMS without the need of a more sophisticated MAS. MAS offers the ability to implement smart agents to provide more complex optimization and bidding strategies that are not available in today's HEMS. For example, three different use cases of more advanced grid functions are provided in Table III. These use cases provide a demonstration of more sophisticated functions that

require utilities to enable device communications under a common framework. A HEMS supporting MAS has the opportunity to perform the appropriate decision making and control.

Table III. Grid Use Cases

Use Case	Description
1. Reduce Critical Peak Load	<p><u>Goal:</u> Reduce load during critical price period.</p> <p><u>Method:</u> Data is collected from each device by separate Device Agents and archived by the Historian Agent. A separate DR Agent assesses the current status of the loads and reports this information to utility distribution management system (DMS). The DMS performs an assessment of the data and estimates the needed overall load reduction. These reductions are issued to the DR Agent which sends control commands to the respective Device Agents and ultimately to the loads.</p>
2. High Penetration of Renewable Energy in Distribution Systems	<p><u>Goal:</u> Reduce voltage impact by renewable generation.</p> <p><u>Method:</u> Data is collected from each device by separate Device Agents and archived by the Historian Agent. A separate DR Agent assesses the current status of the loads and reports this information to utility distribution management system (DMS). The DMS performs an assessment of the data and estimates the needed overall change in load to support PV. The DMS issues the load change to the DR Agent which sends control commands to the respective Device Agents and ultimately the loads.</p>
3. Residential Resiliency through Islanding.	<p><u>Goal:</u> Improve residential resiliency with local energy storage and islanding features.</p> <p><u>Method:</u> Data is collected from each device by separate Device Agents and archived by the Historian Agent. A separate DR Agent assesses the current status of the loads and reports this information to utility distribution management system (DMS). The DMS performs an assessment of the current grid reliability and provides the DR Agent information regarding outage potential. Upon expected outage, the DR Agent issues islanding request to the energy storage Device Agent which is forwarded to the local energy storage system.</p>

## CONCLUSIONS

In this paper, a general framework for integrating a multi-agent-system (MAS) into a home energy management system (HEMS) is proposed. MAS offer additional functionalities and decision making that go beyond the IFFT (if this then that) functionalities present with HEMS today. Two different communication methods between the MAS and HEMS are explained. One communication approach utilizes the RESTful API while the other demonstrates a MQTT broker approach. The MQTT local communication approach is demonstrated in the results. These communication schemes can be applied to any existing system regardless of the programming language implemented.

Besides addressing the interoperability challenge by supporting multiple pathways for communications, this work demonstrates a broadening of intelligence into the HEMS. The addition of an agent-based infrastructure provides new pathways and use case functionalities. In this paper, three utility-based use cases utilizing residential assets such as HVAC, water

heater, energy storage, and PV are discussed. These use cases include: reduction in critical peak load, high penetration of renewable energy in distribution systems, and residential resiliency through islanding.

### **ABSTRACT**

Overall, holistic approach in which the building is integrated into its environment with respect to building physics principles allows for discussion of a variety of passive strategies regarding the building placement (local climatic conditions, microclimate etc.), building types, building materials and technical systems. Bioclimatic design is referred to as a proper approach to highlight the connection of a building with the natural environment, which can be treated as the prerequisite for energy efficient design.

The research results within the reliability studies of building performance become an inspiration for architects and engineers to further discuss tools supporting decisions at the early stage of design process from the reliability perspective. The bioclimatic tools allowing for interpretation of the sense of comfort as a variable dependent on the variability of climatic conditions, and human factors are suggested for the analysis at the early stage of building design. A framework for the probabilistic analysis of comfort performance to be included in bioclimatic design tools is proposed.

The uncertainty of the variables and unknown parameters are critically (qualitatively) examined. Further research is needed to quantify the uncertainty of the boundaries of the comfort caused by the variability of climatic conditions and the uncertainty of human perception of comfort.

### **KEYWORDS**

Bioclimatic design, uncertainty, passive strategies, thermal comfort, reliability.

### **INTRODUCTION**

Low-energy building design, ensuring comfort and safety in built environment, addresses mainly the following three sustainability goals as propagated by United Nations: number 3 – good health and well-being, number 7 – affordable and clean energy, and number 13 – climate action. ‘Energy is the dominant contributor to climate change, accounting for around 60% of total global greenhouse gas emissions’. Reducing the carbon intensity of energy is a key objective in long-term climate goals (goal 13). Hence, choosing a strategy based on integrating the building form and structure with its external environment to take advantage of natural forces (for wind induced ventilation, solar heating, etc.) is an example of design decisions leading towards mitigation of climate change (Pietrzyk & Czmoch 2018). It also promotes using affordable and clean energy (goal 7). Considering uncertainties coupled to climate and comfort conditions will give the chance to make the design process more reliable in achieving good health and well-being in built environment (goal 3).

To encourage architects to consider the passive design strategies to contribute to comfort and health in buildings, tools are needed. Such a tool could be a bioclimatic chart (Givoni 1998) which shows the relationships between climatic parameters (temperature, humidity) and a comfort zone. Introducing certain design solutions (lightweight construction or thermal mass,

natural or mechanical ventilation etc.) does influence the location of the boundaries of the climatic conditions within which the building design can provide interior comfort (Szokolay 2004). Some pedagogically described examples can be found in (Manzano - Agugliaro 2015) and the comfort boundary (in blue) of enhanced ventilation is shown in Figure 3. Significant research has been carried out within the field of thermal comfort in building resulting in the formulation of adaptive criteria that have been included in the International Standards such as ANSI/ASHRAE standard 55 (2013). However, the boundaries of the comfort zones do not include explicitly their uncertainty associated with human behavior (especially its psychological and cultural aspects) and the higher frequency of variability of climatic conditions. The discussion about the variability of comfort performance can be found in (Tuohy et al 2009; Humphreys et al 2013). For an architect it is important to design for the client representing a group of potential users. The uncertainty in human perception should be treated separately from the variability of climatic conditions. Within human perception physiological, behavioral and psychological requirements should be accounted for.

It is proposed to take into consideration the above uncertainties to elaborate on the uncertain boundaries of the adaptive comfort zone using uncertainty/risk analysis tools.

### **Architectural approach – climate as a generative principle for built form**

Bioclimatic approach is not very common in the architectural practice. It seems to be still more related to the traditional architecture and certain climatic zones. One can also find the contemporary designs driven by the philosophy of ‘form follows climate’ where climate is given a generative roll for built form for ex. the houses designed by Philippe Rahm Architects (Rahm 2007).

Rahm creates spaces with stratified level of humidity to be occupied freely according to the weather and the season (Mollier’s house). Activities in the rooms are related to the climate existing in the different parts of the house. It means that functionality is secondary to the climate generated form. In that way the problem of building physics is transformed into an architectural question. Another example is Archimedes’s house designed as a vertical structure reflecting a relation between the house and the air, its temperature and its movement. The various temperature of interior spaces driven by the seasonal changes allow for the seasonal movement of the occupants within the house (migrations from downstairs to upstairs according to the vertical stratification of the temperature). In that way the functionality and the interior conditions are specified as different for various rooms. Those examples show how architect can be inspired by the opportunities created by nature. However, his philosophy can result in infinitely extended comfort zone.

Anyway, this kind of examples could suggest that bioclimatic chart is a good inspiration and communication tool for architects at the early stage of a design process promoting sustainable solutions. During the last 5 years new software became available to support climatic/environmental design based on bioclimatic tools (Climate Consultant, Grasshopper etc.). Starting design brief from the analysis of space in terms of bioclimatic parameters has been also appreciated by the students of architecture studying Building Climatology for Sustainable Design course at Chalmers University of Technology.

## **METHODS AND RESULTS**

**Communication of building climatology principles to support architect decisions at the early stage of design.**

A design process promoting passive strategies should be supported by knowledge and analysis tools from different fields of building climatology (climatology, building physics, physiology/psychology and architecture). Climate is treated as a resource supporting natural ventilation, free cooling, and free heating. Results of the analysis of the climatic/environmental conditions could be synthesized and adapted to architectural expression. In that way, 'architecture can mediate the design with the goals of sustainability' (Brennan 2011).

Designed object offers passive and active controls over the interior climate according to the comfort requirements. A passive control creates an extra climate-comfort loop (see Figure 1).

Figure 1 Bioclimatic thinking at the early stage of the design process – systemic approach; modified from (Pietrzyk 2015).

*Climate*: climate, local climate, microclimate (temperature, moisture content, wind speed, wind direction) in view of uncertainty (Pietrzyk & Czmoch 2018)

*Control*: materials (strengths and vulnerabilities), components, structures form and orientation, technical systems, topography, urban design, wind/surface interaction etc.

*Comfort*: uncertain adaptive comfort zones within enclosure extended by using passive or hybrid strategies of heating, cooling, and ventilating

Architectural criteria include the site of the building (also in urban context), the local environment being the result of feedback loop between natural and man-made elements, and the building orientation, form, layout/volume, material (see Figure 1). The criteria account also for integration of technical systems within building/environment system considering potential of the system to use locally produced renewable energy. The concept could be extended to include the user perception as a variable dependent on the climatic conditions and the design solution. A systems approach provides proper theoretical tool for the analysis of the interrelations between structure, its environment, and its performance. Use of bioclimatic chart (psychrometric chart with comfort zones) in the early stage of design process is considered. It can be considered as a means of raising awareness of the integration of a range of environmental and design parameters. The concept of bioclimatic design has been proposed in (Olgyay 1953) and further developed (see Givoni 1998, Szokolay 2004, etc). The comfort zones refer to both seasonal climatic conditions and the traditional living style (clothing and the level of activity), see Figure 2. It is proposed to consider the relevant variables evaluated for local conditions and to elaborate on the uncertain comfort zone due to cultural/psychological and climatic aspect. In that way comfort zone could be treated as a dynamic concept addressing users' perception related to the local climatic conditions, habits, behaviors, and the level of possible control.

The bioclimatic chart showing the properties of moist air is built on the analysis referred to the perfect gas relations. It could be the valuable visual aid for architects in analyzing different solutions at the early stages of the design process. First the local climate conditions

are collected in the form of averaged values over the period of hour, day or month. Then, the analysis of the neighborhood results in the microclimatic characteristics that are superimposed on the chart. The relation between the outdoor climatic conditions and the required interior conditions gives the indication about the passive/active strategies that could be designed for.

Figure 2 Bioclimatic chart with superimposed boundaries of climatic zones: temperate climate, summer - solid line; hot climate – dashed line from (Givoni 1998) modified from the psychrometric chart from Wikipedia

Building physics tools based on the rough modeling or/and qualitative evaluation are proposed to give the preliminary answers about the potentials of the building/environment system performance. The structure/environment interaction based on the source free enclosure (for example estimation of free running temperature – the temperature inside a naturally ventilated building without any heating source) accounting for wide boundary conditions could give the first evaluation (Ghiaus & Allard 2003). These results will constitute the reference for the qualitative tools developed based on psychrometric chart.

The boundaries of the comfort zones should be modified to visualize different design strategies directed to different groups of end-users. It is meant to be used as a communication tool at early stages of design

### Boundaries of a comfort zone – a probabilistic approach

While evaluating a building performance the very important issue is to find criteria to differentiate between good and bad performance. A critical state dividing the space of the possible results into two subspaces the reliable one and the failure one is related to the performance criterion relevant for the chosen performance aspect. The critical state can be defined by a deterministic value, or by probability distribution function assigned to that parameter. The way of presenting performance criterion depends on the investigated problem and availability of data. Stochastic threshold criterion is built up because of the uncertainties regarding the climatic conditions or humans response (Pietrzyk 2008, Pietrzyk 2015).

Generally, variability in time, space, and among individuals can be included in the performance criterion  $R$  (see Figure 3). The chosen kind of variability depends on the performance aspect considered. In current case the performance aspect is the interior thermal comfort that can be presented in terms of temperature (sensible or operative). When considering the response of people to a certain state described by a physical parameter

(temperature), inter-individual variability in the form of the number of people being affected can be included in stochastic threshold. Variability among individuals in the response to specified interior conditions are caused by their different physical and behavioural conditions. Hence, a criterion for human's wellbeing can be stated for the population, specified group of people or for the individuals depending on the client group in focus, in the form of estimated for the group probability density function (uncertainty is represented by probability). Then, the general standards-based design or client controlled (adapted) design responding to the needs of target group can be considered.

Figure 3 shows the framework for the probabilistic analysis of thermal comfort performance. The results are proposed to be included in the description/communication of the comfort zones in terms of reliability. Reliability is understood as a complement to the probability of failure (P) as given in Figure 3.

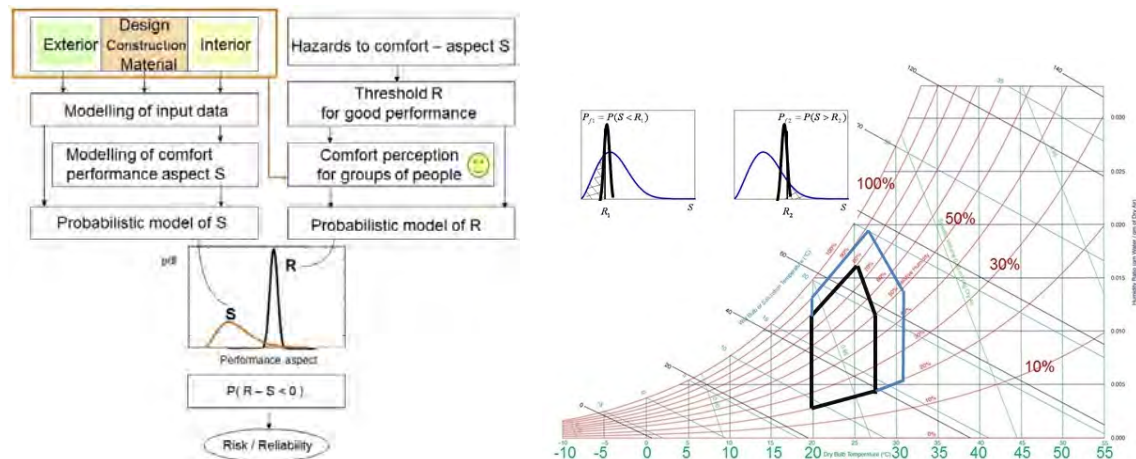

Figure 3 Framework (modified from (Pietrzyk 2015)) for the probabilistic analysis of comfort performance proposed to be included in the description/communication of the comfort zones: for temperate climate – black line: extended comfort zone because of ventilation – blue line. (Psychrometric chart modified from Wikipedia using data from (Manzano - Agugliaro et al 2015)).

Outdoor temperature is an important variable for the boundaries of the adaptive thermal comfort. They are given for each month by the regression equations characterizing lower and upper limits of the comfort zone. Those uncertain limits could be revised with the help of analysis of uncertainties coupled to the probability distribution of outdoor temperature (variability of S) as well as by analyzing the possible contribution of differences in perception/adaptation of various groups of people (variability of R). Eventually, the reliability of the stated boundaries would be estimated to be used in the design process.

Other thermal performance indicators like PPD (percentage of dissatisfied people) or allowable excess of operative temperature in offices could be used to estimate the uncertainties of thermal comfort performance R (Pietrzyk 2008).

## CONCLUSIONS

The purpose of this paper is to elaborate on a reliable visualization tool based on bioclimatic approach that architects could use to effectively follow the strategies of passive environmental design of low energy, comfortable and healthy buildings. Climate is treated as a resource supporting natural ventilation, free cooling, and free heating. The theory and methods of the interdisciplinary field of building climatology (climatology, building physics,

physiology/psychology and architecture) are addressed. The performance aspects (air exchange, heating or cooling load, comfort indicators, etc.) are treated as random, as they are dependent on the random climatic characteristics and uncertain human perception. It is proposed to introduce to the bioclimatic chart the reliability of the boundaries of the adaptive comfort standard dependent on target group's perception. The paper presents only an idea that must be further developed. Research is needed to quantify the uncertainty of the boundaries of the comfort zones in relation to various passive strategies. Different thermal comfort standards and thermal comfort indicators could be considered.

### **ABSTRACT**

Unmanned Aerial Systems (UAS – a.k.a. drones) have evolved over the past decade as both advanced military technology and off-the-shelf consumer devices. There is a gradual shift towards public use of drones, which presents opportunities for effective remote procedures that can disrupt a variety of design disciplines. In architecture praxis, UAS equipment with remote sensing gear presents an opportunity for analysis and inspection of existing building stocks, where architects, engineers, building energy auditors as well as owners can document building performance, visualize heat transfer using infrared imaging and create digital models using 3D photogrammetry. Comprehensive energy audits are essential to maximize energy savings in buildings realized from the design and implementation of deep retrofits for building envelopes, together with energy system repairs or changes. This paper presents a methodology for employing a UAS platform to conduct rapid building envelope performance diagnostics and perform aerial assessment mapping of building energy. The investigation reviews various literature that addresses this topic, followed by the identification of a standard procedures for operating a UAS for energy audit missions. The presented framework is then tested on a university campus site to showcase: 1) visually identifying areas of thermal anomalies using a UAS equipped with IR cameras; 2) detailed inspection applied to areas of high interest to quantify envelope heat-flow using computer vision techniques. The overall precision and recall rates of 76% and 74% were achieved in the experimental results, respectively. A discussion of the findings suggests refining procedure accuracy, as a step towards automated envelope inspection.

### **KEYWORDS**

Unmanned Aerial System (UAS); building Inspection; retrofitting, energy audit; thermography

### **INTRODUCTION**

The buildings sector accounts for about 76% of electricity use and 40% of all U.S. primary energy use and associated greenhouse gas (GHG) emissions. More than half of all U.S. commercial buildings in operation today were built before 1970 and this large existing building stock performs with general lower efficiency. HVAC and lighting loads in existing buildings consume 35% and 11% of total building energy, respectively, which totals more than 17 quads of residential and commercial building primary energy use (U.S. DOE, 2015). In order to achieve substantial energy savings in existing and deteriorating built environments, retrofitting strategies that respond to accurate and reliable energy audits should to be implemented. Unfortunately, predicted savings and delivered savings typically do not match. This can be attributed to imprecise energy audits, which may lead to lower than expected

energy savings, no energy savings or in some cases occasional increase in energy use. A myriad of negative effects follow, including environmental impacts that were not accounted for, discrediting energy efficiency retrofits as well as loss of investment monies. This is typically a result of many challenges that energy auditors face, including insufficient building information that leads to misrepresentation in energy models, overestimated savings, ineffective selection of improvement strategies and incomprehensive improvement scope that result in missed improvement opportunities (Shapiro, 2011). In this paper, we present a methodology to address these critical challenges by employing a UAS platform. More specifically, we employ a drone equipped with a thermal camera, to conduct rapid building envelope performance diagnostics and perform aerial assessment mapping of building energy. The paper aims to identify standard procedures for operating a UAS for energy audit missions, and to automate the envelope assessment method using computer vision algorithms.

Previous research work addressed the use of UAS and thermography in building inspection, diagnostics and energy audits. An earlier attempt by Martinez-De Dios and Ollero presented infrared-based automated detection techniques for thermal heat losses in building windows using UAS (Martinez-De Dios and Ollero, 2006). The use of impulse infrared thermography was introduced by Mavromatidis et al (2014) as a method to examine old civil infrastructure and residential buildings' energy consumption, ageing process and life cycle. A more comprehensive method to reduce manual workflows was introduced by Mauriello and Froehlich (2014). It utilized an unmodified Parrot AR. Drone 2.0 and a FLIR thermal camera to collect RGB and thermal images of a building and generate 3D reconstructions. Automation challenges were further presented, which included data quality, data overload, technical feasibility, privacy and problems of overreliance on automated scans (Mauriello et al, 2015). While UAS platforms were used in various building inspection activities, a comprehensive building envelope inspection procedure was not engaged. We aim to address this gap in the literature by presenting a twofold approach to the inspection of building envelopes: 1) using a geometric data-gathering process, tested in the field, and 2) a computer vision analysis approach for the automation of envelope anomaly detections.

## METHODS

The research framework is divided into two methods. First, the design of flight paths and implementation of data collection using photogrammetry and thermal imaging. Second, the use of computer-vision workflows to analyse and segment thermal images, and autonomously detect thermal anomalies.

### Energy Audit Flight Procedure

*Preflight considerations:* Energy leakage detection relies upon certain environmental conditions. Local climatic factors, such as rain, snow, and heavy wind are not typically appropriate weather conditions for drone flight. Certain environmental factors that can affect external surface temperatures of buildings such as indoor and outdoor temperature, humidity, wind speed, cloud coverage, solar radiation, and precipitation are considered. A temperature difference of about 10° Celsius, as well as a notable pressure difference should be observed between the interior and exterior of the building. (FLIR, 2012).

*Flight path design:* There are two common flight paths that can be adopted for the majority of typical buildings. For flat facades which are mostly vertical, the flight path should begin on a predetermined corner and follow vertical bays upward, move across to the next bay and downward. For flat facades that are mostly horizontal, the path should begin at a predetermined corner and continue to the right before moving up a bay and continuing in a

linear manner to the left. After capturing façades, the drone should move on to capture thermal images of the roof in a similar grid manner, starting from one corner and moving in either a horizontal or vertical pattern along a superimposed grid, until the entire roof has been captured (Eschmann et al, 2012). Based on empirical experimentation and a brief review of the literature, we propose a general distance of 20' away from a building, at changing bay heights of 7-10', with imaging gathered approximately every 5' along the flight path.

*Post-flight analysis:* Gathered data should include pre-flight environmental conditions, pre-flight interior conditions, IR images or videos, and corresponding non-thermal images or videos. The primary goal of drone-based energy audits is to visually identify thermal leaks and support these claims with temporal data extracted from the images (Lee and Ham, 2016). We hypothesize that the following building envelope issues can be identified in post-flight analysis using the designed procedure: 1) Exfiltration / infiltration, 2) Missing / deteriorating insulation, 3) Thermal bridges and 4) Regions of failure (cracks, etc.)

### Computer Vision Algorithms

Our computer vision framework for heat leakage detection is composed of two stages: 1) A global lookup of a thermal image and 2) edge filtering and segmentation, where the actual leakage regions are identified. The detection framework assumes that a thermal anomaly is defined as regions where sudden or abnormal temperature changes happen in the thermal image. When an expert inspects a color-mapped thermal image which is taken outdoor during a cold winter season, she/he observes the leakage as a light (cold) region surrounded by darker (hotter) regions. Therefore, the main concept behind the detection algorithm is to find a sharp temperature change on the thermal image.

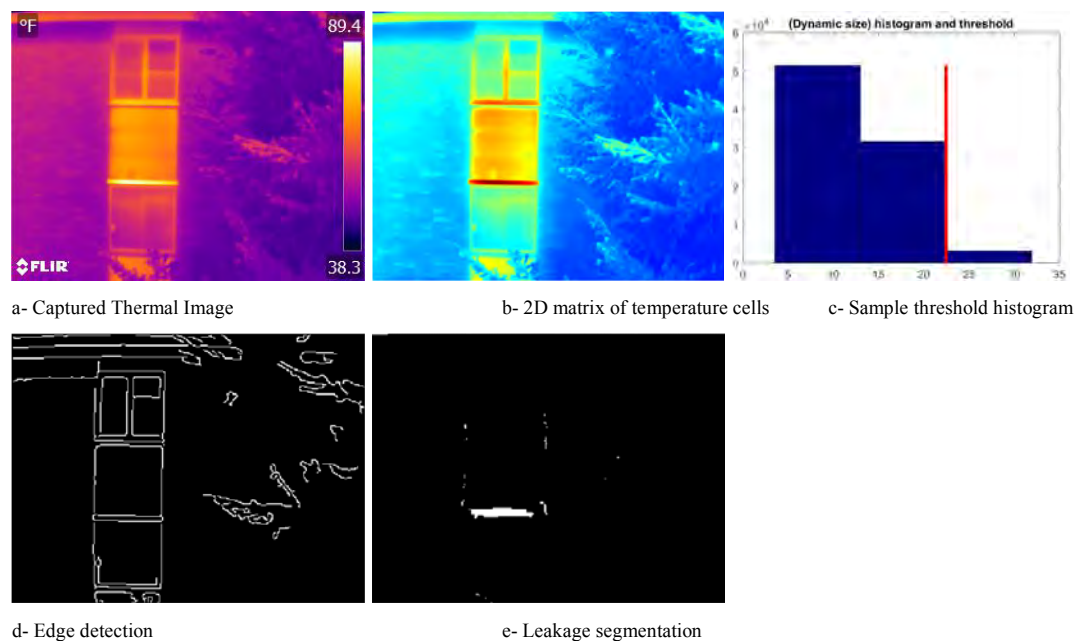

Figure 1. Edge processing and analysis of a sample thermal image.

In this framework, a thermal image is considered as a 2D matrix, whose cells, i.e. pixels, are temperature values. A naïve solution to segment out the heat leakage regions would be seeking “hot-enough” pixels (in winter, for outdoor images) and label them as leakage pixels. However, this approach is expected to introduce multiple false positive results, since this kind of strong, pixel-wise separation simply detects hot regions without taking any distinctive

characteristic of heat leakages into account. We observe that sharp temperature changes on a single-layer thermal image could be explained as nothing but thermal edges, which can possibly be the contours of leakage regions, and thermal anomalies are regions which have thermal edges. Consequently, by detecting those edges, anomaly regions would be segmented out. However, this argument is also not always true, since not all the edges found on thermal images are edges of leakage regions. For instance, red regions in Figure 1-b represent window leakage, and an edge detector would separate those regions. Yet, there are other visible edges, which will be detected on the same image such as trees as seen in Figure 1-c. Therefore, in our framework we eliminate those false detections, and eventually segment out the leakage regions by detecting edges, following them, and applying region growing.

### Experiment Design

For this study, a proof-of-concept experiment was designed by the research team to inspect a cluster of dormitory buildings at a university campus in the United States. The team used a DJI Inspire 1 drone paired with a FLIR Zenmuse XT thermal camera. The accompanying DJI app was used during flight to monitor the thermal data. The flight path was predetermined and automated using the Pix4D app, and the images were processed and analysed using the FLIR Tools program. Figure 2 illustrates the flight path and data gathering processing for computer-vision analysis.

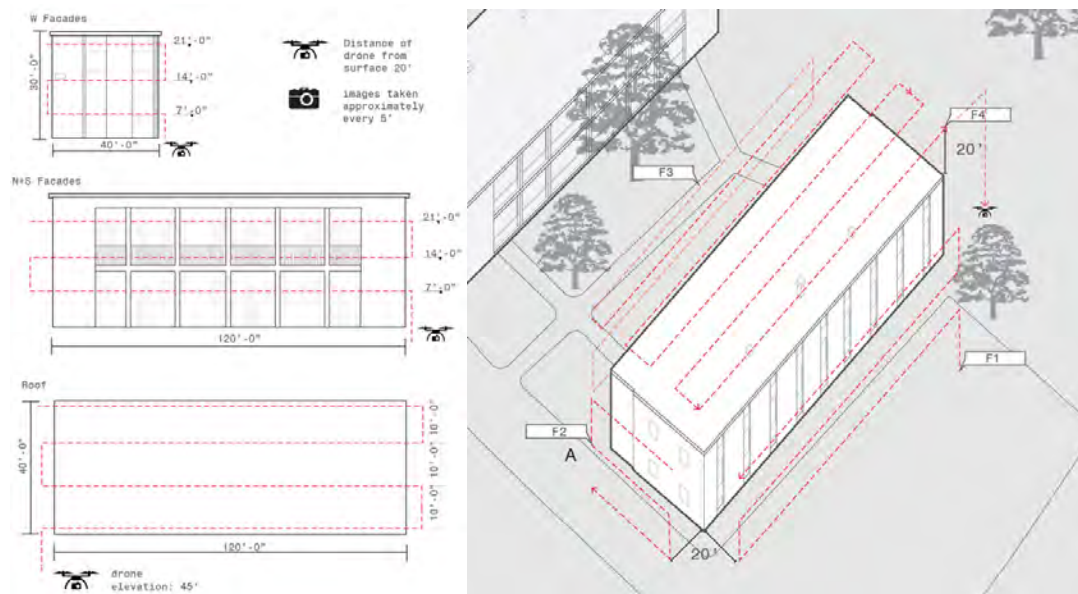

Figure 2. The experiment flight path and imaging procedure.

## RESULTS

### Building Envelope Audit

The audit flight took place on two separate days, the first day inspected 3 buildings using 3 batteries taking infrared video, and the second flight inspected two buildings taking still pictures. Building D was not fully inspected due to the proximity of trees on the southern façade as well. Each flight date was undertaken in 90 minutes. Figure 3 showcases 5 major categories of audit results that include: Rust – showcased through deterioration in the building façade. Water damage – infiltration and puddling of water on the roof at seams. Thermal bridges – due to faulty construction practice while installing roofs. Penetration – malfunction of envelope integrity (in façades and roofs). Brickwork deterioration – at openings and penetrations in the façade.

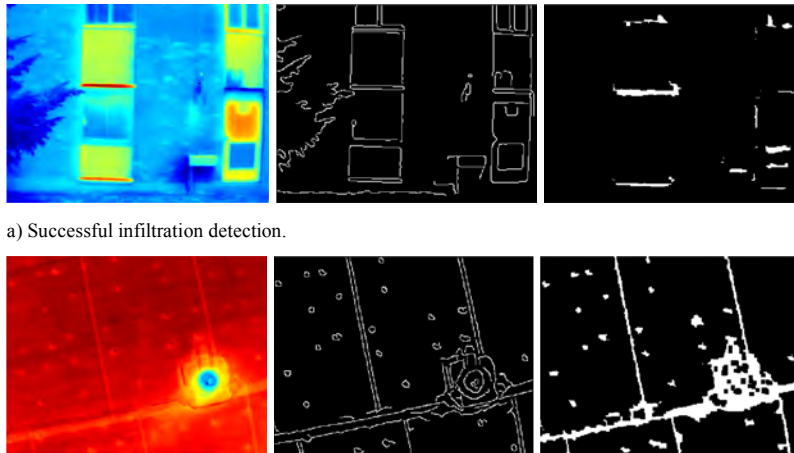

Figure 3. Sample results from building envelope audit.

### Thermal Anomaly Segmentation

We tested the developed algorithm on 149 thermal images that contain a total of 1018 heat leakage regions. From these leakage regions, the algorithm successfully detects 751 of them, and missed 267 actual thermal anomaly regions. The workflow also reported 237 regions that are considered false positives. This resulted in precision and recall rates of 76% and 74%, respectively. These rates will increase as the algorithm is further developed to match expert identification of anomalies. Figure 4 highlights a series of sample heat leakage images and their corresponding detection results.

a) Successful infiltration detection.

b) Successful thermal bridge detection.

Figure 4. Experimental results from various sides of the inspected buildings. In each triplet, the left are IR scenes, middle are edge detection, and right are the segmented leakage regions.

### DISCUSSION

The framework is presented as a workflow for building envelope diagnostic missions that would be administered by auditors to fly the UAS, which allows the use of thermal imaging for structural inspection, heat losses, infiltration, insulation conditions, glazing performance, as well as giving access to challenging to reach situations such as the roof. The proposed solution is being tested as a proof of concept that will significantly reduce the number of hours spent to produce high-quality, large-scale audits. Currently, an auditor may choose a repetitive pattern in a building envelope and assume that the performance is the same for all similar parts of the skin. The developed approach allows for comprehensive and accurate assessment with no such assumptions.

## CONCLUSION

In regard to architectural practice, UAS equipped with thermal cameras present a unique opportunity for building inspection and more specifically, building energy auditing. The use of UAS in conjunction with building inspection and energy audits is ideal for a market saturated with degrading and energy inefficient infrastructure. In this paper, we presented an inspection framework that employs a developed computer vision algorithm to autonomously detect thermal anomalies. The ultimate goal is to enable assessments of entire campuses, neighborhoods and cities and map their energy performance accurately for identification of potential energy savings through retrofitting strategies.

## ACKNOWLEDGEMENT

This publication is based on work funded in part by Gryphon Sensors, Syracuse University's Office of Research (Grant #SP- 29403-2), the Campus as a Lab for Sustainability program at Syracuse University, the National Science Foundation (NSF) under CAREER grant CNS-1206291, NSF Grant CNS-1302559 and NSF Grant 173978. The authors would like to thank Mr. Ian Joyce, the Center for Advanced Systems Engineering (CASE) and the Center of Excellence at Syracuse University for data gathering and faculty development support.

## **Optimal Control Strategies for Passive Heating and Cooling Elements Reduce Loads by Two-Thirds in the Adaptive Reuse of a San Francisco Bay Area Office**

### **ABSTRACT**

Housing crises in urban centers and growing climate concerns are encouraging city planners and building owners to explore the conversion of commercial buildings into energy-efficient dwellings. Passive solar heating, shading, and natural ventilation are attractive in such adaptive reuse projects since they minimize operational energy, but they suffer from the perception of limited effectiveness, and passive heating is often disregarded entirely in cloudy climates. At the same time, passive heating has recently shown promise in the cloudy winters of western Oregon and upstate New York, allowing the San Francisco Bay area to provide an excellent opportunity for further exploration. Passive cooling measures, in turn, are essential to prevent overheating. This work investigates the conversion of a brick office space in Berkeley, CA into a residential loft, using movable insulation, operable windows, thermal mass, and shading to diminish the need for mechanical conditioning to the extent possible. To determine this extent, preliminary explorations in EnergyPlus were followed by Hooke-Jeeves and particle-swarm optimizations of control thresholds, following field-validated techniques for passive heating and cooling simulation. Optimized parameters included skylight tilt; schedules for movable insulation, shading, and natural ventilation; and thermal mass quantity, each required to minimize annual sensible heating and cooling energy while maintaining adaptive thermal comfort. With optimal control, over half of the heating need could be met by passive solar collection and storage; likewise, most cooling (~80%) could be accomplished passively if shading and natural ventilation were well-controlled. Without these controls, most of the benefit was lost. We therefore propose replacing the term “passive” with “well-controlled passive” to reflect the importance of controls in sensing conditions and adjusting movable elements to maximize the performance of these systems.

### **KEYWORDS**

passive solar heating; passive cooling; controls; optimization; adaptive reuse

### **INTRODUCTION**

The U.S. population devotes one-tenth of all energy consumed to the active heating and cooling of living spaces in buildings. This considerable quantity—nearly 10 quadrillion Btu per year—is derived largely from fossil fuels, emitting an estimated 500 million metric tons of CO<sub>2</sub> each year (EIA 2018). As climate concerns increase the pressure to design buildings with smaller carbon footprints (e.g. Nejat 2015), passive heating and cooling systems are regaining interest (Chan 2010), building on historic technical and conceptual explorations (e.g. Olgyay 1963; Givoni 1969) as well as centuries of vernacular development. Operable elements are often essential to passive systems, and recent efforts have compared operational strategies in natural ventilation (Schulze 2013), night ventilation of mass (Santamouris 2010), and shading (e.g. van Moeseke 2007), showing that controls can greatly improve their effectiveness. Numerical optimizations have also been applied to passive heating and cooling systems to inform choices of glazing orientation and type, wall composition, overhang depth, ventilation rate, etc., reviewed by Stevanović (2013). While these efforts have considered the presence vs. absence of operable elements

Figure 1. **Existing building** in (a) section and (b) plan, showing areas of investigation in orange, thermal mass in heavy dashes, and movable insulation in fine dashes.

as optimizable parameters, control thresholds have been pre-established in each case. To our knowledge, only Rempel (2015) has previously optimized threshold values themselves, and then only for cooling, without lower temperature limits. This work expands upon those findings by optimizing thresholds for passive heating and cooling simultaneously, incorporating upper and lower comfort limits throughout the year to predict the heating and cooling energy savings possible by these means. The renovation is planned for late 2018, and energy use will be monitored closely afterward, with the ultimate goal of providing compelling evidence that well-controlled passive systems have excellent performance potential in the Bay Area and similar climates.

## METHODS

Simulations were conducted in EnergyPlus v8.7; windows and skylights were modeled in WINDOW 7.6 and referenced by EnergyPlus. Sensible heating and cooling loads were met by an Ideal Loads Air System, controlled by an adaptive comfort thermostat (Fig. 2a), to eliminate effects of mechanical system efficiency. Optimizations were conducted in GenOpt 3.1.1 using Hooke-Jeeves and particle-swarm optimizations for continuous and discontinuous variables, respectively, minimizing the annual sum of sensible heating + cooling energy.

Table 1. Baseline conditions and changes investigated

Parameter	Baseline Condition	Changes
Floor area	98.25m <sup>2</sup>	-
Orientation	17° W of true south (i.e. 197°)	-
Roof assembly	Bitumen membrane o/ 75mm insul. board o/ 13mm pwd sheathing o/ 154mm batt insul. o/ 16mm gypsum board	-
Wall assemblies	N, S: adiabatic (party walls); E, W: 330mm solid brick (exterior); Porch: wood siding o/13mm pwd sheathing o/ 154mm batt insul. o/13mm pwd o/16mm gypsum board	-
Floor assembly	25mm Douglas fir o/19mm wood subfloor o/154mm batt insul. o/19mm gypsum board o/conditioned space	-
Thermal storage mass	None except for exterior brick walls	Mass wall
Window assemblies	E, W: Double clear, wood frame (7.8m <sup>2</sup> , 1.0m <sup>2</sup> ); W porch: Double, alum. (3.9m <sup>2</sup> ); Sm skylights: Single, alum. (0.74m <sup>2</sup> )	-
Skylight assembly	Acrylic dome, 7.2m <sup>2</sup> : T <sub>vis</sub> =0.53, SHGC=0.5, U=3.2 W/m <sup>2</sup> K	Glazing, tilt
Movable insulation	None	Material, schedule
Infiltration	0.75 ACH	-
Natural ventilation	Operable E, W windows (2m <sup>2</sup> ); operable skylights (2m <sup>2</sup> )	Temp. thresholds
Shading	None	Schedule
Internal gains	People = 2 adults; lighting power density = 1 W/m <sup>2</sup> ; equipment power density = 1 W/m <sup>2</sup>	-

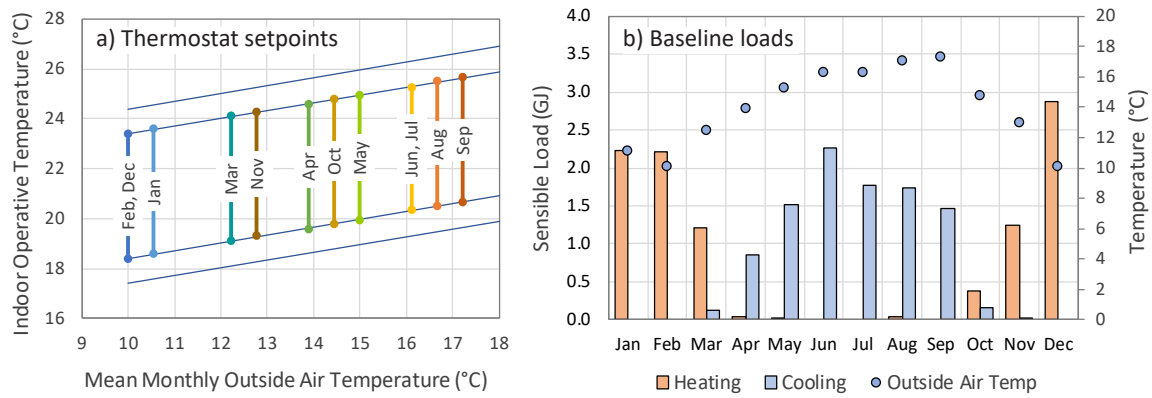

Figure 2. **Thermostat setpoints and resulting heating and cooling loads.** (a) Monthly heating and cooling setpoints, corresponding to the bounds of 90% acceptability in the adaptive thermal comfort zone (ASHRAE 2017); (b) Monthly sensible heating and cooling energy needed to raise or lower baseline-configuration air temperatures to thermostat setpoints.

## RESULTS

The baseline building configuration (Fig. 1, Table 1) required 20.1 GJ of sensible heating and cooling energy annually to maintain conditions within the 90% acceptability limits of the adaptive thermal comfort zone (ASHRAE 2017), distributed between a heating season of October-March and a cooling season of April-September (Fig. 2b). Due to the large unshaded skylight, window heat gains were the greatest contributor to monthly cooling loads (Fig. 3), while infiltration and window heat losses contributed most to monthly heating loads. Because heat-recovery ventilation is generally not cost-effective in this climate, the infiltration target of approximately 0.75 ACH, consistent with provision of fresh air for four people, was not changed.

The first revision replaced the skylight's light-diffusing dome with double-clear uncoated glass ( $SHGC=0.67$ ;  $U=3.5\text{W/m}^2\text{K}$ ;  $T_{vis}=0.72$ ), tilted  $40^\circ$  above horizontal to receive the greatest possible solar radiation during the six-month heating season as estimated by the model of Perez (1990) (Fig. 4). This change did not in itself appreciably diminish the heating load, since thermal mass and movable insulation were not yet present to retain collected heat, but its effects were apparent in subsequent steps (Fig. 7a), and optimally-tilted glazing is generally necessary for excellent passive solar performance when cloud cover is a factor (Rempel 2013).

The second revision added movable insulation ( $k=0.03\text{ W/mK}$ ) and shading ( $T_{vis}=0.3$ ) to all glazing, reflecting the choice of inexpensive, physically manageable, commercially-available materials.

Figure 3. **Heat gain and loss pathways in the baseline configuration**, with prominent heat gains through the existing skylight and heat losses through windows and infiltration.

Figure 4. **Optimal tilt for solar-collecting glass**, shown by incident solar radiation during the heating season on surfaces of varying tilt to be approximately 40° above horizontal.

GenOpt was then used to find optimal hourly schedules for activation and retraction. Results showed, consistent with intuition from decades ago but contrary to recent assumptions (Stevanović 2013, van Moeseke 2007), that movable insulation was optimally activated hours before sunset in many months and often remained in place hours after sunrise; specific uninsulated hours depended on solar radiation utility (i.e. greater in Jan. than in Oct.) and heat loss vulnerability (i.e. greatest on Dec. mornings) (Fig. 5). Shading, similarly, was optimally activated well before the day's hottest hours and optimally retracted well before sunset, remaining retracted all night to promote cooling from glazed surfaces (Fig. 5). Together, these reduced the original heating load by about half and compensated for the cooling load introduced by the new skylight (Fig. 7a).

The third revision added thermal mass in the form of a brick wall north of the skylight (Fig. 1); its thickness was optimized alongside movable insulation and shading schedules due to strong interactions among these elements (Rempel 2015), yielding a final value of 25cm. The mass reduced annual loads only modestly (Fig. 7a), suggesting that seasonally-adjustable thermal mass (i.e. water or potted plants) should be explored. The fourth revision, in turn, sought optimal temperature thresholds, shown to be more effective than hourly schedules (Rempel 2015), for natural ventilation. These values, which reduced cooling loads by ~75% (Fig. 7a), fell within a surprisingly narrow range: above outside temperatures of ~25°C, and below indoor temperatures of ~23.5-24.5°C, natural ventilation had such a dramatic impact in this space, with amply-sized windows well-aligned to the prevailing wind, that overcooling easily resulted. This is evident, as well, in the appearance of small heating loads in April, May, and August (Fig. 6).

Table 2. Optimization parameters

Parameter	Range	Initial Step Size	Initiation Value	Result
Glazing tilt	0° - 90°	10°	n/a	Fig. 4
Movable insulation (Oct-Mar):				
time retracted (morning)	6:00 - 12:00	1:00	6:00	Fig. 5
time activated (evening)	15:00 - 20:00		15:00	
Shading (Apr-Sep):				
time activated (morning)	6:00 - 12:00	1:00	12:00	Fig. 5
time retracted (evening)	15:00 - 20:00		20:00	
Thermal mass thickness	0.01m - 0.3m	0.05m	0.01m	0.25m
Natural ventilation (Apr-Sep):				
indoor minimum temperature	16°C - 30°C	10°C	26°C	Fig. 6
outdoor maximum temperature	20°C - 38°C	10°C	26°C	

Figure 5. **Optimal hours for use of movable insulation** (orange bars) **and shading** (blue bars), as well as hours of full sunrise and full sunset (circles). Note nighttime retraction of shading.

## DISCUSSION

Several useful observations emerge from these results. First, ideal thresholds for operation of movable elements are not necessarily intuitive, and despite accepted research practice (e.g. Ochoa 2008), they cannot be assumed. Here, movable insulation required activation of greater duration than the “nighttime” (sunset to sunrise) default found in EnergyPlus and other simulation engines; similarly, shading required activation hours before overheating occurred and also required removal at night. Where default activation settings exist, they must be overridden; likewise, effective manual operation by occupants cannot be assumed if thermal sensation and/or intuition are the only signals. Second, the penalties imposed by winter overheating and summer overcooling led to optimal thresholds that created small summer heating and winter cooling loads. If modest winter overheating and summer overcooling were permitted, which is not unrealistic given that mechanical heating is often made unavailable in the summer and vice-versa, these new loads would be reduced or eliminated. Third, it appears that even finer-grained optimizations would have been productive, particularly with respect to natural ventilation. The combination of summer overcooling penalties and ample operable window area, in this case, led to a high minimum indoor temperature threshold in May because so little time was necessary for natural ventilation to have sufficient cooling effect; optimizations that explore window area as well as sub-hourly timesteps might reveal better thresholds. The load reductions predicted here are therefore conservative, in the sense that they could be lowered even further, but optimistic in the sense that consistent, near-ideal operation is required to achieve them.

Figure 6. **Optimal temperature thresholds for natural ventilation control.** (a) Typical outdoor temperatures (blue; Oakland CA TMY3) and maximum values above which vents should be closed to avoid overheating (orange); (b) Adaptive thermal comfort zone (blue) and minimum indoor temperatures below which vents should be closed to avoid overcooling (orange).

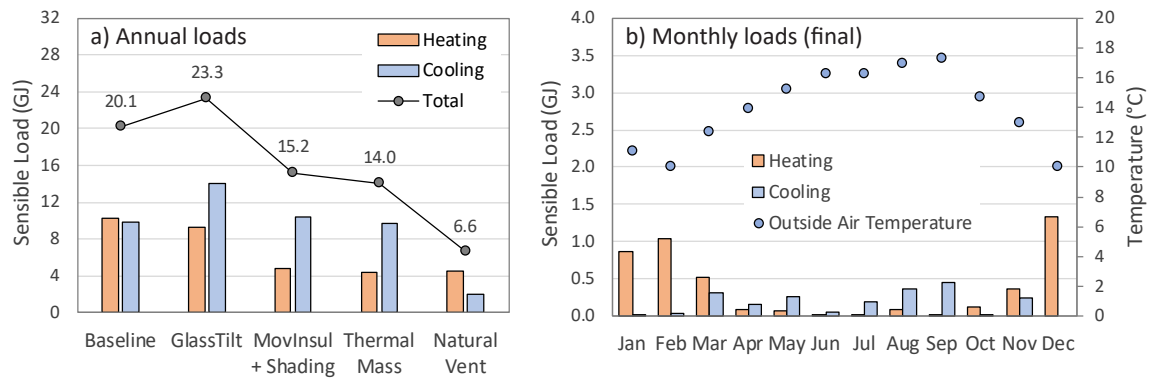

Figure 7. **Final loads with optimized controls.** (a) Annual loads at each stage, with final reductions of 56% (heating), 79% (cooling), and 67% (total); (b) Final loads by month (see Fig. 2b).

## CONCLUSIONS

Together, the results above show the striking potential for well-controlled passive strategies to diminish space conditioning loads, even in a building with minimal insulation in a cloudy winter climate. In reducing the heating load by >50% and cooling load by ~80%, while maintaining adaptive comfort, the strategies that were identified challenge the perception that passive systems are difficult to control and, as a result, cannot contribute reliably to comfort. Instead, they suggest the opposite. While the load offsets found are specific to the building and climate studied, the value of well-operated elements is likely to be widespread in climates with significant diurnal and seasonal temperature variation, and the method for finding control thresholds is valid in general. Because the U.S. contributes disproportionately to the world's greenhouse gas emissions, the potential for well-controlled passive systems to meet such large fractions of heating and cooling demand, in a vital population center, is worth intense investigation and further development.

## **Sensing and Information Technologies for the Environment (SITE); Hardware and Software Innovations in Mobile Sensing Technologies**

### **ABSTRACT**

This research focuses on the development and integration of low-cost Mobile Urban Sensing Technologies (MUST) and immersive environmental data exploration mechanisms with the ambition to inform citizens about their environments and aid scientists in uncovering the relations between the surface attributes and the urban environment. We propose to use 3D immersive environmental visualization techniques to enable a user-centered interactive analysis and rationalization of the available urban environmental data in relation to further urban attributes. With this ambition, we have developed three mobile apps that explore three strategies of Augmented Reality (AR) 3D visualizations of urban environmental data. While some data could be acquired from urban Geographic Information System (GIS) and existing sensor networks, we also developed an urban sensing kit specifically designed for deployment on mobile platforms such as buses or cars.

### **KEYWORDS**

Urban Microclimate, Urban Sensing, Mobile Sensing, Augmented Reality, Environmental Visualization.

### **INTRODUCTION**

Big data is changing urban science. Digitalization of information and ubiquitous sensing in cities are enabling the collection of data at unprecedentedly high temporal and spatial resolutions. This is most true in regard to urban environmental data. Sensor networks, remote sensing, thermal imaging, and crowd-sourced environmental monitoring are rapidly growing the availability of urban environmental data.

While high spatio-temporal resolution urban microclimate data are continuously becoming easier to collect, these data are not always analyzed in relation to further urban properties. We are generally only aware about city scale mean pollutant concentration values, and fail to understand the variable environmental quality conditions present in the urban fabric. One of the reasons for the persistence of this challenge is that while the study of urban sensing tools and strategies has been a consistent focus of research within the environmental and earth science communities, little attention has been placed on the development of data compilation and visualization techniques and methods for interactive exploration of environmental data for urban analysis, both from the scientist's and the interested citizen's perspectives. The result is that urban environmental data fail to reach wide audiences. The hypothesis of this research is that immersive and interactive urban environmental visualizations will enable the engagement of a broad team of stakeholders including scientists, citizens, policy makers and urban planners to reshape the discussion and analysis of contemporary urban environments, and the planning of future cities. This can be achieved through user-centered interactive analysis and rationalization of urban data which 3D immersive visualization techniques enable, thus removing some of the barriers that current tabular data or 2D plots engender. Specifically, we outline the development of novel 3D immersive Augmented Reality (AR) visualizations of urban air quality data. Such visualization strategies, which are currently lacking, aim for the

analysis of environmental data in relation to further urban parameters to enable the participation of a wide audience of users. The scientist would use them to understand how urban attributes modulate environmental quality, while citizens would use them to better understand their city and how to navigate while minimizing their exposure to adverse air quality or heat. However, since current sensor networks in cities mostly consist of fixed stations that cannot provide the spatial information needed to support such visualization of the entire city, we also develop a low-cost sensing kit designed specifically for mobile deployment over cars or buses, for example.

## 2. URBAN SENSING AND VISUALIZATION METHODS

When the access to environmental data of a site under study is limited, the use of mobile weather stations can be an effective low-cost technology to capture high spatial resolution urban air quality data. Mobile weather station studies can enable a fast response and site specific data acquisition methodology to understand parameters such as pollution sources or temperature gradients (Mahoney et al. 2010, Zwack et al. 2011, Kolb et al. 2004, Li et al. 2012). However the deployment of mobile sensing technologies specially so in urban environments still lags behind fixed sensors due to various challenges. The reliance on power sources, deployment constraints, security concerns, and the difficulty to access the kits for maintenance and calibration purposes, are amongst some of the main reasons why urban sensing technologies are not more widespread. Aiming to address these challenges, a robust and low-cost sensing kit has been developed to enable the acquisition of a high spatial resolution urban microclimate data (see Fig.1). This mobile sensing tool is essential to support the visualization techniques described next, which require high spatial resolution data (for further details on the MUST sensing kit see [must.princeton.edu](http://must.princeton.edu)).

Immersive 3D visualization techniques have not yet been explored for urban environmental data representations. However urban data visualization strategies have recently been experiencing a rapid transformation with the arrival of Augmented Reality (AR) (also referred to as Mixed Reality (MR)) technologies. Urban augmented reality applications are changing the way we navigate the city. Apps such as ARCity or Yelp aid citizens to navigate the city based on the information of traffic, road conditions or amenities. Apps such as England's Historic Cities add historic layers to the city also enable citizens to navigate the city while traveling in time. However while various weather apps are available both in iOS and Android, augmented reality technologies have not yet been explored for the visualization of urban environmental data. In this context, this research explores AR technologies for environmental visualization aiming to encourage the engagement of wide communities including scientist and citizens in the discussion and management of urban environments. With this ambition three 3D immersive AR environmental visualization apps are being developed. These apps utilize the acquired mobile sensing data from the MUST sensing kits and visualize it following 3 strategies. The Navigating Urban Environments (NUE) app targeted for wide audiences, uses a mobile phone to explore a 3D urban navigation strategy where environmental data is spatially represented in relation to the physical structures of the city to enable a first person and on site exploration of the environmental data in relation to the visible urban

properties. The Virtual Urban Environments (VUE) app introduces a 3D immersive off site map visualization strategy to explore the environmental data over a city map marker deployable in interiors and exteriors; it typically uses a tablet and is aimed at very engaged citizens or city managers and policy makers. Finally the Holographic Urban Environments (HUE) app uses augmented reality smart glasses to enable further degrees of interactivity with the environmental data through spatial user hand textures or voice activation; it is designed for scientists and urban planners who want to interact with various scenarios to gage their impact on urban environmental quality.

Figure 1. MUST Sensing Kit

## 2.1 NUE

Despite the increasing availability of 2D and 3D urban navigation apps, urban navigation has not yet been explored to enable on site environmental visualization. Environmental navigation in cities could however transform the way citizens travel across cities. The Navigating Urban Environments (NUE) app is an augmented reality mobile app that aims to aid citizens navigate the city informed by environmental data. The app operates in two modes, i) the first-person view, and ii) the map view. In the first-person view, locational services of the user's mobile device are accessed, and the geo-tagged environmental data are overlaid on the camera view as graphic filters (see Fig.2). The map view is developed using Google Map API services over which environmental gradients are overlaid. The app queries data from the online server where the MUST sensing kit data are stored, as well as from other online web services such as OpenWeatherMap and AQICN. Through these combined sources, data on temperature, humidity and air quality are compiled. Furthermore, through GeoNames geocoding, the location for the different urban intersections is stored. This setup enables that when a geocoded user points the smartphone towards a nearby intersection, the app draws a marker over the intersection to show the street names as well as the relevant environmental data for that given intersection. Thus the app allows the user to decide on the most favorable path towards their destination, as well as to associate certain temperatures or AQI values with the urban fabric.

Figure 2. NUE app.

## 2.2 VUE

Not only the average citizen, but also city managers and policy makers can benefit from AR visualizations to understand their urban domain. Virtual Urban Environments (VUE) is a marker based augmented reality mobile app that aims to enable off-site environmental data visualization and analysis. To test the app, environmental data on the city of Seoul have been collected. The app recognizes a marker composed by the map of the city of Seoul and scales the environmental data over it. Historical air quality data from 1986 to 2016 can be viewed through interacting with a slider and dropdown menu. Data for PM10, PM2.5, O<sub>3</sub>, SO<sub>2</sub>, NO<sub>2</sub>, and CO were available. Furthermore, the app enables real time data to be visualized over the city map. The air quality data is queried from the same sources as NUE. The setup aims to encourage the user to make correlations between the historical and real-time air quality data, while viewing the complexity of urban and geographic layers. This would help urban planners or policy makers to understand what modulates urban environmental quality.

Figure 3. Left figure, VUE app. Right Figure, HUE app.

## 2.3 HUE

Holographic Urban Environments (HUE) is an augmented reality mobile app that utilizes a smartglass headset to enable immersive environmental data visualization and analysis. The app uses an environmental visualization platform based on the game engine Unity and the Microsoft Hololens smartglass headset. The app queries data in real time from real-time data

is queried from online weather station databases and visualized as a particle simulation. The environmental data are mapped onto 3D physical model that the Hololens kit uses as a marker. This app is being developed aiming for a further degree of interactivity with the environmental data through spatial user hand textures or voice activation. It would allow for example, once couple to modeling tools, city planners or scientists to see what is the effect of altering the cityscape on environmental quality.

## RESULTS

The MUST sensing kits and the developed AR environmental visualization applications were tested at the 2017 Seoul Architecture and Urbanism Biennale. Four MUST sensing kits were installed in the Seoul intercity bus network, collecting data from August 30<sup>th</sup> until October 4<sup>th</sup> 2017. Data on temperature, humidity, CO<sub>2</sub> and PM2.5 were acquired at time intervals of 30 s. Given that the sensing kits were powered by a solar panel, the battery was only charged when the weather conditions were good, thus from the time the kits were installed, only 26 days of data were acquired. The data was initially compared against a nearby Seoul city weather station and it was found in agreement with the weather station observations. In Figure 4b the averaged CO<sub>2</sub> and temperature data for the 31<sup>st</sup> of August are shown. With the ambition to relate the acquired environmental data with the urban spatial differences present in this area of the city, a district scale analysis has been developed. The buses travelled through 9 different districts in the city of Seoul. The Kolmogorov-Smirnov test with a 5% significance level was tested for every pair of these 9 districts (in Fig.4a the pdf distributions for temperature and for all 9 districts are shown); it showed that data from neighboring district are likely to be related (drawn from the same distribution), as expected.

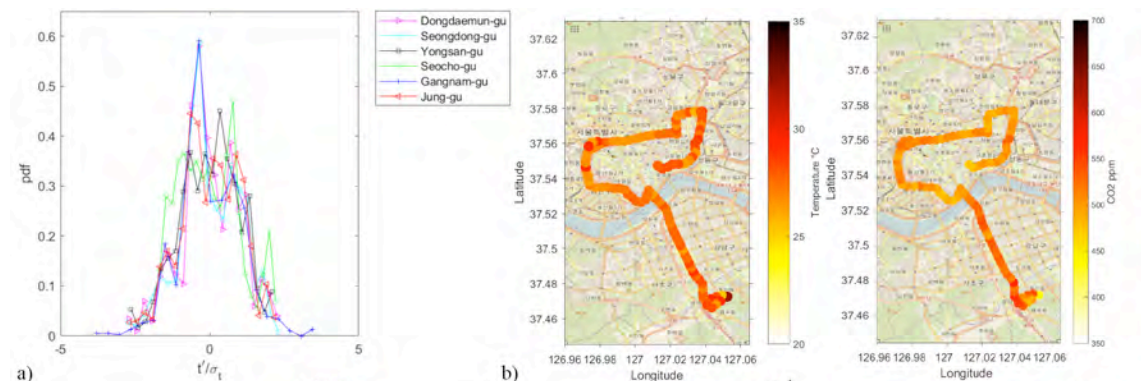

Figure 4 a) PDF of the acquired temperature for the different districts in Seoul. b) Spatial map for temperature and CO<sub>2</sub> collected on the 31<sup>st</sup> of August.

Two of the developed augmented reality applications were displayed in the Seoul architecture and urbanism biennale in an exhibition with the title Seoul On-Air. For the VUE app, a 2.5m diameter map of the city of Seoul was installed on the exhibition floor around which 5 iPads displayed the app enabling visitors to experience real time and historical air quality data of the city of Seoul. The NUE app was also displayed in the exhibition space. Given that this app is to be used for outdoor urban environmental navigation purposes, it was only included as a video recording for the visitors to become familiar with the functionalities of the application.

Both apps accessed the real time data collected from the MUST sensing kits and local weather stations.

## CONCLUSIONS

Aiming for the acquisition of low-cost and high spatial resolution urban environmental data, a mobile urban sensing technology has been developed. The prepared sensing kits were mounted over the Seoul intercity network, and environmental data was acquired for 26 days. The data collected from the sensing kits was utilized to communicate the real time high spatiotemporal resolution air quality data to the Seoul Citizens through 2 augmented reality applications. These apps were launched at the 2017 Seoul architecture and urbanism biennale to motivate an inclusive discussion between the different stakeholders that can affect how our cities are and will be designed in the future, including scientists, urban planners, architects, policy makers and citizens. The apps were made available in an exhibition space where city planning authorities and the citizens of Seoul interacted with the applications and provided very positive feedback about their experience. A third application has also been presented which utilizes immersive smartglasses for immersive environmental visualizations. A field experimental campaign for the city of New York is currently under development where the MUST sensing kits in combination with the three AR applications will be tested. We are also currently working on an updated version of the AR apps, aiming to introduce features that make them more immersive and interactive.

### ABSTRACT

Current modelling approaches for energy simulations in green roofs use a range of values for parameters such as stomatal resistance ( $r_s$ ) of the vegetation.  $r_s$  reflects the capability of a plant to transpire, thus it has a direct relation to the cooling potential of green roofs in buildings. Therefore,  $r_s$  values need to be revised based on differences among species and contrasting environmental conditions, considering anatomical and physiological characteristics among species and their changes throughout the day. In order to provide real data on species commonly used for green roofs in semiarid climates, this paper aims to evaluate the stomatal resistance of nine species of groundcovers and to compare this data with current models.  $r_s$  was measured for each species at 8:00 h, 12:00 h, 16:00 h and 20:00 h during day and night-time in winter in a leaf located at the middle of the stem. The results of this study showed that  $r_s$  varies significantly among species, throughout the day and between the side of the leaf (adaxial or abaxial). The lowest  $r_s$  values for species was at noon ranging from 264 to 807 s m<sup>-1</sup> and the highest  $r_s$  was at night ranging from 568 to 973 s m<sup>-1</sup>. *Sedum spurium* red, *Sedum* hybrid, and white and pink *Verbena* sp. had the largest  $r_s$  variation in the day-night cycle. The results of  $r_s$  are higher than those values recommended for some energy simulation models.

Cooling potential, plant physiology, *Sedum*, stomatal conductance,

### INTRODUCTION

As a component of green infrastructure, green roofs have become more relevant in recent years because of the ecosystem services they provide, including the reduction of energy consumption in buildings (Tabares-Velasco and Srebric 2011; Zhao et al. 2014) and Urban Heat Island (UHI) (Gill et al. 2007). The cooling service of green roof vegetation relies on the abilities of different species to transpire, provide shade, reflect radiation back to the atmosphere or absorb it through photosynthesis (Cook-Patton and Bauerle 2012; Blanus et al. 2013; Vaz Monteiro et al. 2017). Transpiration relates to the water vapour movement from the plant to the atmosphere through stomata, which are pores distributed in the epidermis of leaves that allows CO<sub>2</sub> and O<sub>2</sub> exchange. The stomatal resistance ( $r_s$ ) corresponds to the rate of transpiration of water vapour by the leaves through opening and closing of stomata based on the environmental conditions. In nature  $r_s$  relates to the species, their morphology and anatomy of the leaves, such as stomatal density on the adaxial and abaxial side and also temperature, water availability and photosynthetic active radiation (PAR) present, among other characteristics. In models of heat and mass transfer from green roofs to buildings,  $r_s$  is one of the most relevant parameters that defines them (Jaffal et. al, 2012; Sailor, 2008) and although its importance,  $r_s$  information comes mainly from research performed in agricultural

crops, but not from species commonly used in green roofs (Cook-Patton and Bauerle, 2012). That is why in green roof modelling, selected  $r_s$  values come from the literature available and the researcher's criteria and not from empirical data that acknowledges species variability. In this study,  $r_s$  values were obtained throughout the day in nine species of groundcovers commonly used in green roofs, to check for interspecific variation. Secondly, these  $r_s$  values were compared to those ranges proposed in the heat and mass transfer models from green roofs to buildings, to check whether these values were under or over estimating the true cooling potential of a green roof, according to a species.

## METHODS

Seven succulent species *Aptenia cordifolia*, *Basella sp.*, *Sedum* hybrid, *Sedum palmeri*, *Sedum spurium* red, *Sedum spurium* green, *Sedum spurium* variegated and two herbaceous species *Verbena sp.* white and *Verbena sp.* pink grown in a heated greenhouse were used in this study. The experiment consisted in a completely randomized design (DCA), with three replicates, each consisting of four pots with one plant. The parent plant material was obtained from commercial nurseries and then propagated using four cm long cuttings, with three to four leaves, dipped in a mixture of indole butyric acid (IBA) plus Captan (Anasac Garden ®). Cuttings were placed in a greenhouse for four weeks until transplant into 1.4 L pots filled with a mixture of peat and perlite 2:3 (v:v). Plants were irrigated to container capacity, every two days and five weeks after transplant,  $r_s$  was measured with a calibrated Leaf Porometer (model SC-1, Decagon Devices, USA) throughout the day at 8:00, 12:00, 16:00 and 20:00 hours during the fall. Measurements were taken in a marked leaf located in the middle of the stem, on its adaxial and abaxial side during six consecutive days with sky clear conditions. PAR and temperature were recorded. Data was analysed by ANOVA and mean separation was carried out by Fisher's Least Significance Test (LSD) when differences were significant.

The minimum and maximum  $r_s$  values obtained in this study were compared to those reported by Sailor (2008) and Zhao et al. (2014). In Sailor (2008), the user can choose an  $r_s$  value between 50 to 300  $\text{s m}^{-1}$ , which are values found in different plant species. On the other hand,  $r_s$  values proposed by Zhao et al. (2014) ranged from 225 to 1125  $\text{s m}^{-1}$  and were derived from studies on desert plants by Tabares-Velasco and Srebric (2011).

## RESULTS

### *Stomatal resistance ( $r_s$ )*

Stomatal resistance ( $r_s$ ) was significantly higher ( $P < 0.01$ ) in five species at the adaxial side compared to the abaxial side of leaves. In addition, the mean  $r_s$  was species dependent ( $P < 0.01$ ) (Fig. 1). Herbaceous species such as white and pink *Verbena sp.* had on average, an  $r_s$  value of 417  $\text{s m}^{-1}$ , while succulent species, such as *Basella sp.* had the highest  $r_s$  with 880  $\text{s m}^{-1}$ . On the other hand, *Sedum* species  $r_s$  ranged between 536 to 692  $\text{s m}^{-1}$ .

$r_s$  changed within the species across the day ( $P < 0.001$ ) and was lower at 12:00, compared to 20:00 h, with the exception of *S. spurium* var. that had no significant differences. *S. spurium* red, for example had a 71% higher value of  $r_s$  at 20:00 than at 12:00, while *Basella sp.* had the lowest variations of  $r_s$  across the day (15%). Although PAR radiation was highest at noon, all species showed their lowest  $r_s$  values at midday while the highest values were found at night (PAR values of 0.0  $\mu\text{mol m}^{-2} \text{s}^{-1}$ ). In general,  $r_s$  values at 8:00 h and 16:00 h were similar across species.

*Stomatal resistance ( $r_s$ ) comparison with current models*

When comparing the  $r_s$  values obtained on this study (Table 1) with those proposed in the heat and mass transfer models from green roofs to buildings of Sailor (2008), only the mean  $r_s$  values at 20:00 of the herbaceous White and Pink *Verbena sp.* and *S. spurium* red were within the range. On the other hand when comparing the  $r_s$  values obtained with the ones proposed for desert plants by Zhao et al., (2014), all species had values within that range.

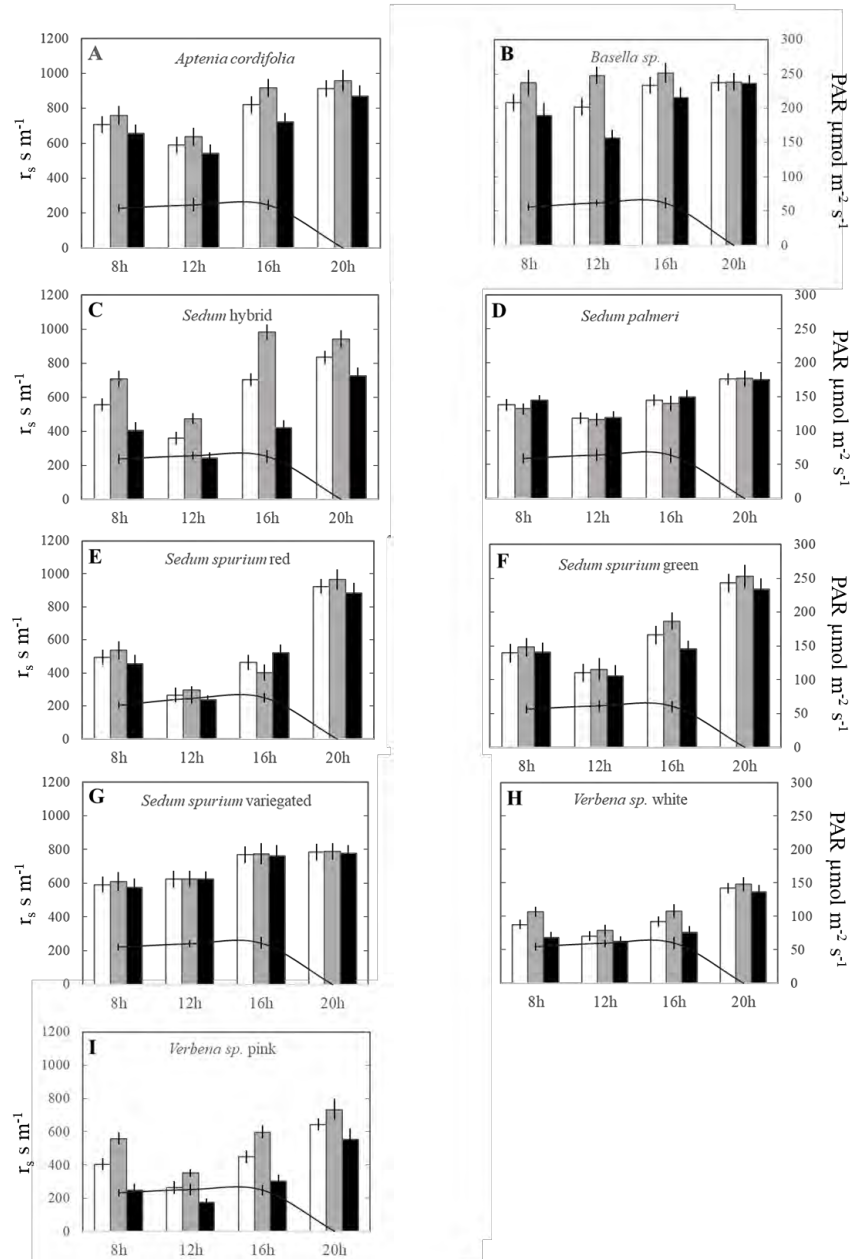

Figure 1. Photosynthetic active radiation (PAR) ( $\mu\text{mol m}^{-2} \text{s}^{-1}$ ) and mean (white), adaxial (grey) and abaxial (black) stomatal resistance ( $r_s$ ) ( $\text{s m}^{-1}$ ) on of (A) *Aptenia cordifolia*, (B) *Basella sp.*, (C) *Sedum hybrid*, (D) *Sedum palmeri*, (E) *Sedum spurium* red, (F) *Sedum spurium* green, (G) *Sedum spurium* variegated (H) *Verbena sp.* White and (I) *Verbena sp.* Pink, at 8:00 h, 12:00 h, 16:00 h and 20:00 h.

Minimum and maximum  $r_s$  values obtained in this study were higher than the ones proposed by Sailor (2008), and they were closer to the  $r_s$  values proposed by Zhao et al. (2014) (Table 1).

Table 1. Minimum (min) and maximum (max) stomatal resistance ( $r_s$ ) ( $s\ m^{-1}$ ) of the nine species of groundcovers of this study and  $r_s$  values proposed by the simulation models of Sailor (2008) and Zhao et al. (2014).

Species	$r_s (s\ m^{-1})$	
	$r_s\ min$	$r_s\ max$
<i>Aptenia cordifolia</i>	589	914
<i>Basella sp.</i>	807	948
<i>Sedum</i> hybrid	358	834
<i>Sedum palmeri</i>	471	703
<i>Sedum spurium</i> red	266	923
<i>Sedum spurium</i> green	440	973
<i>Sedum spurium</i> var.	624	784
<i>Verbena sp.</i> white	282	568
<i>Verbena sp.</i> pink	264	643

<b>Zhao et al. (2014)</b>	<b>225</b>	<b>1125</b>

## DISCUSSIONS

In nature, most species have hipo-stomatic leaves, meaning that stomatal density is higher on the abaxial compared to the adaxial side of the leaf (Lallana, 2003), which is also related to differences on cells of inner tissues on both sides (Fukushima and Hasebe, 2014). This anatomical and morphological characteristic of leaves is considered to be part of the plant adaptive response to avoid water loss through excessive transpiration on the adaxial side, which is directly exposed to solar radiation (Clements, 1905). In the case of the nine species evaluated in this study, stomatal density on the abaxial versus the adaxial side of the leaves was also higher (unpublished data) in line with previous information, which could be responsible for the lower  $r_s$  values on the abaxial side. It is also possible that the stomatal size, could increase or decrease  $r_s$  values together with the characteristics of the epidermis and accessory elements in leaves.

In this study, succulent species commonly grown in green roofs showed higher  $r_s$  values compared to non-succulents. Succulent species have fewer stomata per unit of area (Sayed, 1998). The opening and closing of stomata relates not only to  $r_s$ , but also with  $CO_2$  assimilation for photosynthesis and environmental limiting factors such as vapour pressure, radiation, relative humidity, water availability and temperature (Farquhar and Sharkey, 1982), which explains the broad variability of  $r_s$  during the day, between species and in the same species. Succulents species adapted to open their stomata for  $CO_2$  uptake during night times and close them during the day to limit water loss, do not showed crassulacean acid metabolism performance in their  $r_s$  behaviour through the day. All this morphological and anatomical traits have evolved in succulents as an adaptive response to water deficit and high temperatures, leading to higher  $r_s$  values in these species.

Irrigated plants, usually have higher transpiration rates due to the opening of stomata and, therefore,  $r_s$  is lower compared to plants under water stress. In this study though,  $r_s$  was higher compared to the values proposed in the heat and mass transfer models from green roofs to buildings of Sailor (2008) and were within the range proposed by Zhao et al. (2014). Sailor (2008) is overestimating the cooling potential of the species, by means of using  $r_s$  values commonly found in agricultural crops, while the values proposed by Zhao et al. (2014) are based on desert plants (Tabares-Velasco & Srebric, 2011), similar to the ones used in this study. Nevertheless, it is worth mentioning that  $r_s$  measurements were carried out at the end of fall under irrigated conditions, when  $r_s$  values are naturally lower, however, the cooling potential of plants and  $r_s$  values are more important over summer, when temperatures are higher. This information could be useful in green roof design, where the principal consideration should be to maximize transpiration in plants with low levels of irrigation. In addition, we think that specifically in the case of *Sedum spurium* red, the lowest  $r_s$  at noon could be related with the red pigmentation in both sides of the leaves, could be increasing the capacity to transpire even in hours with high temperature and irradiation.

## CONCLUSIONS

This study has denoted a broad variability of  $r_s$ , both within species across the day and between species of common use in green roofs. Also, the results showed that the values currently used in heat and mass transfer models of green roofs are in some cases underestimating  $r_s$ . This emphasizes the need of empirical data to support species selection in green roofs in order to maximize the energy savings in buildings by means of supporting greater transpiration of plants, with the use of species with lower  $r_s$  values especially at noon, when temperatures outside buildings are higher.

It is essential to create a biological database of species commonly used in green roofs and their parameters values, such as  $r_s$ , that will support designers and modellers to improve species selection to maximize energy savings in buildings. On the other hand, a common criteria, that includes the species natural variation and their behaviour across the day is relevant to design methodologies that will aid to standardize the data collection. Also, we expect that this results will raise awareness on the biological diversity that exists in green roof vegetation, in order to identify further parameters that are currently used in green roofs from data extracted from agricultural crops which would bring greater benefits to the area of sustainable construction.

## ACKNOWLEDGEMENT

We would like to thank the Department of Plant Science of the Faculty of Agriculture and Forestry from the Pontificia Universidad Católica de Chile, for partially providing the resources to develop this research. Also, this project was partially funded by research grants FONDECYT 1150675 and FONDECYT 1181610. We thank professor Jorge Gironás from the Department of Hydraulic and Environmental Engineering for facilitating the Leaf Porometer used in this research.

## Greening rooftops to reduce heat islands: How large is large enough?

Jiachuan Yang\*, Elie Bou-Zeid

### ABSTRACT

Green roofs, with adequate water supply, have been proven as effective measures to reduce urban environmental temperature. The benefits of large-scale deployment of green roofs have been studied mainly through numerical simulations with unrealistic high penetration scenarios, where all rooftops across the entire metropolis is assumed to be retrofitted. In this study, the scale dependence of the cooling effect of green roofs is investigated with a coverage of 25% over buildings at local, city, or regional scales. We compared results at 6 major U.S. cities to assess the response of the scale dependence to geoclimatic conditions. High-resolution weather simulations reveal that the cooling of near-surface air temperature by green roofs increases non-linearly with the scale of deployment. The shape and geoclimatic setting (geographic and climatic characteristics) of metropolitan areas control the scaling that some city centers are not able to achieve a significant cooling by greening their own rooftops. Uniform deployment of green roofs at the regional scale, on the other hand, provides a substantial temperature reduction with a very low cooling efficiency per intervention area. Cities should carefully revisit the scale dependences of cooling benefit and efficiency of green roofs to develop resilient plans meeting their expectations.

### KEYWORDS

Cooling efficiency; Green roof; Heat island mitigation; Urban planning

### INTRODUCTION

Urban heat island (UHI), a phenomenon that urban areas are significantly warmer than surrounding rural areas, is a big sustainability challenge that has been documented in global cities (Peng et al. 2011). Elevated temperatures adversely affect energy demand, water resource, and resident health in urban environment that cities have recognized the need to mitigate heat island effects under the changing climate (Grimm et al. 2008). Among the proposed strategies in the literature, green roof has gained increasing popularity due to its environmental benefits including temperature reduction, storm water retention, aesthetic improvement and habitat provision (Carter and Fowler, 2008).

In-situ measurements reported that replacing conventional roofs with green roofs can reduce daily maximum surface temperature by up to 30 °C (Wong et al. 2003). Consequently, reduced diurnal temperature variation substantially cut building heat gain and increase energy efficiency (Parizotto and Lamberts 2011). These measurements are consistent with building-scale numerical simulations (Sailor et al. 2012). At the large scale, however, the benefits of green roofs to the whole city can only be evaluated through simulations because no urban region has yet achieved a sufficiently extensive intervention. Recent developments allow accurate simulations of green roofs in climate models (Yang et al. 2015). Nevertheless, existing studies have focused on the maximum potential benefit of green roofs, i.e., 100% coverage uniformly over the entire metropolitan area (Georgescu et al. 2014).

In reality, land use development, economic activity and government structure diverge vastly among districts and communities at the sub-city scale as well as between different metropolitan areas that execution of mitigation policies can vary extensively. Take the New York metropolitan area for example, green roofs can be implemented by the city for its dense urban core (Manhattan), for the whole New York city, or in cooperation with surrounding counties in the state of New Jersey. Temperatures in cities are closely related to the fraction and spatial configuration of urban green space (Jin and Dickinson 2010), yet the quantitative scaling laws of cooling benefits from green roofs remain unknown. This study provides a first attempt to bridge this gap by simulating green roofs in different cities to address the following questions: How large does green roof need to be to produce a considerable cooling for city centers? How do the cooling benefits from green roofs scale with their spatial extent? Will the scale dependence change with geoclimatic conditions?

## METHODS

In this study, we used the Weather Research and Forecasting (WRF) model, a non-hydrostatic regional climate model developed by the National Center for Atmospheric Research (Skamarock and Klemp 2008), to simulate the effects of green roofs on regional climate. The WRF model has successful applications over major metropolitan areas around the world (Chen et al. 2011), whose parameterization of green roofs was developed and tested based on field measurements (Sun et al. 2013). Six metropolitan areas across the United States were selected for high-resolution weather simulation in this study, including Los Angeles (LA), New York City (NYC), Miami, Chicago, Phoenix and Pittsburgh. For each studied region, the fine-resolution domain (see Figure 1) has 160 by 160 grid cells covering the entire metropolitan area. Each grid is 1 km long and 1 km wide. To assess the performance of green roofs in a “typical” summer, we referred to the 1981-2010 climate normal released by the National Centers for Environmental Information for different metropolis. As a result, Pittsburgh and Chicago were simulated for year 2013, and LA, Miami, Phoenix, and NYC were simulated for year 2014. All simulations were run from 0000 UTC on 10 July to 0000 UTC on 14 August.

Metropolitan areas in this study have developed sustainability plan to mitigate climate change. Though the primary goal of these actions is to reduce greenhouse gas emissions, the need of mitigating urban heat islands is explicitly outlined and the use of green roofs is recognized by Chicago, NYC, and Pittsburgh. To obtain plausible scenarios of green roofs, we went through the land use planning and development map for each studied metropolitan area and identified three (local, city, and regional, Figure 1) levels of implementation. A set of three simulations was then carried out to estimate the cooling benefit of green roofs at three levels, assuming a 25% areal coverage on building rooftops. To focus on the effect of geoclimatic conditions and to exclude the impact of water availability, green roofs were well irrigated in all runs such that soil moisture maintained evapotranspiration at 75% of the potential evapotranspiration rate. Following previous studies (Sun et al. 2013), thermal properties of roofs were (1) conventional roof: albedo ( $a$ ) = 0.3, thermal conductivity ( $k$ ) = 1.0 W m<sup>-1</sup> K<sup>-1</sup>, heat capacity ( $C$ ) = 2.0 MJ m<sup>-3</sup> K<sup>-1</sup>; (2) green roof:  $a$  = 0.3,  $k$  = 1.1 W m<sup>-1</sup> K<sup>-1</sup>,  $C$  = 1.9 MJ m<sup>-3</sup> K<sup>-1</sup>.

## RESULTS

Figure 2 shows the reductions in average  $T_2$  (air temperature at 2 m above the surface) over the local-scale planning area (red areas in Figure 1) with different levels of green roof implementation. We focus on these areas because they are the urban cores with the highest population density within the city. Temperature reductions among studied regions are found to scale with green roof areas differently. In the first group of metropolitan areas, including

NYC, LA and Pittsburgh, the cooling benefit increases considerably with the area of green roofs. Upscaling the deployment of green roofs from the local scale to the regional scale, daytime mean  $T_2$  reduction increases from 0.03 °C to 0.21 °C for NYC, from 0.03 °C to 0.12 °C for Pittsburgh, and from 0.05 °C to 0.18 °C for LA. In the second group of cities (Chicago, Miami, and Phoenix), however, temperature reductions over urban cores by green roofs are largely independent of the intervention scale. Daytime mean  $T_2$  over Chicago center decreases by an additional 0.02 °C after increasing green roof areas from 0.52 km<sup>2</sup> in the local plan to 679.19 km<sup>2</sup> in the regional plan. The scale dependence of nighttime cooling for individual metropolitan areas is consistent with the daytime trend.

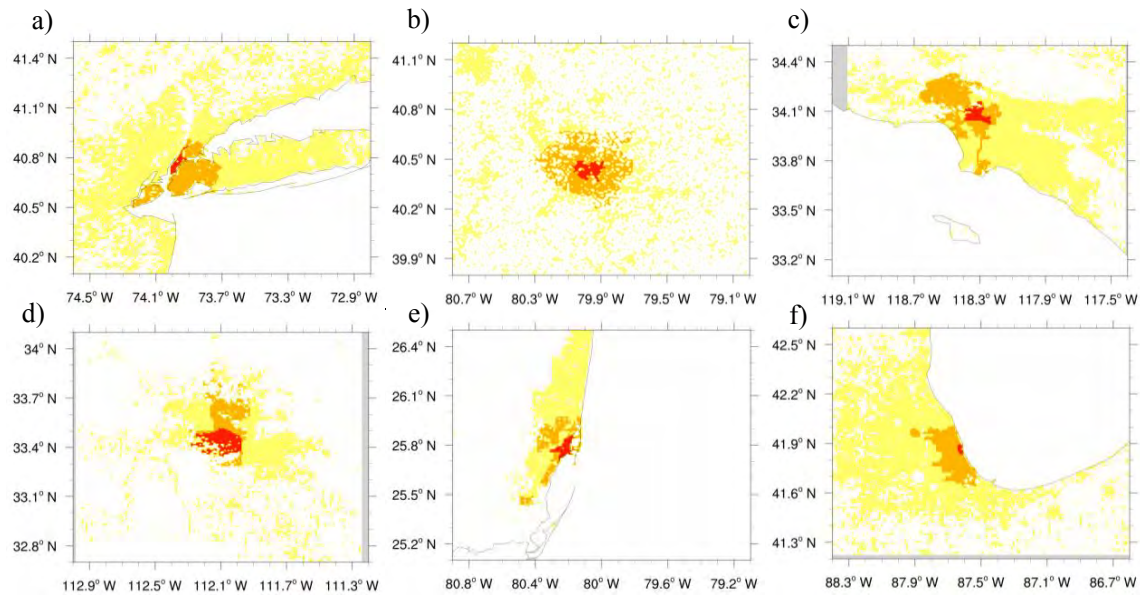

Figure 1. Spatial extent of green roofs at local (red), city (orange), and regional (yellow) scales. a) NYC, b) Pittsburgh, c) LA, d) Phoenix, e) Miami, f) Chicago.

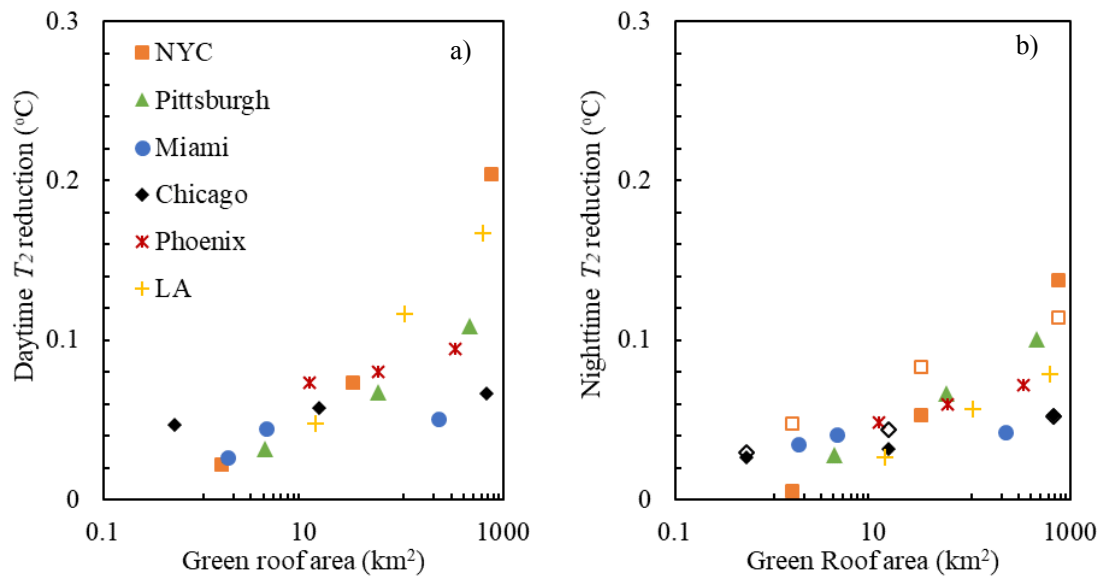

Figure 2. Scale dependence of simulated reductions in 2-m air temperature over the local planning areas by green roofs. a) daytime (0700-2000), b) nighttime (2100-0600).

Spatial distribution of the cooling by different green roof plans is plotted in Figure 3. Chicago and NYC are shown as examples to explain the dissimilar scale dependence between the two groups of cities. Greening 25% of Manhattan's rooftops leads to a negligible cooling over Manhattan and causes a small cooling downwind to the west and to the north of NYC. Adopting green roofs at the city scale creates surface cooling in upwind areas, consequently Manhattan is able to achieve a reduction of about 0.15 °C in  $T_2$  at 1400 local time. And a uniform implementation of green roofs over the entire metropolitan area can reduce  $T_2$  over Manhattan by about 0.36 °C at 1400 local time. Due to the existence of sea breeze, city and regional plans provide cooling benefits for Manhattan by greening its upwind areas. Similarly, strong scale dependences of the cooling benefit in LA and Pittsburgh are caused by implementing green roofs over buildings in upwind areas.

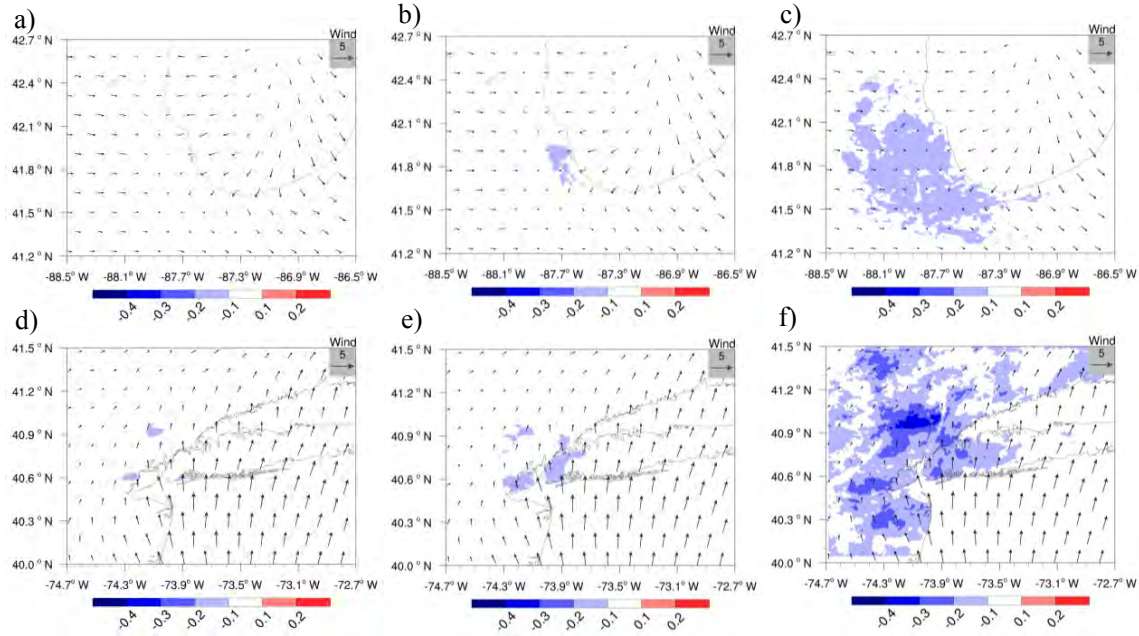

Figure 3. Simulated reductions in 2-m air temperature at 1400 local time with 10-m wind overlaid from deploying green roofs. a), b), c) local, city, and regional scales in Chicago; d), e), f) local, city, and regional scales in NYC.

The cooling effect of green roofs is more local and homogeneous in Chicago. At all levels, urban areas with green roofs are able to receive a noticeable temperature reduction. Nevertheless, a weak scale dependence is found because upscaling the mitigation plan for Chicago mainly involves altering downwind built areas. The comparison between results in Chicago and NYC demonstrates that both the geography of the metropolitan area and the climatic conditions play important roles in regulating the regional benefits of green roofs.

The scale dependence of cooling benefits in different metropolitan areas is very useful, but it is expected that larger green roof areas result in stronger temperature reductions. Cooling efficiency is a key factor if green roofs are to be implemented as a city-scale plan or regional policy. Here we estimated the cooling efficiency per unit area of green roofs at different scales in the studied metropolitan areas. The reductions of 2-m air temperature over the entire fine-resolution domain is considered to account for cooling benefits in downwind areas:

$$CE = \int \frac{\sum_{x=1}^{N_x} \sum_{y=1}^{N_y} \Delta T_{x,y}(z) A_{grid}}{A_{int}} dz, \quad (1)$$

where  $N_x$  and  $N_y$  are the number of grid cells in x and y directions,  $\Delta T_{x,y}(z)$  is the temperature drop of each grid cell in the fine-resolution domain relative to the baseline without green roofs,  $A_{grid}$  and  $A_{int}$  denote the area of model grid and green roofs, respectively. In this study, we focused on a 1m thick slab centred at 2m and used  $T_2$  to represent  $\Delta T_{x,y}(z)$ . Note that the integration over depth in equation 1 is necessary for obtaining a cooling efficiency over a physical volume. Figure 4 shows that cooling efficiency per unit area of green roofs decreases rapidly with the implementation scale. Different from the trend in Figure 2, geoclimate conditions are found to play a negligible role in determining the cooling efficiency over the fine-resolution domain. With an area of about 1.6 km<sup>2</sup> (e.g., local plans in NYC), daytime  $T_2$  cooling efficiencies is about 30 °C m. At the regional scale, the daytime and night maximum efficiencies of about 2.8 and 2.5 °C m are found at NYC.

Figure 4. Scale dependence of the cooling efficiency of green roofs. a) daytime (0700-2000), b) nighttime (2100-0600).

## DISCUSSIONS

Modelling results with a uniform 100% penetration intervention are at present the best available resource to guide green roof policy in context of long-term environmental adaptation. The 25% areal coverage used in this study is at the lower end of previous studies (Yang et al. 2015), but is still beyond the practical implementation potential in the foreseeable future. Using plausible scenarios based on cities' land use development map, this study provides new insight into effective green roof planning as mitigation strategies of heat island. We find that the scale dependence of  $T_2$  reduction over urban cores is controlled by the geography of metropolitan area and its climatic conditions. To maximize the regional cooling benefits, deployment of green roofs should therefore focus on upwind areas. These upwind areas are critical to the thermal environment in the city during windy periods. Although wind direction varies continuously, planners should be able to identify the most probable wind directions. On the other hand, during periods of calm weather, the benefits of green roofs are more local.

## CONCLUSIONS

This paper quantitatively examines and compares the scale dependence of cooling benefit and efficiency of green roofs for mitigating urban heat islands in six major U.S. metropolitan

areas. Increasing the spatial extent of green roofs is usually treated as an effective way to mitigate heat islands. Our finding in this study, however, suggests that green roofs at city and regional scales may or may not provide significant additional benefits for urban cores. Green roofs have a direct impact on energy consumption of the building. Nevertheless, in terms of cooling the city, the effect is more indirect and cities should account for this scale dependence and for their unique geoclimatic setting.

## ACKNOWLEDGEMENT

### **ABSTRACT**

Vegetation in cities provides natural cooling of the climate and is therefore increasingly integrated as an essential part of Urban Heat Island (UHI) mitigation strategies. In the present study, the influence of trees on the local climate in a street canyon is studied using an integrated vegetation model in OpenFOAM. Vegetation is modeled as porous medium providing the necessary source terms for the heat, mass and momentum fluxes. Additionally, a radiation model is developed to model the short-wave and long-wave radiative heat flux exchanges between vegetation and the surroundings. The study investigates the influence of transpirative and shaded cooling due to vegetation on the pedestrian comfort inside a street canyon. The study shows that both shading and transpiration have a direct positive influence on the temperatures measured in the street canyon. Moreover, the cooling due to shading is seen to be larger than the transpirative cooling, especially under the tree.

### **KEYWORDS**

CFD, transpirative cooling, shading, vegetation, UHI

### **INTRODUCTION**

Vegetation in urban environments has a natural cooling effect on the urban climate and can mitigate Urban Heat Islands (UHI). The natural cooling is provided through heat extraction during transpiration and through shading from vegetation on the surrounding buildings and the ground below. However, trees can also negatively influence the ventilation characteristics in cities as the foliage obstructs air movement. This effect can further deteriorate the airflow characteristics at the pedestrian level and may reduce pedestrian thermal comfort. Thus, vegetation can have non-trivial impact on the comfort in cities and numerical models are needed to assess the influence of vegetation in cities.

The interaction between vegetation and the environment is a multi-physical phenomenon. Vegetation exchanges momentum, heat and mass with the air and undergoes radiative exchanges. A computational fluid dynamics (CFD) approach (Hiraoka, 2005; Liang et al., 2006; Boulard et al., 2008) can be used to identify the interactions between vegetation and environment, where the vegetation is modeled using a porous medium approach. Such an approach is shown to provide a good estimation of the thermal impact of vegetation and was used to study the influence of vegetation in urban areas (Bruse and Fleer, 1998; Gromke et al., 2014; Robitu et al., 2006). An urban microclimate model that can model the airflow and radiation in an integrated approach provides the means to accurately assess the environmental impact of vegetation for a given complex urban topology.

In the present study, the influence of vegetation, namely trees, on the microclimate of a street canyon is studied using a CFD model in OpenFOAM. Vegetation is modeled as a porous medium, providing the source/sink terms for heat, mass and momentum fluxes. A radiation model is developed to model the short-wave and long-wave radiative heat fluxes between the leaf surfaces and the surrounding environment. The radiation model enables to model the impact of the diurnal variations of solar intensity and direction, and the long-wave radiative fluxes between vegetation and nearby urban surfaces. Using the developed model, we investigate the cooling potential of vegetation on the microclimate of a street canyon exposed to a moderate wind in June. The influence of transpirative cooling and shading due to vegetation on pedestrian thermal comfort inside a street canyon is studied. The thermal comfort for pedestrians is evaluated using the Universal Thermal Climate Index (UTCI) (Fiala et al., 2001).

## MATERIALS AND METHODS

### Numerical method

The mean flow field in the street canyon with vegetation is modeled using the Reynolds-Averaged Navier-Stokes (RANS) equations,

$$\frac{\partial \rho \bar{u}_j}{\partial x_j} = 0, \quad (1)$$

$$\frac{\partial \rho \bar{u}_i \bar{u}_j}{\partial x_j} = \frac{\partial}{\partial x_j} \left[ -\tilde{p} \delta_{ij} + \mu_{eff} \left( \frac{\partial \bar{u}_i}{\partial x_j} + \frac{\partial \bar{u}_j}{\partial x_i} - \frac{2}{3} \frac{\partial \bar{u}_k}{\partial x_k} \delta_{ij} \right) \right] + \rho g_i + s_{u_i}, \quad (2)$$

$$\frac{\partial \rho \bar{e} \bar{u}_j}{\partial x_j} = \frac{\partial}{\partial x_j} \left( k_{eff} \frac{\partial \bar{T}}{\partial x_j} \right) + s_h, \quad (3)$$

$$\frac{\partial \rho k}{\partial x_j} = \frac{\partial}{\partial x_j} \left( \rho D_k \frac{\partial k}{\partial x_j} \right) + \rho G - \frac{2}{3} \rho \frac{\partial \bar{u}_k}{\partial x_k} k - \rho \varepsilon + s_k, \quad (4)$$

$$\frac{\partial \rho \varepsilon}{\partial x_j} = \frac{\partial}{\partial x_j} \left( \rho D_\varepsilon \frac{\partial \varepsilon}{\partial x_j} \right) + C_{1,\varepsilon} |S_{ij}| \varepsilon - C_{2,\varepsilon} \rho \frac{\varepsilon^2}{k + \sqrt{\nu \varepsilon}} + s_\varepsilon, \quad (5)$$

$$\frac{\partial \bar{w}}{\partial x_j} = \frac{\partial}{\partial x_j} \left( D_{eff} \frac{\partial \bar{w}}{\partial x_j} \right) + s_w, \quad (6)$$

where  $s_{u_i}$ ,  $s_h$ ,  $s_k$ ,  $s_\varepsilon$ ,  $s_w$  are the source terms of vegetation for momentum, energy, turbulent kinetic energy (TKE), TKE dissipation rate and humidity ratio (Manickathan et al., 2018a). The Reynolds stresses are closed using Boussinesq eddy-viscosity hypothesis where the eddy-viscosity is determined from the realizable  $k - \varepsilon$  model. The air domain is coupled with the ground and building facades to model the transport of heat and moisture therein, to take in account of dynamics of the thermal and hygric storage in the street canyon (Kubilay et al. 2017).

### Simulation setup

The simulations are performed for a street canyon with a vegetation zone of  $2 \times 10 \times 4 \text{ m}^3$ , representing a row of trees which are surrounded by two buildings of  $10 \times 50 \times 10 \text{ m}^3$  ( $x \times y \times z$ ), as shown in Figure 1. This vegetation zone has a foliage height of 4 m (with  $z_{min} = 4 \text{ m}$ ), leaf area density  $LAD = 10 \text{ m}^2 \text{ m}^{-3}$ , leaf drag coefficient  $c_d = 0.2$  and leaf size  $l = 0.1 \text{ m}$ . The meteorological data are based on a typical meteorological year and the total solar radiation intensity is for a clear sky on the 21<sup>st</sup> of June in the city of Zurich, Switzerland (Kubilay et al. 2017). The wind speed at the building height is  $U_{ref} = 5 \text{ m s}^{-1}$ , the ambient temperature varies between 11°C and 19 °C with solar noon at 13:28 and the relative humidity

varies between 62% and 86% RH. These are the boundary conditions applied at the inlet. A slip, symmetry and pressure outlet boundary conditions are applied at the top wall, side walls, and at the outlet, respectively. The ground outside the street canyon is defined to be adiabatic. Whereas, the wall temperatures inside the street-canyon is determined from the heat and moisture transport equations.

Figure 1. Simulation setup of a street canyon composed of two buildings with a vegetation band in the middle, representing a row of trees (Manickathan et al. 2018b).

## RESULTS AND DISCUSSION

The cooling potential of trees in the street canyon is quantified by studying the diurnal variations of air temperature and humidity for three distinctly different configurations: street canyon without tree, street canyon with trees but only providing shading and, finally, street canyon with trees providing both transpirative cooling and cooling due to shading. The configuration of trees that only provide shading in the street canyon is achieved by artificially closing the stomata in the model. Figure 2 shows the diurnal variation of air temperature and humidity ratio below the tree at  $z = 2$  m (point at the middle of the street canyon) for these three configurations. The figure shows that, without the trees, the air temperature is quantifiably higher throughout both day and night. However, once the trees are present, both shading and transpiration provide cooling in the street canyon, with an average decrease of  $0.5^{\circ}\text{C}$  in presence of shading and of an additional  $0.2^{\circ}\text{C}$ , when transpiration is added to shading. The cooling due to shading is seen to be higher than the cooling provided from transpiration. The study on the diurnal variation of humidity ratio inside the street canyon, Figure 2b, shows that the humidity in the street canyon is increased when the trees transpire. This could potentially negatively affect the pedestrian comfort below the tree.

a) Air temperature  $T$  ( $^{\circ}\text{C}$ )

b) humidity ratio  $w$  ( $\text{g kg}^{-1}$ )

Figure 2. Diurnal variation of a) air temperature  $T$  (°C) b) humidity ratio  $w$  (g kg<sup>-1</sup>) below the tree at ( $z = 2$  m) for three configurations: no tree, with shading and with transpiration and shading.

Figure 3. Spatial distribution of the universal thermal climate index (UTCI) (°C) at the vertical centre-plane of the street canyon with vegetation at 06:00, 09:00, 12:00 and 15:00 local time. The buildings are indicated by the grey zones and the vegetation inside the street canyon is indicated by the outlined rectangle.

The universal thermal climate index (UTCI) is employed to study the influence of vegetation on pedestrian comfort inside the street canyon. Figure 3 shows UTCI distribution at the vertical centre-plane of the street canyon at four distinct local times: 06:00, 09:00, 12:00 and 15:00. It

is apparent that the pedestrian comfort is significantly compromised due to the exposure to solar radiation at noon. However, inside the shaded zone of the trees, the thermal comfort is substantially improved, as indicated by the reduced UTCI values. In contrast, the impact of humidity generated from the trees is not discernible in the UTCI distribution. This means the transpiration of the trees does not negatively affect pedestrian comfort in the case studied, although an increase in relative humidity could reduce the thermal comfort.

## CONCLUSIONS

The integrated model is used to study the influence of transpirative cooling and cooling due to shading of trees inside a street canyon. From this case study, both transpirative cooling and cooling through shading are seen to reduce the temperatures. Furthermore, the transpiration from the vegetation is seen to increase the humidity inside the street canyon. Although, this additional humidity is seen not to have a significant impact on pedestrian comfort, measured through universal thermal climate index (UTCI), as the comfort provided by the tree shading is substantially higher and counters the negative impacts of increased humidity. However, factors such as leaf area density (LAD), vegetation position, vegetation size, ambient conditions, etc. can have an influence on the outcome. Therefore, the influence of these parameters should be investigated to accurately estimate the impact of the vegetation in urban area.

### ABSTRACT

The Green Roof on the Onondaga County Convention Center in Syracuse, NY is planted with several varieties of sedum over an area of 0.56 hectares. The roof was constructed in 2011, and has been instrumented with sensors to enable research and education over an extended period. The purpose of the current work on this roof is to quantify its performance with respect to water storage and energy transfer, and to identify chemical constituents in the runoff that might be contributed by the growth medium. The scope of the project also includes a number of measurements on traditional roofs in the vicinity of the Convention Center as controls. Experimental methods include measurements with temperature probes installed in different layers of the green roof, a meteorological station, soil moisture sensors positioned around the roof, and an electromagnetic flowmeter connected to the roof drains. Chemical analysis of incoming precipitation and stormwater runoff is conducted by ion chromatography.

Besides the research underway, an educational website is under construction that shows real-time data from many of the instruments. The website includes explanations of the energy flow through the roof layers, water flow and water storage in the growth medium, and runoff through the roof drains. The website is designed for use by teachers of K-12 and undergraduate courses to enable students to learn about green roofs as a tool for managing urban stormwater.

Results of the research show that heat flow through the roof is largely controlled by extruded polystyrene insulation below the growth medium, and that the growth medium is not a major barrier to heat flow. Substantial amounts of stormwater can be stored by the roof, as long as the growth medium is able to dry somewhat between storms. Precipitation events in close succession may cause the growth medium to stay saturated, preventing the roof from storing additional stormwater. The results of this work are important for assisting designers and engineers to improve the performance of green roofs.

### KEYWORDS

Green roof, water balance, evapotranspiration, soil moisture, stormwater, runoff chemistry

### INTRODUCTION

Green roofs can benefit urban areas in many ways. Much has been written about urban heat islands, where densely populated cities experience higher air temperatures compared with vegetated landscapes just outside the city (e.g., Golden et al., 2004); green roofs can help reduce high urban temperatures. In climates where heating in winter or air conditioning in summer is needed, a green roof may offer some additional insulation to reduce heating or

cooling costs (Zhang et al., 2017). Furthermore, green roofs can provide wildlife habitat, e.g., for birds, and vegetation on a green roof can reduce concentrations of certain air pollutants.

Especially important is the role of green roofs in reducing flooding and combined sewer overflow. In this regard, many studies have investigated the hydrologic performance of green roofs. For example, Stovin et al. (2017) present data from several green roofs on metrics to define stormwater detention, such as time delay between peak rainfall and peak runoff, time delay between 50% cumulative rainfall and 50% cumulative runoff, and attenuation of peak runoff flowrate compared with peak rainfall flowrate. Elliott et al. (2016) examine the hydrologic performance of a green roof with thick growth medium (100 mm) and a green roof with thin growth medium (31 mm) in different seasons in New York City. Cipolla et al. (2016) report on the total amount of stormwater runoff prevented by a green roof in Bologna, Italy during 69 storms over a full year. They compare their experimental data with predictions from the commercial software SWMM 5.1, and conclude that SWMM results show reasonable agreement with data under certain conditions.

In this paper, we report on preliminary results on the performance of the green roof on the Onondaga County Convention Center in Syracuse, New York. This facility offers opportunities to expand green roof research in new directions. The climate of Syracuse includes more extremes of temperature and precipitation compared with other instrumented green roof sites. For example, according to the National Weather Service, the average accumulated snow depth for the season over the past 66 years in Syracuse is 299.5 cm, making it one of the snowiest cities in the country. The green roof measures 50 meters by 111 meters and is fully instrumented to enable energy flow as well as hydrologic studies.

There are three objectives of the research described in this paper. First, the hydrologic behavior of the roof is studied to examine factors influencing the amount of water the roof can store. Second, the benefit of the green roof in reducing heat loss from the building in winter is considered. Finally, the role of the green roof in altering the chemistry of incoming rain is examined. Besides these research goals, there is an educational goal, namely to use the green roof as an educational tool to help students learn about the benefits and challenges of using green roofs for urban stormwater management.

## **METHODS**

The temperatures in the various layers of roof are measured using Campbell Scientific T109 probes, while the air temperature and relative humidity are measured using a Vaisala HMP-155 sensor. Windspeed and wind direction data are obtained using an R.M. Young 03-002 anemometer and wind vane set. Precipitation is measured with a Texas Electronics TE-525 tipping bucket as well as a Belfort AEPG-1000 weighing gauge for rain and snow using a double alter-shield to reduce the influence of wind. Soil moisture is measured using Campbell Scientific CS-616 reflectometers calibrated in our laboratories using samples of growth medium taken from the green roof. Runoff through the roof drains is measured with an M-2000 Badger electromagnetic flow meter calibrated on-site. All of the instruments are connected to CR-1000 Campbell dataloggers, and the data are subjected to quality assurance/quality control procedures.

Fresh rain samples are collected on the roof of the Biological Research Laboratory building at Syracuse University, about 1.6 km east of the green roof, simultaneous with collection of runoff samples from the roof drains on the green roof. Sampling during rain events usually takes place over several hours, hence the distance between the University site and the green

roof is expected to be negligible compared with the movement of rain clouds during the sampling intervals. Both sets of samples are analysed using a Dionex DX-500 ion chromatography system with anion columns to enable analysis of  $\text{Cl}^-$ ,  $\text{SO}_4^{2-}$ , and  $\text{NO}_3^-$ . Field and lab blanks are collected during every experiment to estimate uncertainties in the concentrations. Additional experiments are conducted to estimate dry deposition of these chemical species onto the green roof during periods of dry weather.

The experiments related to the chemistry of precipitation, runoff, and dry deposition are conducted as the weather permits. Weather and hydrology data are collected continuously, allowing interpretation of data for any periods of interest.

Modeling of the hydrology is underway using the U.S. Environmental Protection Agency Stormwater Management Model (SWMM). Modeling of heat flow through the roof makes use of the model Combined Heat, Air, Moisture and Pollutant Simulations in Building Envelope Systems (CHAMPS-BES).

## RESULTS

### Hydrology of the Green Roof

For each rain event, the tipping bucket and weighing gauge are used to determine the intensity as well as the total amount of precipitation. Using the magmeter data, it is also possible to determine the partitioning of the precipitation between storage in the growth medium and runoff exiting the roof via the drainage system. Figure 1 shows an example of this type of data.

Figure 1. Partitioning of rain between runoff and storage in the growth medium of the green roof between April 20, 2015 and July 31, 2017. Events with snow are excluded. Black portion of each bar represents amount stored in the growth medium, while the gray portion indicates amount of runoff flowing into the roof drains.

### Energy Flow through the Green Roof

Temperature data from various layers of the roof are used to estimate the performance of the roof in providing a barrier for energy flow from indoors to outdoors during cold weather. A cross section of the roof with locations of the temperature probes is shown in Figure 2. The layer providing the greatest barrier to heat flow is the 7.6 cm thick extruded polystyrene

insulation with a value of  $R = 2.6 \text{ m}^2 \text{ K per watt}$ , as given by the manufacturer. If we choose a time period when the heat flow is in quasi steady state, we can assume the heat flow in  $\text{watts/m}^2$  is constant through the roof and thus use the temperature data to estimate values of  $R$  for the other roof layers.

Figure 2. Cross section of the green roof, showing locations of temperature probes installed at A, B, C, and G. This sequence of 4 probes was installed at 5 locations across the roof. Three more widely spaced probes were affixed to the ceiling below the roof at Y.

Preliminary data for this roof reported by Squier and Davidson (2016) show that the total thermal resistance across all layers of roof is about  $3.1 \text{ m}^2 \text{ K per watt}$ , including the extruded polystyrene. Data obtained during the winter of 2017-2018 confirm this value based on a larger dataset. The  $R$  values of the other roof layers are in the range  $0.14$  to  $0.3 \text{ m}^2 \text{ K per watt}$ , which is very low compared with the extruded polystyrene. This suggests that the growth medium does not provide a significant barrier to heat loss in cold weather.

### Chemistry of Green Roof Runoff

Concentrations of several anions have been measured in fresh precipitation and runoff from the green roof during measurement campaigns over the past few years. Results show that chloride and sulfate concentrations are generally much greater in green roof runoff than in the incident rain. Nitrate in runoff, on the other hand, can be either greater than or less than the levels in the rain.

Examples of concentration data for sulfate are shown in Figure 3 for 2014 and 2017. The levels in rain are small compared with the runoff draining from the growth medium of the green roof.

### DISCUSSION

Figure 1 shows that the fraction of rain stored in the roof for each event varies between 0% and nearly 100%, depending on the intensity and total amount of rain in the storm. The fraction of rain stored also depends on the timing of the previous rainstorm and whether the growth medium had a chance to regenerate its storage capacity through evapotranspiration. The overall average storage per event is 51% over this time period, although many of the larger storms have much lower storage capability.

The wide range of values for the fraction of rain stored in the roof agrees with prior studies, and the overall average value of 51% is also within the range of prior work. Analysis is underway to compare values for specific events with results of modeling which accounts for the timing of successive rain events, evapotranspiration during dry periods between storms, and characteristics of the growth medium and vegetation on the roof.

Figure 3. Average concentration of sulfate in fresh rain and in runoff from the growth medium of the green roof for storms sampled in 2014 and in 2017. Measurement campaigns included four storms in 2014 and ten storms in 2017.

The studies of energy flow using temperature data from layers of the roof show that the presence of a snowpack can serve as insulation when air temperatures drop below freezing. Data from the past three winters show that the temperature of the growth medium remains at or near 0° C when a snowpack is present, even when the air temperatures fall to minus 20° C.

Although not significant as an insulator in winter, the growth medium and vegetation of the green roof can prevent temperatures from reaching high values in bright daylight conditions in summer, relative to a traditional roof surface such as asphalt. This can result in reduced space cooling demand during the short air conditioning season in summer in Syracuse.

The CHAMPS-BES model is being used to estimate heat flow through the green roof under different conditions. Results of this modeling agree with estimated heat flow based on the temperature data from the roof layers for certain conditions.

Finally, the chemistry data in Figure 3 suggests a source of sulfate associated with the green roof. Todorov et al. (2018) report higher concentrations of sulfate in runoff from a different green roof compared with incident precipitation in Syracuse. The source of this sulfate is currently being investigated. Other researchers have reported high concentrations of phosphate and nitrate in green roof runoff, e.g., Hathaway et al. (2008) and Gregoire and Clausen (2011). These nutrients are often in fertilizer added to the growth medium when a green roof is first installed to assist growth of the vegetation on the roof. High levels of nitrate were measured in runoff from a few storms in the current study, although phosphate was not observed at detectable levels in any of the samples from the Convention Center green roof.

## CONCLUSIONS

The green roof on the Onondaga County Convention Center in Syracuse, NY can store incident rain at times when the growth medium is not saturated. The stored rainwater can then evapotranspire to the atmosphere rather than contributing runoff to the combined sewers. Given the amounts of rain per event, its intensity, and the timing of rain events, the fraction of rain in each event that was stored in the roof averaged 51% over the period April 2015 to July

2017. Small events generally had most of their rain stored, but large storms had smaller fractions. The factors that influence this fraction are under investigation, and the results are expected to help designers of green roofs achieve greater amounts of rainwater storage. The growth medium and vegetation of this green roof are not observed to be significant barriers to heat loss from the building in cold weather. The extruded polystyrene insulation has a greater capacity to reduce heat loss. The chemistry of the runoff from this roof is different from the chemistry of the incident precipitation. Consistently higher levels of chloride and sulfate in the runoff compared with incoming rain are observed; the results for nitrate are mixed, with some events showing higher concentration in runoff but others showing lower concentrations. This work is important in assessing which contaminants can be contributed to runoff by a green roof, and which contaminants in incoming rain can be removed by a green roof.

## ACKNOWLEDGMENT

This work was supported in part by NSF grant #1444755, Urban Resilience to Extremes Sustainability Research Network (UREx SRN), by the NSF EMPOWER NRT program, and by Syracuse University Water Fellowships. The authors acknowledge Onondaga County Department of Facilities Management, especially Han Phan and Archie Wixson, for the use of the Convention Center green roof. The authors also acknowledge the help of many undergraduate students at Syracuse University for assistance in different parts of this project.

### **ABSTRACT**

Green roofs are increasingly implemented in cities around the world. They have the potential to improve thermal performance of building systems through evapotranspiration, thermal mass, insulation and shading. Several studies have analyzed the heat flow impact of green roofs in hot weather, but few studies have examined the thermal performance during cold conditions. Roof membranes are known to fail in cold climates due to stress caused by large temperature fluctuations. A green roof can reduce the daily membrane temperature fluctuations ( $T_{max} - T_{min}$ ) by an average of 7°C. This study presents an experimental investigation of a large extensive green roof on the Onondaga County Convention Center in Syracuse, NY from November 2017 to March 2018. The model known as CHAMPS has been applied to simulate the temperature profile through the layers of the green roof. In early winter without snow, the temperatures of the growth medium and roof membrane follow the diurnal cycle of ambient air temperatures with smaller amplitude. An average seven hour peak delay is observed. Under extremely cold weather, snow acts as an insulator. The temperature of the growth medium on the Convention Center remains slightly above freezing and is relatively steady when there is significant snow, even during extremely cold temperatures. Heat flux is dominated by the temperature gradient between interior space and the snow layer. On the basis of this work, it is shown that the CHAMPS model can play a valuable role in informing green roof design decisions.

### **KEYWORDS**

Green roof; temperature fluctuation; snow; CHAMPS; roof membrane

### **INTRODUCTION**

Green roofs normally consist of multiple layers, for example, vegetation, growth medium, drainage, waterproof membrane, and roof surface. They can vary from one design to another based on regional climates. While green roofs have been implemented in cities for years, the interest in installing green roofs in both retrofit and new construction is still increasing. Thermal benefits of green roofs include saving energy for space heating and cooling, and mitigating urban heat island effects due to evapotranspiration, direct foliage shading, the insulation effect of the soil and other factors. Another benefit is that the green roof can block solar radiation, thus protecting the base roof membrane from temperature fluctuations. In winter, a green roof can shield the roof membrane from extreme cold and from sudden changes in ambient air temperatures. Daily temperature fluctuations create thermal stress in the roof membrane and reduce its longevity (Teemusk and Mander, 2010).

The need for tools that designers and architects can use to assess the potential thermal benefits of green roofs is growing. Some studies investigate numerical models in DesignBuilder, PHPENICS, and EnergyPlus for green roof energy consumption simulations (Ran and Tang, 2017; Zhang et al. 2017; Lazzarin et al. 2005). In this paper, we present a new platform to inform the design process, the CHAMPS-BES model (Combined heat, air, moisture and pollutant simulations in building envelope systems). This model is used to assess the long-term energy and durability performance of building envelop systems.

Snow cover may provide a natural insulation layer in winter, which affects the cold weather performance of green roofs. There are two objectives of this study, both related to minimizing temperature variations that can damage the waterproof membrane on a roof. The first objective is to determine the impact of adding a green roof as a retrofit to a traditional roof on a large building in a cold climate. The second objective is to determine the impact of a significant snowpack on the retrofitted green roof.

## METHODS

### Study Site

This project focuses on the green roof on the Onondaga County Convention Center in Syracuse, NY. Syracuse is located at the northeast corner of the Finger Lakes region. It is known for its snowfall, in part due to the lake effect from nearby Lake Ontario. Based on the data from the weather station at Hancock International Airport (National Weather Service, 1938-2016), there are on average 65.2 days with snow per year. Total yearly snowfall depth is increasing (Fig.1). Snow mainly falls between the months of November and March. January is the coldest month and also has the most snowfall (Fig. 2).

Figure 1. Yearly snowfall depth (1938-2016)

Figure 2. Daily snowfall and daily minimum and maximum air temperature (1938-2016)

The Convention Center green roof was retrofitted in 2011. The roof consists of the following layers: a steel deck, a gypsum board, extruded polystyrene insulation, a second gypsum board, a drainage mat, a waterproof membrane and a coarse growth medium layer (Fig. 3). The insulation layer and layers below are original to the building. Table 1 summarizes the main thermal properties of the layers of the green roof. The total area of the green roof is 5600 m<sup>2</sup>. Plant species on the roof include *Sedum album*, *Sedum sexangulare*, *Sedum rupestre*, *Sedum floriferum*, and *Phedimus taksimense* (Squier and Davidson, 2016).

Figure 3. Schematic drawing of the Conventional Center green roof

Table 1. Thermal properties of the Conventional Center green roof

Layers	Thickness (cm)	Density (kg m <sup>-3</sup> )	Thermal conductivity (W m <sup>-1</sup> K <sup>-1</sup> )	Specific heat capacity (J kg <sup>-1</sup> K <sup>-1</sup> )
Growth medium	7.62	790	0.36	1000
Drainage mat	0.63	1000	0.92	1000
Waterproof membrane	0.12	1400	0.43	1000
Gypsum board 2	1.59	700	0.16	870
Extruded polystyrene insulation	7.62	100	0.03	1300
Gypsum board 1	1.27	700	0.16	870
Steel deck	7.62	3600	20	700

### Instrumentation and measurement

The thermal monitoring system of the green roof has been equipped with CR1000 Dataloggers and AM 16/32B Multiplexers (Campbell Scientific). A weather station on the roof includes air temperature, relative humidity, wind direction and windspeed. T109 temperature sensors (Campbell Scientific) are positioned at five different heights within the green roof (Fig. 3). This temperature profile is measured at five locations on the roof; only one location (station1) is used in this study. Temperature data are averaged and reported at hourly intervals. Interior temperatures are controlled by an HVAC system. Temperature sensor Y is mounted on the ceiling of the Exhibit Hall of the Convention Center to measure the indoor temperature. Solar radiation data are obtained from Syracuse University Weather Station, which is 1.9 kilometers from the green roof. The measuring period used for thermal analysis of the green roof is November 2017 to March 2018. Manual snow depth measurements have also been conducted.

### CHAMPS simulation

Several input parameters are needed in the CHAMPS model. The weather data discussed above are used as inputs. Properties for the layers of the green roof are taken from manufacturer specifications. Snow cover is not considered in the simulation. The exchange coefficient of heat transfer is taken as 15 W/m<sup>2</sup>K, due to the large surface area of sedum plants. To assure the validity of the simulation results of CHAMPS, the model is validated using parameters for the green roof with experimental data from early November (11/1/2017-11/7/2017). After the validation, two case studies are performed based on the objectives:

- To determine the impact of the retrofit, CHAMPS is run for the case of the Convention Center traditional roof before the retrofit. The output of CHAMPS is compared with the experimental data from the green roof.
- To determine the impact of a snowpack on the green roof, CHAMPS is run for the green roof without snow. The output of CHAMPS is compared with experimental data from the green roof with a significant snowpack.

## RESULT

### Winter thermal performance

During the experimental campaign period, there were 87 days with snowfall in Syracuse. The average ambient temperature on the roof was  $-0.24^{\circ}\text{C}$ . Temperature profiles for nine days in early November and early January are shown in Fig. 4. The extruded polystyrene layer contributes most to the effective insulation across the roof layers, where the largest temperature difference is between sensor A and sensor B. Early November represents typical early winter without snow in Syracuse. The temperatures of layers above the extruded polystyrene insulation (B, C, and G) follow the diurnal pattern of ambient air but with slightly smaller diurnal variation. An average of 7 hours delay in peak temperature is observed based on the temperature in the growth medium (G), compared to the ambient temperature. Early January represents a typical snowy winter period in Syracuse with a significant snowpack over the full nine-day period. Snow depth along the roof from west to east measured on January 9, 2018 is highly variable (Fig. 5). The snow depth on top of station 1 was 0.1 m. Figure 4 shows that the temperature of the growth medium was roughly constant at around  $0^{\circ}\text{C}$ . This is true even when the ambient air temperature was  $-20^{\circ}\text{C}$  on occasion. This shows that the impact of snow accumulation on roof temperature is significant. A similar finding was reported by Getter et al (2011).

Figure 4. Temperature profiles in early November (no snow) and January (snow cover)

Figure 5. Snow depth measurement on Jan-9-2018

### Model validation

The developed green roof model in CHAMPS has been validated using the data of the first week in November. The simulated growth medium temperature is compared with the measured data (temperature sensor G) in Fig. 6. On average, the CHAMPS model overpredicts the measured

temperature by only 17%. The simulated green roof model appears to be reliable and can be used to simulate the traditional roof and green roof without snow cover.

Figure 6. The validation of the CHAMPS model using experimental data for layer G

### Temperature fluctuations on the membrane

The daily fluctuation is defined as the difference between daily maximum temperature and daily minimum temperature. A traditional roof model was developed in CHAMPS by deleting the growth medium and drainage mat layers. The temperature fluctuations of membrane on the traditional roof are far greater than those measured on the green roof in early winter (Fig. 7). The growth medium and drainage mat clearly play an important role in reducing temperature fluctuations on the membrane.

Figure 7. Temperature fluctuations at the membrane of the simulated traditional roof and measured on the green roof

Figure 8. Temperature of the membrane for two conditions: simulated result with no snow cover and measurements with snow cover

### Insulation effect of the snow cover

The green roof is simulated without a snow cover using early January meteorological data in CHAMPS. The membrane temperatures without a snow cover are compared with the measured membrane temperatures under snow (Fig. 8). The role of snow accumulation in reducing temperature fluctuations is significant. Without snow cover, under the same weather conditions, the membrane temperature could range from -18 °C to 0 °C. Under the accumulation of snow, the protection provided by the growth medium becomes negligible compared with the protection provided by the snow. The benefit of having a green roof is decreased in cold weather. This result has been reported in other studies (Lundholm et al. 2014).

### DISCUSSIONS

Green roofs modify membrane temperature fluctuations in the winter. During times without snow cover, those membranes absorb solar radiation and are subjected to moderate temperatures. At night, exposed membranes re-radiate the heat and their temperatures drop (Liu & Baskaran, 2003).

Extreme temperature fluctuations are a major cause of membrane failure. Vegetation and growth media of green roofs improve the insulation properties of buildings and decrease the absorption of solar radiation, protecting the membranes. During snowy winter periods, snow cover promotes higher survival of perennial plants due to warmer soil temperatures. The snow cover also decreases temperature fluctuation at the membrane. In this study, a simulation using CHAMPS has been based on an energy balance through layers. Wind effects and moisture properties have not been considered due to lack of data, although those are crucial factors in assessing the overall energy performance of green roofs. Next, moisture and wind effects will be added to the simulation.

## CONCLUSIONS

In this study, a large extensive green roof in Syracuse, NY was monitored during the winter months to understand its thermal performance. Furthermore, a green roof model was developed and verified by CHAMPS software. During early winter months, the plants and growth medium add thermal mass to decrease the membrane temperature fluctuations. In very cold weather, snow accumulation acts as effective natural insulation, isolating the roof from the ambient environment. CHAMPS software enables the user to add a green roof to any roof design. It is a systems model accounting for heat, air, and moisture. CHAMPS is a useful tool to the quantitative evaluation of the energy benefits of green roofs under regional climates, and can be of value to designers when considering retrofit additions of green roofs on buildings.

### ABSTRACT

Building materials that are commonly used in urban areas generally have higher sensible heat storage and radiation entrapment, while having lower moisture storage and evapotranspiration, in comparison to the materials found in rural areas. These differences play a significant role in the occurrence of the urban heat island (UHI) effect, which has adverse impacts on thermal comfort, energy use and public health. Coupled numerical simulations of computational fluid dynamics (CFD) with the heat and mass transfer (HAM) in porous urban materials are performed to estimate the evaporative-cooling potential of different pavements in a street canyon. The local thermal comfort following a rain event on different pavements is compared with the one in presence of a grass-covered surface. The results show that the grass-covered ground provides better pedestrian thermal comfort, followed by porous material with large liquid permeability.

### KEYWORDS

Urban climate, Thermal comfort, Computational fluid dynamics, Porous media, Vegetation

### INTRODUCTION

Pedestrian thermal comfort is influenced by mean radiant temperature and local parameters such as air temperature, relative humidity and wind speed. Urban areas generally have increased sensible heat storage and radiation entrapment while having a decreased amount of evapotranspiration. Therefore, urban materials strongly influence the outdoor thermal comfort. The present study aims to investigate the evaporative-cooling potential of various urban pavement materials, showing different thermal and moisture transport properties.

Figure 1. Schematic of the main physics implemented in the coupled urban microclimate model (CFD: Computational fluid dynamics, HAM: Heat and moisture transport).

A fully-integrated urban microclimate model is developed, where CFD simulations of wind flow around buildings are coupled with the heat and mass transport (HAM) in porous urban materials. The model solves for wind flow, transport of heat and humidity in the air and

transport of heat and moisture in building materials (Fig 1). Solar (short-wave) and thermal (long-wave) radiative heat exchange between surfaces and the sky are taken into account with multiple with diffuse reflections. Surface wetting due to wind-driven rain (WDR) is calculated based on an Eulerian multiphase model.

The proposed model is applied on a street canyon, where the three-dimensional heat and mass transport within the street-canyon ground and facades is coupled with the wind flow. The study at local scale ( $< 100$  m) allows for parametric studies, where different contributions to thermal comfort can be evaluated in detail, such as shading, convective cooling, sensible heat transfer due to rain and evaporation. Detailed temporal and spatial analyses can be performed. The present study focuses on the drying period of different porous urban materials following a rain event. The impact of drying of pavement materials on outdoor thermal comfort is compared with the impact of evapotranspiration from a grass-covered surface. The thermal comfort for pedestrians is evaluated using the Universal Thermal Climate Index (UTCI) (Fiala et al. 2001). UTCI provides the perceived temperature based on surface temperatures, air temperature, relative humidity and wind speed.

## NUMERICAL MODEL AND METHODOLOGY

### Governing equations

The wind flow is solved using 3D steady Reynolds-averaged Navier-Stokes (RANS) with the standard  $k-\epsilon$  model. Additionally, transport equations for heat and moisture are solved. Heat is considered as an active scalar, where buoyancy is modeled by using a compressible formulation of the Navier-Stokes equations and calculating air density based on ideal gas law instead of the Boussinesq approximation. Moisture is modeled as a passive scalar, where the transported quantity is the humidity ratio, i.e. ratio of the mass of water vapor to the mass of dry air. Grass is modeled as a porous zone, providing the source/sink terms for heat, moisture and momentum (Manickathan et al. 2018a). Transpiration from grass blades is calculated based on leaf stomata resistance. Grass leaf temperature is calculated with an iterative energy balance calculation based on latent and sensible heat fluxes (Manickathan et al. 2018b).

Absorption, transport and storage of heat and moisture are simulated within the building materials using coupled heat and moisture transport equations for porous media. The present study uses the continuum modeling approach, where the different phases are not distinguished separately at a certain point in the material but, instead, the macroscopic behavior of the porous material is modeled. Within porous urban materials, the coupled heat and moisture transport equations are solved (Janssen et al, 2007):

$$(c_0\rho_0 + c_l w) \frac{\partial T}{\partial t} + \left( c_l T \frac{\partial w}{\partial p_c} \right) \frac{\partial p_c}{\partial t} = -\nabla(q_c + q_a) \quad (1)$$

$$\frac{\partial w}{\partial p_c} \frac{\partial p_c}{\partial t} = -\nabla(g_l + g_v) \quad (2)$$

where  $w$  denotes moisture content,  $p_c$  capillary pressure,  $c_0$  specific heat of dry material,  $\rho_0$  density of dry material,  $c_l$  the specific heat of liquid water,  $T$  absolute temperature. The fluxes  $q_c$  and  $q_a$  denote conductive and advective heat transfer, whereas  $g_l$  and  $g_v$  denote liquid and vapor moisture transfer including latent heat. The moisture exchange at the exterior surfaces of building materials comprises the rain flux and the convective vapor exchange, whereas the heat exchange comprises the convective heat transfer, the radiative heat transfer, the sensible

heat transfer due to rain and the latent and sensible heat transfer due to vapor exchange. Wetting due to rain on each surface in the computational domain is predicted using an Eulerian multiphase model (Kubilay et al. 2014), which solves for different sizes of raindrops and calculates the WDR intensity.

Solar and thermal radiative fluxes are calculated with separate systems of linear equations based on a radiosity approach. The direct component of incoming solar radiation is calculated with ray tracing. Multiple reflections of both solar and thermal radiation are calculated using view factors, which are calculated based on algebraic relations between surfaces. All building surfaces are assumed to be opaque to both longwave and shortwave radiation. The model further assumes that the building surfaces are grey, i.e. emissivity and absorptivity are equal and independent of wavelength. Absorption of solar radiation within the grass zone is modeled based on the Beer-Lambert law.

The numerical multi-transport model is implemented into OpenFOAM. The general framework and the detailed methodology of the model were given in an earlier paper (Kubilay et al. 2017).

### **Coupling algorithm**

The coupling between the air and porous domains is performed by sequentially solving the steady RANS equations in the air and the unsteady heat and moisture transfer in porous building materials. This approach is valid due to the fact that the time scale of transport in building materials is larger than the time scale of transport in air. For the air domain, Dirichlet boundary conditions are used, where the values for temperature and humidity ratio are defined at the coupled boundaries. For the porous domains, Neumann boundary conditions are used, where the heat and moisture fluxes are defined at the material surfaces.

Transient heat and mass transport in porous domains are simulated using adaptive time steps (Janssen et al. 2007), during which the solution of the air domain remains constant. At each time step, internal iterations between heat and moisture equations are performed until temperature and moisture content values converge, while the thermal radiative heat fluxes are updated accordingly. Finally, the new values for temperature and moisture at the solid boundaries are used to solve the steady air flow for the next exchange time step. This information exchange between domains is repeated at each exchange time step (Saneinejad et al. 2014). In this study, an exchange time step of 10 min is chosen. For a more detailed description of the model, the reader is referred to Kubilay et al. (2017).

### **DESCRIPTION OF THE CASE STUDY**

The case study is performed on an isolated three-dimensional street canyon, which is composed of two buildings with flat facades and horizontal roofs with a north-south orientation. Both buildings have the dimensions of height  $\times$  length  $\times$  width of  $10 \times 10 \times 50 \text{ m}^3$ . The computational domain is shown in Fig 2 as well as the orientation of the street canyon with respect to the wind direction and sun. For simplicity, wind speed is assumed constant at 5 m/s at the building height and wind direction is assumed perpendicular to the street canyon, i.e. from west. The variation of ambient temperature and total solar radiation intensity are based on June 21<sup>st</sup>, a typical early summer day with moderate ambient temperatures in Zurich, Switzerland. The ambient temperature varies between 11°C and 19°C, while the relative humidity (RH) varies between 62% and 86%. The simulations are run for several days with ‘dry’ conditions with no rain event until the conditions reach a daily thermal cycle that is

independent from the initial values. For 'rainy' conditions, a rain event of 1 mm/h intensity is applied for a duration of 10 hours at nighttime.

The leeward and windward facades of the street canyon are finished with an exterior layer of brick masonry with a thickness of 0.09 m. For the outer layer of the street-canyon ground, which has a thickness of 0.10 m, different materials are considered: concrete, soil and brick. Beneath this layer, an additional soil layer with a depth of 1.90 m is present for each case. Thermal properties for the dry materials are given in Table 1. For the simulations with grass, no rain event is modeled, however, transpiration rate is calculated based on the assumption that enough moisture is available in the soil at all times. Grass blades of 10 cm height are considered on the street-canyon ground (soil). Leaf area intensity (LAI) is taken as 2 and leaf drag coefficient as 0.2.

Figure 2. Computational domain and orientation of the street canyon with respect to wind direction and sun trajectory.

Table 1. Thermal properties of the dry porous media.

Material	Density [kg/m <sup>3</sup> ]	Specific heat [J/kgK]	Thermal conductivity [W/mK]
Bare soil	1150	650	1.500
Concrete	2280	800	1.500
Clay brick	1600	1000	0.682

## RESULTS

Fig 3 compares the surface temperature at the center of the street-canyon ground for a duration of two days. Before the rain event, the surface temperatures for bare soil, concrete and clay brick reflect the thermal diffusivity and specific heat of the respective materials. After the rain event, due to evaporation, the maximum surface temperature decreases as much as 20°C for brick and 15°C for soil. A slightly larger reduction of temperature is observed for brick than for soil as the brick is capillary active and has a larger liquid permeability than soil in this case. For concrete, the decrease in maximum temperature is negligible as a much smaller amount of water is absorbed in concrete. Grass-covered soil temperature is in general at around the same values as concrete as it is shaded by grass, while the maximum grass leaf temperature is 26°C as a result of latent heat due to evaporation.

Fig 4 compares the conditions at pedestrian height (1.75 m) at the center of the street canyon, namely the air temperature, air relative humidity and the UTCI. Before the rain event, as a result of evapotranspiration, the lowest air temperature and the highest relative humidity are

observed for grass-covered street canyon. After the rain event, air temperature decreases by up to  $1.4^{\circ}\text{C}$  for brick. However, simultaneously, a considerable increase of relative humidity is observed as shown in Fig. 4(b). Overall, the lowest UTCI is observed for grass (Fig. 4(c)). The decrease in UTCI due to rain event is up to  $2.0^{\circ}\text{C}$ .

Figure 3. Variation of surface temperature at the center of the street-canyon ground for different materials.

Figure 4. Variation of a) air temperature, b) air relative humidity and c) UTCI at pedestrian height at the center of the street canyon.

## DISCUSSION AND CONCLUSIONS

The influence of different porous urban materials exposed to environmental loading is investigated. Evaporative-cooling potential for the materials is compared to the conditions provided by the grass-covered area. While the results obtained for the isolated street canyon cannot be generalized for complete range of urban areas, the study indicates several significant results. It is found that the effect of transpirative cooling due to grass is apparent both in terms of air temperature and of UTCI. While, the increase in relative humidity has an adverse effect on thermal comfort, overall, improved conditions are observed for the grass-covered surface. The evaporative-cooling effect due to the absorption and evaporation of rain water in porous urban materials increases as the liquid permeability of materials gets larger. We note that the conclusions depend on several factors such as total wetting amount due to rain, wetting period of the day, leaf area intensity of grass and local wind flow conditions. The transpiration from grass is also dependent on the water availability in the soil. Further work is planned on including on evaluating the local effects of heat waves, at neighborhood scale.

## **An investigation on the quantitative correlation between urban morphology parameters and outdoor ventilation efficiency indices**

Yunlong Peng, Zhi Gao, Wowo Ding\*

### **ABSTRACT**

Urban outdoor ventilation and pollutant dispersion have important implications for the urban planning and design of urban morphology. In this paper, two urban morphology parameters including Floor area ratio (FAR) and Building site coverage (BSC) are attempted to investigate the quantitative correlation with urban ventilation indices. Firstly, we present an idealized model including nine basic units. The FAR of model is constant 5.0, and the BSC increases from 11% to 77%, which in consequence generates 101 non-repetitive asymmetric forms. Next, the Computational Fluid Dynamics (CFD) is employed to evaluate the ventilation efficiency of pedestrian level within each model's central area. Six indicators including air flow rate (Q), mean age of air ( $\tau_p$ ), net escape velocity (NEV), purging flow rate (PFR), visitation frequency (VF) and resident time (TP) are used to assess the local ventilation performance. Results clearly show that when the FAR of the plot is specified, the local ventilation performance does not present an obvious linear relationship. As the BSC increases, the ventilation in the central area does not keep reducing. On the contrary, some forms with low BSC have poor ventilation and some particular forms with high BSC have better ventilation performance. This shows that for an urban, it not always exists poor local ventilation under the high-density conditions. The local ventilation performance can be effectively improved by rationally arranging the architectural arrangement within the plot. These findings suggest a preliminary way to build up the correlation between urban morphology parameters and ventilation efficiency. Even though the application of these results to the real cities require further research, but for this paper, it presents a feasible framework to the urban designers.

### **KEYWORDS**

correlation research, urban morphology, ventilation indicators

### **INTRODUCTION**

Past few decades the urbanization has become a global phenomenon. The urbanization process has accelerated the increase of urban density, which leads to significant differences between urban morphology and original form in natural conditions (such as the number of streets, height of buildings, void spaces, etc.). Due to the compact urban spaces, air pollutant cannot be diluted and dispersed in time and it probably causes a series of health problems.

Flow rate (Q) was used to assess the effective flow which passes through the urban canopy layer (Hang et al., 2009). The concept of mean age of air ( $\tau_p$ ) is a statistical measure of the time it takes for a parcel of air to reach a given point in the flow field after entering this flow field, and large mean age of air implies a poorly ventilated region. Purging flow rate (PFR), was introduced to predict the net rate of removing pollutant in the urban domain by (Bady et al., 2008). The visitation frequency (VF) is the number of times a pollutant enters the domain and passes through it. The residence time (TP) is the time a pollutant takes from once entering

or being generated in the domain until leaving the domain. The feasibility of PFR, VF and TP using to evaluate the urban ventilation has been verified by (Kato and Huang, 2009). The concept of net escape velocity (NEV) proposed by (Lim et al., 2014) represents the effective velocity at which the contaminant is transported/diluted from a target point, and a high NEV indicates fine removal efficiency of the pollutants.

Ventilation indicators abovementioned have been validated by wind tunnel measurement and numerical simulations. Nevertheless, morphological parameters associated with most of them are purely geometric parameters such as urban street aspect ratio ( $H/W$ ), building height ( $H$ ), building packing density ( $\lambda_p$ ) (Cheng et al., 2007), etc. However, with the increase of urban density, the floor area ratio (FAR) within urban plots is the first key factor considered by urban designers and planners, which involves economics, policy and urban development strategies, etc. In the early planning stage, the FAR of urban plot has been determined first, so it may be of great significance to investigate the relationship between building site coverage (BSC) and ventilation performance in a specific area when the FAR is constant. Previous research (Peng et al., 2017) has preliminary explored the relationship between FAR, BSC and ventilation performance, but only the average wind ratio was employed. In this paper, more comprehensive ventilation assessment indicators and substantial forms will be adopted for comprehensive research.

## METHODS

### Morphology characteristics of idealized models

During the early stage for urban planning and designing, the floor area ratio (FAR) within urban plots has been formulated, which is closely related to the cost, benefit, development strategies etc. Once the FAR of plots has been specified, it will not be easily changed. The main factors affecting the morphology of plots include the building site coverage (BSC) and the architectural arrangement within the plots. The idealized model is consisted of 9 basic units, and each unit size is a 30-meter square. The central square is the interested area which does not to be covered by building. The other eight units around the central may be covered with buildings. The FAR of all possible forms are constant 5.0, and the initial BSC is 11%, meaning that there is only one high-rise building. Meanwhile, there are five possibilities for the position of building in the plot (excluding symmetry conditions).

In order to explore the correlation between morphology and performance, all possible forms should be classified. As shown in Figure 1. according to the architectural layout around the central area, the model is divided into Form C and Form B. The Form C configuration means that the front and back directions of the central area are not blocked and there have a channelling effect. The Form B1~B3 means the number of building along the windward projection. The Form B(F1~F3) means the number of building front (in the first two rows) along the windward projection. In this study, there only one incoming wind direction ( $\theta=90^\circ$ ) is considered. As a consequence, the symmetrical configurations along the east-west direction are exclude. When the BSC increases from 11% to 77%, a total of 101 asymmetrical forms are generated.

Figure 1. Idealized models with BSC increasing from 11% to 77%

## CFD simulation setup

Figure 2. Schematic sketch of geometry and boundary conditions used in CFD simulations

The computational domain size is shown in Figure 2, the inflow and lateral boundaries are set 5H and away from the buildings. The outflow and the top boundaries are respectively 15H and 6H. Mesh resolution fulfils the major simulation requirements as recently recommended by (Franke et al., 2007) and by the Working Group of the Architectural Institute of Japan (AIJ). The comparison showed that the k- $\epsilon$  model can be used for such configurations and that there is a good agreement in terms of the essential features of the mean flow. The inlet profiles of mean wind speed  $U$ , turbulent kinetic energy  $k$  and turbulence dissipation rate  $\epsilon$  were identical for all simulations. A logarithmic mean speed profile was fitted to the measured profile using Eq. (1) where  $z_0$  is the aerodynamic roughness length taken as 0.2m,  $k$  the von Karman constant equal to 0.42 and  $z$  the height coordinate. Turbulent kinetic energy profile was calculated as in Eq. (2), where  $I_u$  is the measured longitudinal turbulence intensity, and the turbulence dissipation rate  $\epsilon$  was calculated as in Eq. (3).

$$U(z) = \frac{U_{ABL}^*}{\mathbf{K}} \ln \left( \frac{z + z_0}{z_0} \right) \quad (1)$$

$$k(z) = \frac{u_{ABL}^{*2}}{\sqrt{C_\mu}} \quad (2)$$

$$\varepsilon(z) = \frac{u_{ABL}^{*3}}{\kappa(z + z_0)} \quad (3)$$

The indicators used for correlation studies with morphological parameters in this study include flow rate (Q), local mean age of air ( $\tau_p$ ), net escape velocity (NEV), purging flow rate (PFR), visitation frequency (VF) and residential time (TP). Due to the limitation of pages, the calculation equations for these indicators are not listed here. Uniform release method is applied in this study (Hang et al., 2009). In this paper we used uniform tracer gas source from ground up to 2 m for ventilation analysis. The tracer gas emission rate  $S_c = 10^{-7} \text{ kg/m}^3 \text{ s}$  to ensure the source release produced little disturbance to the flow.

## RESULTS

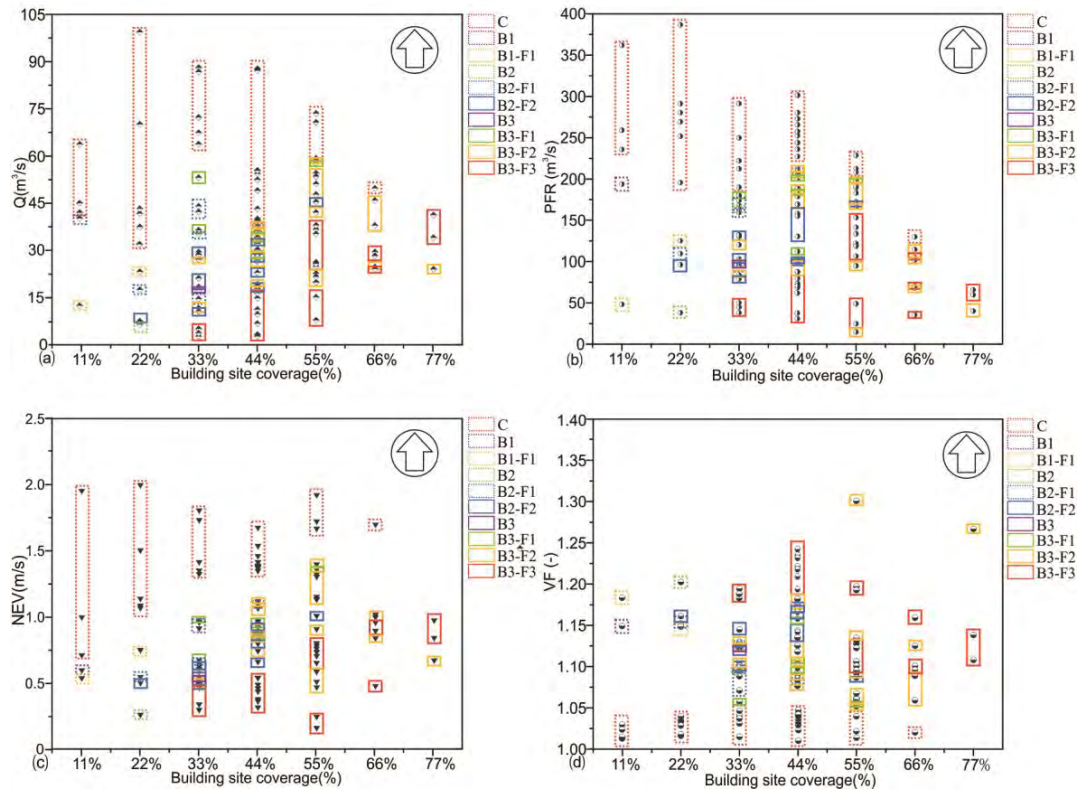

Figure 3. The value of ventilation indices within each configuration of BSC increasing from 11% to 77% (a) Q, (b) PFR, (c) NEV, (d) VF

Figure 3 shows the results within the study domain at pedestrian level for the BSC increasing from 11% to 77%. Results clearly show that the level of ventilation efficiency within the central area decreased as the BSC increased in general, due to the increase of buildings within the plot. However, it is not absolutely that with the gradual increase of the BSC, the ventilation performance of the central area is declining in particular in the calculation result of NEV and VF (Fig. 3c, 3d). When the BSC continues to increase from 44% to 77%, the NEV and VF become slightly better. However, the result of each model in Figure 3 does not intuitively

reflect the relationship between ventilation indicators and morphological parameters. Also, the number of configurations corresponding to various BSC is also different and it is difficult to make comparisons. Therefore, the average value and the error are calculated for each configuration, which can reflect the intuitive relationship between the indicators and the morphology as the BSC changes.

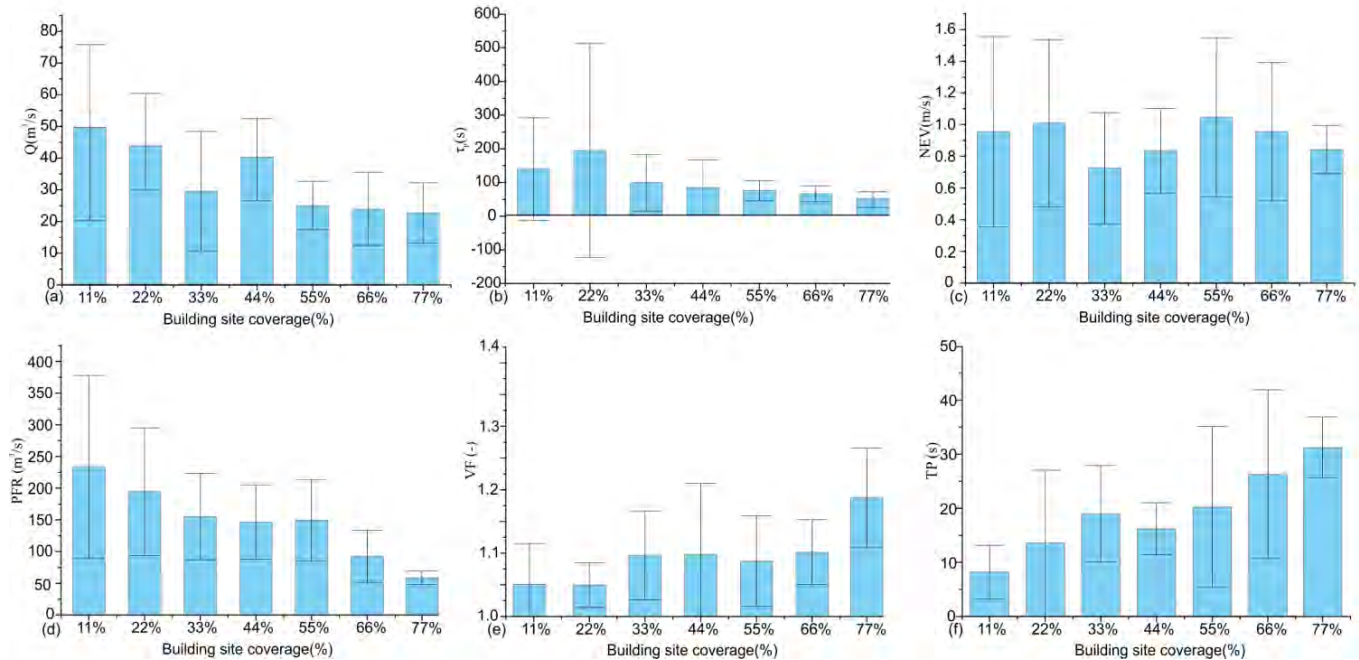

Figure 4. The average value and variance of each index corresponding to BSC increasing from 11% to 77% (a)  $Q$ , (b)  $\tau_p$ , (c) NEV, (d) PFR, (e) VF, (f) TP

In Figure. 4, results of different indicators show that the ventilation performance at the pedestrian level in the central area is slightly lower as the BSC increases. In particular, when the BSC is 44%, values of six indices show that the capacity of removal pollutant obvious enhances. With the BSC ranges from 44% to 77%, although the buildings density in the plot is gradually raise, meanwhile the channeling effect is interrupted and weak. Due to the constant of FAR, the building height gradually decreases with the BSC increasing. The air flow flush the central area is mainly mean flow when the BSC is at a low level. As the BSC increases, and the building height reduces, especially the BSC is 55%, the fresh air entering the domain through the turbulent flow from the roof of building enhances obviously, which is consistent with the research results of (Hang et al., 2015), the fresh air flow flush and remove the concentration of pollutants in the central area and plays a role in improving ventilation performance.

## DISCUSSIONS

It can be explained that for an urban area where the density is at a high level, the wind channeling effect is not the only and effective way to dilute or remove air pollutants. When the average building height is relatively low, the effect of turbulence flow can effectively remove the pollutants at the pedestrian level and improve the local ventilation performance. At the same time, the results also yield that the BSC is not the only factor that determines the ventilation performance within the urban plot, and the building patterns within the plot also plays a significant role on the pollutant dispersion.

## CONCLUSIONS

First of all, to make constant the FAR to 5.0, the BSC gradually increases from 11% to 77%, resulting in a total of 101 asymmetrical idealized plot configurations. Second, we propose six indicators for correlation with morphological indicators. Simulation, and statistical results show that when the BSC is 11%, 22%, and 33%, the ventilation performance at pedestrian level within the domain decreased significantly, which illustrates when the BSC is below 33%, the building height is at a high level. With the increase of BSC, the fresh airflow flushes into the center area is interrupted by isolate building, resulting in an increase in the concentration of pollutants. When the BSC increased to 44%, 55%, 66%, and 77%, though the ventilation performance was slightly lower than before, due to the lower average building height, the fresh air flows into the center area which is mean flow to turbulent flow through building roof. The results in this study show that BSC and FAR are effective morphological parameters for establishing correlation studies. For high-density cities, the ventilation performance of void spaces can be effectively improved by reducing the average height of buildings.

Moreover, this study is still an idealized configuration. Subsequent research will add secondary roads within the central area, and discuss which indicators are most sensitive to morphological changes and more suitable for in-depth correlation research with BSC and FAR.

### ABSTRACT

Today, ongoing discussions on climate change, depletion of fossil fuels and energy efficiency emphasize the need for a more sustainable built environment and thus the need to reduce energy consumption in buildings and urban textures and reduce greenhouse gas emissions. Therefore the evaluation of building energy performance with a holistic approach, taking the effect of urban textures and microclimates into consideration has become very significant in the recent years. Urban texture is a commonly accepted expression including the form and height of buildings, the width of streets, their orientation, spatial configuration and arrangement in space intersection, vegetation and so on. This study aims to develop and suggest a model which allows the evaluation of the level of effects of the design parameters which should be considered at the scale of urban textures, on the energy performance of buildings to design sustainable, energy efficient built environments. In the first stage energy performance of a reference building modeled in different urban texture alternatives was evaluated. The evaluations are performed through DesignBuilder simulation program for the location of Istanbul representing temperate-humid climatic region. The parameters of aspect ratio (H/W) and orientation were used to develop different urban texture alternatives. In the second stage, analyses of outdoor thermal comfort of the existing condition and the condition with the added effect of vegetation for the alternatives with the lowest overall energy consumption were conducted with the ENVI-Met program. The thermal comfort parameters of air temperature, mean radiant temperature, wind speed and physiological equivalent temperature (PET) index were used to evaluate outdoor thermal comfort in streets. As a result, the urban texture alternative which achieved the optimum result for energy performance and with regard to outdoor thermal comfort was determined.

### KEYWORDS

Sustainable Built Environment, Urban Texture, Building Energy Performance.

### INTRODUCTION

With the rapid growth of urban areas all around the world, urban textures are considered to be the main source of CO<sub>2</sub> emissions responsible for climate change. Therefore, urban textures and buildings in these areas should be planned, developed and used optimally in relation to energy consumption and CO<sub>2</sub> emissions caused by the consumed energy. On the other hand, when the relation between urban textures and climate is examined, it is possible to conclude that design parameters including layouts, building forms, building envelopes, and landscape planning have an impact on the urban climate, and urban climate has an impact on the energy performance of buildings and on the use of urban open spaces. Therefore, the correlation between urban texture and building energy consumption underlines a complex balance that includes climate parameters and urban canyons and buildings. Thus, design of urban textures and study of building energy consumption within the designed urban textures to achieve sustainable built environment have gained speed. The term “urban texture” means a territorial, planning and constructive organization, which has homogeneous characteristics from the

point of view of the historical transformation and of the formal and dimensional relationship between public and private spaces (Tiziana and Marianna, 2013). Urban texture is a commonly accepted expression including the form and height of buildings, the width of streets, their orientation, spatial configuration and arrangement in space intersection, vegetation and so on (Ratti et al. 2005). To describe and model the interaction of the urban texture with the climate and energy, the following parameters should be considered: aspect ratio, street orientation, sky view factor, local and neighborhood scale, street trees and urban parks (Oke, 1976; Golany, 1995; Sanaieian et al. 2014, Jamei et al. 2016). The most important parameter among those that are considered to define urban textures that affect outdoor comfort conditions based on climatic characteristics is the ratio of average building height (H) to average street width (W). This aspect ratio, which defines the relations among buildings in the sections of urban textures, controls solar access and wind movements with limitations of orientation and causes changes in micro-climate data. Additionally, it can affect comfort conditions of the buildings within an urban texture. Urban textures in temperate climatic regions are mostly designed based on the building requirements to have access to solar radiation during a heating period, but the level of effect of this approach on outdoor conditions is not evaluated. Therefore, the H/W ratio is taken as the primary parameter in many studies aiming to analyze outdoor thermal comfort. The orientation effect is also taken into consideration to evaluate outdoor conditions according to changing aspect ratios (Toudert and Mayer, 2006; Andreou 2013; Kariminia et al. 2015; Yang and Li, 2015). Thus, parameters such as H/W ratio, orientation and the use of green spaces that strongly affect energy performances of buildings and outdoor thermal comfort conditions should be taken into consideration during the design stage. This study aims to develop a model with which, in addition to urban texture-building interaction, outdoor thermal comfort, can also be analyzed to design sustainable, energy efficient environments. The effect of the design parameters of urban textures (building height/street width, street and façade direction, vegetation) is analyzed using the alternatives defined for this purpose. The analyses are conducted for Istanbul representing temperate-humid climate where the heating period is longer than the cooling period and the design alternatives suggested based on the findings can be applied to other regions with temperate-humid climate conditions.

## METHODS

The objective of the study is to evaluate the effect of urban texture alternatives developed with the defined design parameters on the outdoor comfort conditions and energy consumption of the buildings within those urban textures. In order to evaluate the effect of urban texture alternatives on energy consumption of the buildings, a reference building is defined for each urban texture and energy consumption is calculated for this reference building. The reference buildings are given in Figure 1. Thus, the steps to be followed in this study are given below.

### Defining design parameters for urban textures

In order to analyze the outdoor thermal comfort level as well as the urban texture-building interactions, first the design parameters for urban textures should be defined. For this purpose, various urban textures were created based on the H/W ratio commonly used to define urban textures, and the effects of such urban textures were analyzed. In order to develop different urban textures, the H/W ratio is taken as 1.00 for uniform canyon; 0.50 for shallow canyon and 2.00 for deep canyon (Ahmed et al. 2015). To determine street widths for the three different H/W values used in the study, a 5-story residential building representative of the residential buildings commonly used in Istanbul was evaluated. The created urban texture alternatives with different H/W ratios are oriented to north-south, east-west, northwest-

southeast, northeast-southwest in order to determine the effect of orientation on outdoor thermal conditions (Figure 1).

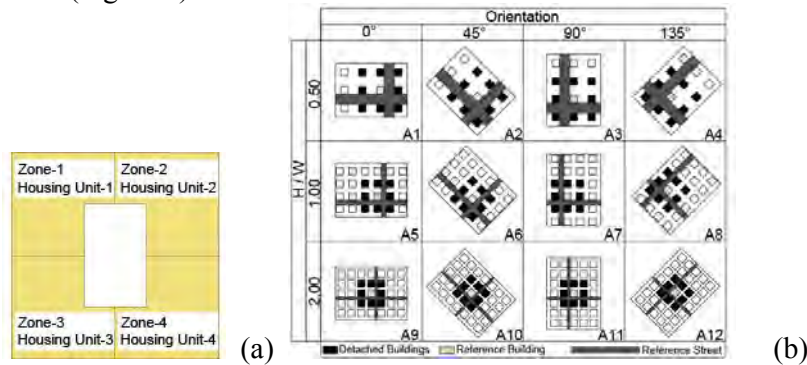

Figure 1. Floor plan of the reference building (a) and urban texture alternatives (b).

### Defining design parameters for the reference buildings

In order to achieve general acceptance to define the design parameters for the reference building in the urban texture, residential building types built by TOKI (Housing Development Administration of Turkey), which plays an important role in the construction of residential buildings in Turkey, were researched and assessed. Based on the research, housing units with a building coverage of  $100\text{m}^2$  were chosen. The A/V ratio (total external surface / building volume) is 0.2; the total floor area of building is  $400\text{m}^2$  and the total building height is 15.00 m. While developing the details for the layering of building envelope of the reference building, the building envelope sections which are commonly used in the existing mass housing projects were used and the total heat transfer coefficient values ( $U$ ,  $\text{W}/\text{m}^2\text{K}$ ) of the opaque and transparent components of the building envelope comply with the limit values set for Istanbul in TS 825 (2013) ( $U_{\text{wall}}:0.57\text{ W}/\text{m}^2\text{K}$ ,  $U_{\text{g\_floor}}:0.53\text{ W}/\text{m}^2\text{K}$ ,  $U_{\text{roof}}:0.38\text{ W}/\text{m}^2\text{K}$ ,  $U_{\text{window}}:1.40\text{ W}/\text{m}^2\text{K}$ ). The transparency ratio (total transparent area / total façade area) was assumed as 30% for all façades. There are four housing units on each floor of the building and each housing unit was accepted as a single conditioned zone (area which is heated/cooled). The indoor comfort temperature was accepted as  $20\text{ }^\circ\text{C}$  for the heating period and  $26\text{ }^\circ\text{C}$  for the cooling period.

### Development of alternatives based on the defined designed parameters

In order to evaluate energy performance of the reference building, based on the urban textures with the H/W values determined to develop alternatives for design parameters, it is assumed that the urban textures consist of detached buildings in a study area of approximately  $30,000\text{m}^2$ . The number of buildings in the urban textures varies depending on the alternatives and is shown in Figure 1.

### Evaluation of energy performance and outdoor thermal comfort of the alternatives

The DesignBuilder simulation program (DesignBuilder Software, 2018), which is the comprehensive interface of the EnergyPlus dynamic thermal simulation engine, was used to evaluate the energy performance of the reference building within the urban texture alternatives. Energy consumption data obtained in the calculations were reviewed and the ENVI-met program that can simulate the effects of vegetation in addition to complex urban textures based on daily micro-climatic dynamics was used to evaluate outdoor thermal comfort conditions at the street level for the developed urban texture alternatives. Annual heating, cooling and lighting energy consumption as well as overall energy consumption

(heating + cooling + lighting) of the alternatives in which the reference building is in the urban texture or as a single building are shown in Figure 2.

Figure 2. Energy consumption of 12 alternatives in which the reference building is located in the urban texture (a) and total energy consumption of the alternatives in which the reference building is located in the urban texture and the reference building is as a single building (b).

As seen in Figure 2, solar access of the housing units is increased with the proportional widening of street widths as the H/W ratio gets smaller, and consequently heating, lighting and total (heating + cooling + lighting) energy consumption decrease and cooling energy consumption increases. Additionally, as the heating energy consumption exceeds the cooling and lighting energy consumption, it is also determinant when the total energy consumption values are compared. When we compare total energy consumption of the alternatives in which the reference building is in the urban texture with the alternatives in which the reference building is accepted as a single building; the differences vary according to the aspect ratio. Since the streets are wider (30 m) in the four alternatives with H/W:0.50, very small differences in energy consumption are observed. However, due to the decreased street widths in 8 alternatives with H/W:1.00 and H/W:2.00 (15 m and 7.5 m respectively), the total energy consumption of the alternatives in which the reference building is modeled as single building is min. 5% and max. 16% less than the total energy consumption of the alternatives in which the reference building is in the urban texture. When the results for orientation are examined, due to the fact that the reference building in the alternatives has a symmetrical plan, it is possible to note that the percentage of change in energy consumption due to orientation is rather low. Among the 12 urban texture alternatives evaluated in this study, the highest heating and the lowest cooling energy consumption is achieved when the H/W ratio is 2.00. However, when the total energy consumption is taken into consideration, since the heating period is longer than the cooling period, heating energy consumption has more impact on the total energy consumption. Therefore, the alternatives with H/W ratio of 2.00 (A9, A10, A11 and A12) and the alternatives with the orientation angles of 0°, 45° and 135° (A1, A2, A4, A5, A6 and A8) do not give favourable results for total energy consumption. So, these alternatives are not included in the evaluation of outdoor thermal comfort in the next stage.

The outdoor thermal comfort evaluation is performed for the selected alternatives of A3 and A7 (with 90° orientation and the aspect ratios of 0.50 and 1.00 respectively) which resulted in lowest total energy consumption in the first stage. The evaluation is done at street level, through ENVI-Met microclimate simulation model for a period of 24 hours on July 21<sup>st</sup>. The meteorological inputs are entered through simple forcing method through which temperature and humidity profiles in 24 hourly values are forced onto the simulation model. The standards TS 1576 (2012) and TS 12174 (2012) were used to define street layouts in the alternatives. The surface material for sidewalks is assigned as concrete. Besides the analysis of the base cases of A3 and A7, potential improvements by the use of vegetation were evaluated through

the simulation of the urban texture alternatives A3-t (3 rows of trees) and A7-t (2 rows of trees) (Figure 3).

Figure 3. Street sections of alternatives for outdoor thermal comfort evaluation.

The thermal comfort parameters of air temperature ( $T_a$ ), mean radiant temperature (MRT), wind speed ( $V_a$ ) and physiological equivalent temperature (PET) (personal parameters based on "standard human" as defined in TS EN ISO7730 (2002) and with a summer clothing factor of 0.5 clo) were calculated at indicated street midpoints, at a height of 1.2m ( $z$ ) from the ground (Figure 4).

Figure 4. Temporal distribution of thermal comfort parameters.

When the hourly distribution of the thermal comfort parameters at the street midpoint are compared, the model A7 with H/W: 1.00 could have up to 16 °C higher PET values compared to A3 with H/W: 0.50 thus creating more comfortable outdoor urban spaces. The addition of trees has changed the mean radiant temperature and PET values in a similar manner. The addition of trees has reduced PET values at street midpoint up to 15 °C during day time and increased PET values slightly, up to 2 °C during the night time. During the day time, the mean radiant temperature in the streets with trees (A3-t and A7-t) is up to 32 °C lower, compared to the streets without trees (A3 and A7). On the other hand, after 19:00, the mean radiant temperature in the streets with trees gets slightly higher than the streets without trees. However, as the night time temperatures are already low, this result is not a significant drawback. Looking at the results for air temperature, the addition of trees has lowered the air temperature up to 1 °C around 13:00. Finally when the results for wind speed are compared, the addition of trees have reduced the air velocity up to 50%. Despite the reduction in air velocity and slight increase in PET values at night, the overall improvement in outdoor thermal comfort by the addition of trees is very significant.

## CONCLUSIONS

Urban texture is the most important parameter that affects long term building energy consumption because an urban texture continues to exist for many years without any major change and affects the performance of the buildings that belong to that urban texture. Therefore, inclusion of the effects of urban microclimates in all evaluations of building energy performance, is critical for making correct decisions for sustainable, energy efficient buildings and urban texture design. This study aims to develop a model with which, in addition to urban texture-building interaction, outdoor thermal comfort, can also be analyzed to design sustainable, energy efficient environments. The effect of the design parameters of urban textures (building height/street width, street and façade direction, vegetation) was analyzed using the alternatives defined for this purpose for Istanbul representing a temperate-humid climatic region. The findings are compared and presented. However, similar studies using a high number of alternatives should be conducted in order to have an acceptable general conclusion.

### **ABSTRACT**

The rapid urbanization of the last century coupled with local climate change imputable to anthropogenic actions triggered a huge research effort aimed at investigating urban microclimate. Typically, cities present a variety of microclimates due to the internal variation of their landscapes in terms of morphology, surfaces properties, presence of greenery, etc. Location-specific microclimate conditions affect both (i) building energy needs and (ii) citizens' quality of life. For these reasons, a small-scale analysis from the citizen perspective with high-time-resolution environmental data is required. Recent studies tried to reach that level of precision by using remote sensing, movable observational transects or dense network of weather stations located in specific points of the urban settlement. Within this framework, the current study presents a new bottom-up methodology which aims at identifying granular microclimates within the same built environment. The method consists of a cluster analysis of experimental data collected by a wearable miniaturized weather station which allows the monitoring of outdoor parameters at the pedestrian height and with high-time resolution. Experimental campaigns were conducted in five different case studies, where a planned monitoring path was repeated at different times during the day. The heterogeneity of the context demonstrates the replicability of the proposed method, suitable for clustering different areas of a same urban context characterized by variable local microclimate. The study contributes to better understand the variability of building boundary conditions for energy need prediction and indoor/outdoor environmental comfort assessment.

### **KEYWORDS**

Urban Microclimate, Urban heat island, Outdoor thermal comfort, Monitoring, Environmental quality.

### **INTRODUCTION**

The urban population is continuously growing, and it will reach the 60% of the world population in 2030 according to United Nation predictions (2016). The urbanization process progressively changes land usage, consequently modifying the energy balance in cities leading to the well-known phenomenon of the Urban Heat Island (Oke, 1973;). UHI negatively affects both citizens' health (Serrat et al., 2006;) and building stock energy consumption (Akbari et al., 2001). Moreover, such negative consequences are going to be exacerbated in the next decades due to climate change since extreme weather events as the heatwaves are predicted to be more intense and more frequent (Founda and Santamouris, 2017). Nevertheless, the complex and heterogeneous morphology of cities causes sensible diversification of the microclimate within the urban canopy layer. As a matter of fact, Jonsson (2004) found out an intra-urban temperature difference of the same magnitude as the detected urban-rural differences in Gaborone, Botswana. Intra-urban temperature differences up to 5°C were also detected in Wien, Austria, by Mahdavi et al. (2017). Moreover, the study

demonstrated how specific microclimate conditions affect the building thermal performance leading to a mean annual heating load variation up to 16.1 kWh/m<sup>2</sup> per year among the analysed areas.

Within the presented framework, the detection of intra-urban microclimate diversifications and how much they are related to different urban structures is a key point for the scientific community. To get this goal, high-spatial-resolution weather data are required. Nowadays, the most common implemented methodologies include: (i) remote sensing (Voogt and Oke, 2003;), (ii) permanent network of weather stations (Paolini et al., 2017), and (iii) observational mobile transects (Hart and Sailor, 2009; Parace et al., 2016). Nevertheless, an investigation procedure focused on the pedestrian perspective is still missing. This work presents a new bottom-up methodology which aims to identify different and distinctive microclimates within the same built environment from raw environmental data collected accordingly to the pedestrian perspective. An innovative monitoring wearable system is presented and the obtained outcomes are post-process through *k-means* clustering procedure. The outlined methodology is applied to five different case studies to test its validity in different urban configurations. The final findings can therefore help policymakers to select suitable mitigation strategies for the most critical areas of their cities in terms of both outdoor thermal comfort and building stock energy consumption.

## METHODS

The present work proposes a bottom-up process to detect local urban microclimate conditions based on collected experimental data. The main environmental parameters are monitored by means of a miniaturized wearable weather station which can be easily worn by a pedestrian (Pigliatile and Pisello, 2018). Therefore, the perspective of the monitoring campaign is human centred, and the collected data represent what citizens are subject to, in terms of environmental forcing, air quality, and thermal overheating/overcooling. The collected data are therefore statistically analysed by means of clustering to identify the intra-urban microclimate diversification.

### Monitoring campaigns

The monitoring system is a miniaturized weather station coupled with GPS tracer to link the collected environmental data to their site-specific location, i.e. latitude, longitude, altitude and attitude. The system is settled upon a common bike helmet and records all the parameters listed in (Pigliatile and Pisello, 2018) every 2 seconds, such as air temperature, relative humidity, global solar radiation, wind speed, CO<sub>2</sub> concentration, and geographical coordinates.

Five different monitored case studies are here presented. Every case study deals with different urban contexts as summarized in Table 1. All the monitoring pathways were planned to pass through areas characterized by different (i) geometrical configuration, (ii) orientation, (iii) amount of anthropogenic sources, and (iv) greenery. The equipped operator covers the same pathway at least twice during a day, i.e. around midday and around sunset, to have both (i) space and (ii) time daily variation of the key environmental parameters. Moreover, the length of each pathway allows to complete a single recording session in less than one hour on foot, so all the parameters fluctuation can be assumed to be space- and no time-dependent.

Table 1. Monitoring campaigns details

Case study	Typology	Start Time	Day	Length	
Knossos Palace archaeological site, Greek	Open area	9:00 a.m.	07/04/2017	1.2 km	~40 minutes
		3:00 p.m.		1.6 km	~40 minutes
		7:00 p.m.		1.3 km	~40 minutes

Gubbio historic centre, Italy	Packed, historical	8:30 a.m.	08/02/2017	2.6 km	~45 minutes
		2:30 p.m.		2.8 km	~45 minutes
		6:30 p.m.		2.7 km	~45 minutes
New York City (Soho), USA	Packed, low rise building	1:00 p.m.	11/30/2017	2.4 km	~35 minutes
		6:30 p.m.	11/28/2017	2.4 km	~35 minutes
		2:00 p.m.	11/29/2017	3.7 km	~45 minutes
New York City (Upper East Side), USA		5:30 p.m.	12/01/2017	3.6 km	~45 minutes
		11:45 a.m.	11/29/2017	-	~25 minutes
New York City (Wall Street), USA	Packed, high rise building	5:00 p.m.	11/30/2017	3.3 km	~25 minutes

### Data analysis

After having collected the abovementioned data, we grouped them adopting the k-means algorithm (Lloyd, 1982) which classifies data through a priori fixed  $k$  number of clusters. This allowed us to figure out potential relationships within the huge amount of observations derived from the monitoring sessions. The iterative grouping procedure minimizes the distance between the observations belonging to the same cluster and, in turn, maximizes the distance among observations belonging to different clusters. The algorithm minimizes the following objective function:

$$J(V) = \sum_{j=1}^k \sum_{i=1}^n \left( \|x_i^{(j)} - c_j\| \right)^2 \quad (1)$$

where,  $\|x_i^{(j)} - c_j\|$  is the chosen Euclidian distance between an observation  $x_i^{(j)}$  and its cluster centre  $c_j$ , i.e. its centroid. The authors assumed three different numbers of final clusters  $k$ , i.e. 2, 5, and 8, to get the sensitivity of such bottom-up approach in determining the intra-urban microclimate variation. Moreover, we grouped data considering a 3D reference space defined by three environmental parameters which are recognized as affecting the citizens well-being: (i) the global solar radiation ( $\text{W/m}^2$ ), (ii) the  $\text{CO}_2$  concentration (ppm), and (iii) the apparent temperature ( $^{\circ}\text{C}$ ). The obtained data partitions are therefore analysed in terms of their spatial distribution linking the belonging cluster and the GPS coordinates of each observation. The length of each segment, defined by space-contiguous observations belonging to the same class, is calculated and only segments longer than 5m are considered for the analysis. Figure 1 summarizes the adopted methodology for the data analysis.

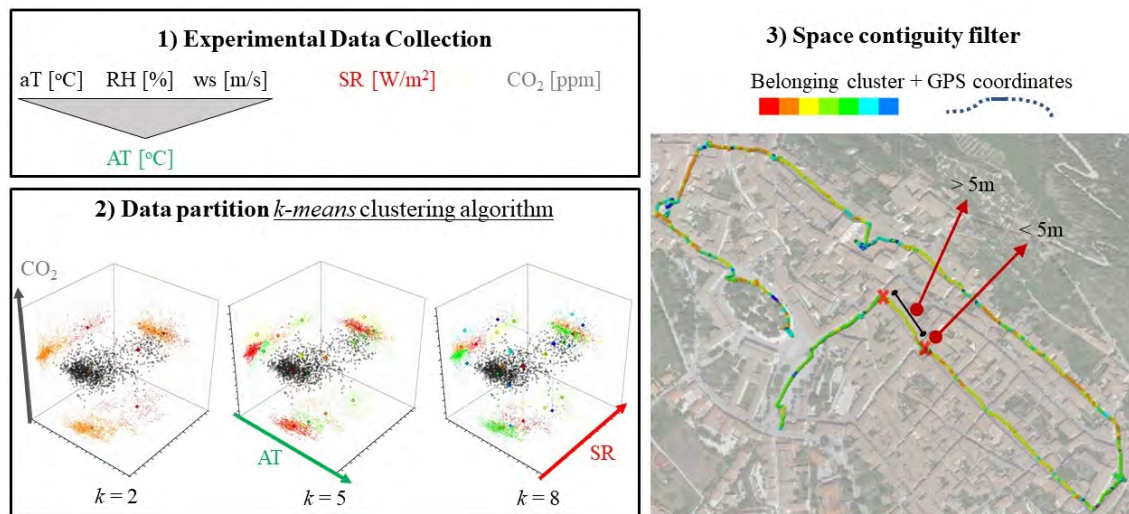

Figure 1. Scheme of the applied methodology.

## RESULTS

The presented analysis aims to find out different microclimate conditions within all the considered case studies. The application of the *k-means* algorithm with a *k* value of 2 recognizes the solar radiation as the main driver of the clustering procedure. As a matter of fact, the two centroids representative of the data subgroups are mainly distinguished by their values of solar radiation. Such differences are more evident at midday and in low density urban areas, i.e. the Knossos palace archaeological site, where a maximum centroids' distance of  $733.4 \text{ W/m}^2$  is highlighted in terms of solar radiation (Figure 2a). On the contrary, less evident is the data partitioning due to solar access at pedestrian level within the more packed urban contexts, i.e. the three monitored areas of New York City. In particular, the partition of data collected in New York City high-rise building settlement, i.e. Wall Street (Figure 2b), is driven by the  $\text{CO}_2$  concentration which presents the widest range of collected values. Therefore, the two data sub-groups are identified by centroids which are really close in terms of apparent temperature and solar radiation, i.e.  $0.6^\circ\text{C}$ ,  $0.1^\circ\text{C}$  and  $4.5 \text{ W/m}^2$ ,  $6.1 \text{ W/m}^2$  at day- and night-time respectively but differ from each other for 130 ppm and 100 ppm of  $\text{CO}_2$  concentration at 2:00 p.m. and 5:30 p.m. respectively.

The two data sub-groups are equally distributed in space in the open site of Knossos and in the packed historic centre of Gubbio at 2:30 p.m. The low solar radiation data in Knossos, i.e. centroid's value of solar radiation equal to  $53.5 \text{ W/m}^2$ ,  $94.8 \text{ W/m}^2$ , and  $60.3 \text{ W/m}^2$  at 9 a.m., 3:00 p.m., and 7:00 p.m. respectively, correspond to the areas shaded by the existing greenery. Similarly, the low and high radiation clusters in Gubbio, i.e. centroids' radiation of  $101.7 \text{ W/m}^2$  and  $776.7 \text{ W/m}^2$  respectively, identify urban canyons mainly characterized by different orientations, i.e. north-south and east-west oriented respectively (Figure 2c). On the other hand, low incoming solar radiation areas are prevalent in the monitored zones of New York City. Nevertheless, areas with high level of incoming radiation are mainly concentrated in north-south oriented canyons and at crossroads.

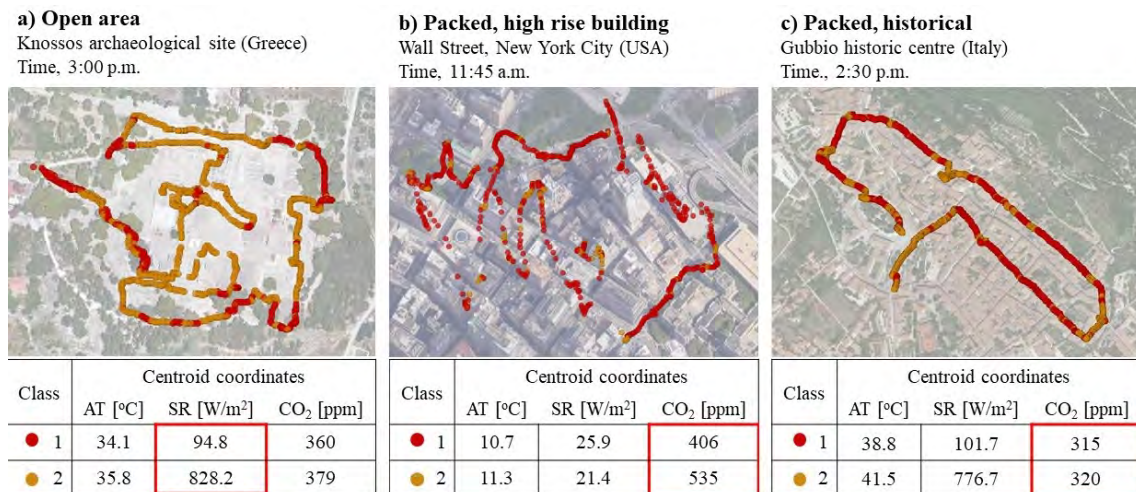

Figure 2. Spatial distribution of the two data clusters ( $k=2$ ) obtained for the monitored open area (a), packed high rise (b), and packed historical configuration (c).

The data partition into 5 sub-groups generates diversified clusters in terms of both solar radiation and  $\text{CO}_2$  concentration values in all the considered case studies. Therefore, such partition identifies different microclimate situations of low and high incoming solar radiation combined with less or more polluted air conditions. The generated clusters depict quite well the distinction among open areas and different typologies of urban canyons in all the packed

urban case studies, especially during day-time. Moreover, such partition highlights site-specific critical conditions in terms of CO<sub>2</sub> concentration level just before traffic-lights almost in all the monitored areas of New York. This condition is particularly evident in SoHo (Figure 3) where data clusters related to detected high level of CO<sub>2</sub> concentration, i.e. 600 ppm and 514 ppm in correspondence of low and high solar radiation values respectively, continuously cover up to a maximum of 46 m for a total amount equal to the 13.4% of the whole monitored path length.

Figure 3. Spatial distribution of the five data clusters (k=5) obtained in SoHo, New York City.

Nevertheless, not the whole 5 data sub-groups can be considered representative of site-specific conditions. The application of the minimum length filter, i.e. 5 m, reduce up to 67.1% the total amount of recorded data in the open archaeological site of Knossos. It means that the environmental parameters in mainly open and natural areas are more sensitive to temporary weather changes rather than being affected by specific spatial configurations.

Finally, the clustering procedure with 8 pre-defined number of classes does not show up further significant intra-urban variations of the monitored environmental parameters leading to redundant fragmentations of the data samples.

## DISCUSSIONS

The statistical analysis of the collected data provides an intra-urban detection of specific microclimate conditions. The spatial distribution of each generated data cluster shows distinctive urban configurations along the monitored pathways during day-time and with a  $k$  of 2. The availability of incoming solar radiation at pedestrian height is depicted as the most influencing parameter for the microclimate diversification. The selection of 5 final clusters points out a relatively more detailed intra-urban microclimate detection considering also other environmental parameters, i.e. CO<sub>2</sub> concentration variation. Nevertheless, such high number of classes, i.e. 5, is not suitable for open areas, i.e. Knossos archaeological site, where the environmental parameters fluctuations are more time- than space-dependent. Finally, the selection of 8 final data clusters seems to be too much detailed for the detection of site-specific microclimate conditions also in high urbanized and packed contexts.

## CONCLUSIONS

The presented bottom-up approach to detect the intra-urban microclimate variation shows its promising effectiveness being applied in different contexts and seasons. The statistical data analysis through *k-means* algorithm can identify those areas presenting similar configuration within each case study. The proper number of final clusters depends on the monitored context

typology in order to obtain spatially significant data sub-grouping. A further development of this work will focus on the evaluation of the right  $k$  value for each defined urban configuration typology.

Nevertheless, the outlined data clusters are associated to peculiar comfort conditions within the same urban context. Therefore, the presented methodology could help urban policymakers to figure out criticalities. A rank of risk in terms of human health or building stock energy consumption peak can be assigned to the obtained environmental data clusters. In this way, areas needing priority intervention can be easily highlighted.

## ACKNOWLEDGEMENT

This work has received funding from the European Union Horizon 2020 Programme in the framework of the “HERACLES” project under grant agreement n° 700395. Additionally, the first author is supported by Ministry funding and university funding of the PhD school in Energy and Sustainable Development. Part of this research is carried out within the framework of COLO ARTE project supported by Fondazione Cassa di Risparmio di Perugia, (Grant Cod. 2016.0276.02)

### **ABSTRACT**

Using model for the heat transfer between pavements and runoff during rainfall, we investigate the importance of different pavement and rainfall properties, as well as crucial energy budget terms that drive the cooling processes. The results indicate that the pavement and runoff temperature and energy fluxes are very sensitive to the rain temperature. In addition, pavement albedo has a significant effect on the simulated temperature since it modifies the initial pavement temperature before the rain starts. The results also indicated that among the different energy budget terms, evaporation and long wave radiation are the main cooling terms, while the shortwave radiation dominates energy input into the runoff-pavement system.

### **KEYWORDS**

Pavements, rainfall, surface energy budget

### **INTRODUCTION**

There are a variety of phenomena in the atmosphere that are affected by earth surface temperature such as urban microclimatology, turbulent transport, and surface energy budgets. In urban areas, the materials of which the pavements are made (i.e. impervious pavements with low albedo values), as well as other urban canopy properties, result in hotter surfaces than rural areas. This is the main reason for urban heat islands in metropolitan areas. However, during rainfall, hot ground surfaces cool down very fast, mainly due to the runoff advection and/or infiltration of heat. Previous investigations have proposed runoff-pavement heat transfer models to predict the surface and runoff temperature during rainfall [Van Buren *et al.*, 2000; Herb *et al.*, 2009; Janke *et al.*, 2009; Kertesz and Sansalone, 2014]. A few of these studies have reported the sensitivity of the cooling to the input and model parameters; however, these analysis either were conducted on limited ranges of target parameter or were not extended to indicate the influence of model inputs on the energy budgets of pavement-runoff [Herb *et al.*, 2009]. Therefore, a lack of extensive analysis still hinders the understanding of how different input parameters, especially the pavements properties, alter the heat transfer between the runoff and pavement during rainfall, and what is their effects on surface temperature and on the driving energy budget terms (such as evaporation and sensible heat) before, during and after rainfall. A more detailed sensitivity analysis of the runoff-pavement heat transfer model helps us to determine, which input parameters need to be carefully measured. In addition, determining the influence of different energy budget terms on key model outputs (such as ground surface temperature) would allow the identification of the dominant heat transfer processes in the problem, and can lead to the development of simpler and more computationally efficient models. Such reduced models would be more suitable for implementation in coarser geophysical models, such as Urban Canopy Models (UCMs), or Weather Research Forecast (WRF) models.

In this paper, we use a runoff-pavement heat transfer model to investigate the sensitivity of different temperatures and fluxes to various pavement and rain properties. In addition, we evaluate the effects of various energy flux terms on the ground surface temperature. First the model is briefly explained, and then a metric for comparing the model sensitivity to different input parameters is introduced. Finally, we present the results, and conclude the paper with a discussion and future directions.

## METHODS

### Model description

The model used in this paper is a 2D heat transfer model (validated by experimental data) to solve for the runoff and pavement temperature and energy fluxes during rainfall [Omidvar *et al.*, 2018]. In this section, we summarize the main model elements. The model has two parts:

1- The runoff dynamics part, which solves for the runoff velocity and depth by combining the shallow water continuity equation and the kinematic wave approach for laminar flows [Brutsaert, 2005]. With a boundary condition of zero velocity at the upstream boundary, and an initial condition of dry ground, the solution of the horizontal ( $u$ ) and vertical ( $v$ ) velocities inside the runoff, and of the runoff depth ( $h$ ) are as follows:

$$u(x, y, t) = \frac{gs_0}{\nu} (hy - y^2 / 2) ; \quad v(x, y) = \begin{cases} 0 & \text{for } x \geq \frac{t^3 s_0 g i^2}{3\nu} \\ -\frac{s_0 g h y^2}{6\nu x} & \text{for } 0 < x < \frac{t^3 s_0 g i^2}{3\nu} \end{cases} \quad (1)$$

$$h(x, t) = \begin{cases} it & \text{for } x \geq \frac{t^3 s_0 g i^2}{3\nu} \\ \left( \frac{3x\nu i}{s_0 g} \right)^{\frac{1}{3}} & \text{for } x < \frac{t^3 s_0 g i^2}{3\nu} \end{cases} \quad (2)$$

where in equations (1) and (2),  $s_0$  is pavement slope;  $\nu$  is runoff kinematic molecular viscosity ( $\text{m}^2 \text{s}^{-1}$ );  $h$  is runoff depth (m);  $i$  is the rain intensity ( $\text{m s}^{-1}$ ); and  $t$  is time (s).

2- The heat transfer part, which uses the advection- diffusion equation in order to solve for the runoff temperature ( $T_w$ ), and a 2D conduction equation (assuming no infiltration) for solving the temperature of subsurface ( $T_g$ ) as follows:

$$\frac{\partial T_w}{\partial t} = D_w \frac{\partial^2 T_w}{\partial y^2} - \left( u \frac{\partial T_w}{\partial x} + v \frac{\partial T_w}{\partial y} \right) ; \quad \frac{\partial T_g}{\partial t} = D_g \left( \frac{\partial^2 T_g}{\partial y^2} + \frac{\partial^2 T_g}{\partial x^2} \right) \quad (3)$$

In equations (3),  $D_w$  ( $\text{m}^2 \text{s}^{-1}$ ) is the heat diffusivity of the runoff, which is modified from the molecular diffusivity to take into account the excess mixing due to the penetration of rain droplet into the runoff (an optimum value of  $4 \times$  molecular diffusivity is obtained from the experimental data);  $D_g$  ( $\text{m}^2 \text{s}^{-1}$ ) is the thermal diffusivity of the subsurface; and  $x$  and  $y$  are the horizontal and vertical distances. Surface energy budget equations are solved to get the temperature of the interfaces between the ground surface and the runoff (equation (4), left), and the interface between the runoff surface and the air (equation (4), right):

$$R_{sw} + Q_{wb} + G = 0 ; \quad R_{lw} + LE + Q_r + H + Q_{wt} = 0. \quad (4)$$

where  $R_{sw}$  and  $R_{lw}$  are net shortwave and longwave radiation fluxes respectively;  $Q_{wb}$  is heat exchange flux between ground surface and runoff;  $G$  is ground heat flux;  $LE$  is latent heat

flux;  $Q_r$  is net rain heat flux;  $H$  is sensible heat flux; and  $Q_{wt}$  is heat exchange flux between runoff and its surface (all in  $\text{W m}^{-2}$ ). Among these energy terms, downwelling shortwave and longwave are the inputs of the model, and the rest are solved for.

A zero-heat flux boundary condition is considered for the bottom boundary of the subsurface, while a constant diffusive heat fluxes at the right and left of the subsurface domain are imposed. Equations (3) and (4) in conjunction with the discussed boundary conditions are solved numerically to obtain the ground surface and runoff temperatures as well as the energy budget fluxes during rainfall.

The downwelling radiative fluxes and other meteorological inputs of the model (i.e. air humidity, temperature, and pressure, wind speed) are obtained from an eddy covariance station at Princeton University (coordinates:  $40^\circ 20' 46.9''\text{N}$ ,  $74^\circ 38' 36.5''\text{W}$ ). A rainfall event starting from 2 PM local time on 30 of July 2016, with a duration of 3 hours, is chosen. The rain temperature is assumed to be equal to the air temperature. In addition, to get the ground surface temperature before and after rain, surface energy budget with similar terms as equation (4) are solved without any runoff model. The model for the dry surface is run for 12 hours before start of the rain (assuming a dry surface and no evaporation), then for 3 hours during rainfall, and, after rainfall stops, the model is run for an additional 2 hours and 20 minutes (until the downwelling shortwave radiation becomes zero).

### Sensitivity analysis method

The model that we described in the previous section is used to conduct a set of sensitivity analyses with different pavement and rain properties. For an input ( $r$ ) and output ( $z$ ) of the model, we use the following metric in order to compare the sensitivity of the model to different inputs and outputs:

$$\gamma = \frac{\delta z}{\partial r / r}, \quad (5)$$

In this equation, the dimension of  $\gamma$  is as same as the dimension of the output ( $z$ ), and indicates how much the output  $z$  changes for a 100 % change of input  $r$ . The model inputs we choose to conduct the sensitivity analysis are: (1) pavement thermal conductivity,  $k$  for the range of  $0.3 - 3.1$  ( $\text{W m}^{-1} \text{K}^{-1}$ ) [Côté and Konrad, 2005; Kodide, 2010], (2) pavement albedo,  $\alpha$  for the range of  $0.01 - 0.23$  [Li et al., 2013; Wang, 2015], (3) rain intensity,  $i$  for the range of  $5 - 105$  ( $\text{mm h}^{-1}$ ), and (4) rain temperature,  $T_{rain}$  for the range of  $T_{air} - 5^\circ \text{C}$  to  $T_{air} + 5^\circ \text{C}$  (as its deviation from equilibrium with air temperature ( $T_{air}$ ), which is the baseline assumption). The average  $T_{air}$  during the rainfall is  $23.3^\circ \text{C}$  in the input data). The input ranges chosen represent the typical value of each input in the urban areas. Finally,  $\gamma$  values for each of the inputs are calculated for 8 model outputs: time averaged temperature of the ground surface during ( $T_{gs}^r$ ) and after ( $T_{gs}^{ar}$ ) rainfall, time averaged temperature of runoff during rainfall ( $T_w$ ), initial temperature of ground surface temperature before rain starts ( $T_{gs}^i$ ), time averaged latent heat flux during ( $LE^r$ ) and after ( $LE^{ar}$ ) rainfall, and time averaged sensible heat flux during ( $H^r$ ) and after ( $H^{ar}$ ) rainfall. All the output variables are averaged along the pavement except  $T_w$ , which is averaged both vertically and along the pavement. For each input,  $\gamma$  is averaged over the input range and the average value is reported ( $\langle \gamma \rangle$ ).

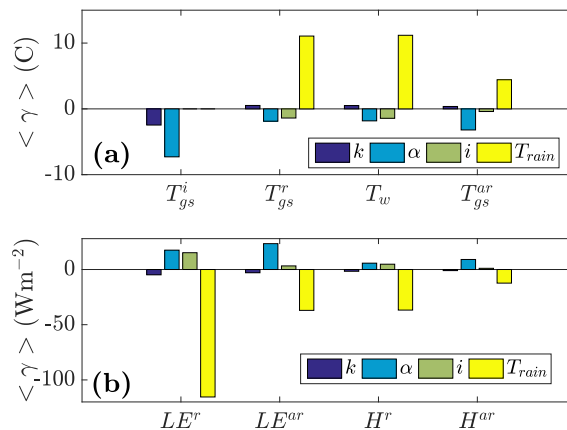

## RESULTS

Figure 1a shows the comparison of  $\langle \gamma \rangle$  for different model inputs, and for the temperature outputs. Note that rain intensity and rain temperature do not affect the initial temperature of the ground surface, so their  $\langle \gamma \rangle$  values are zero in the plot. As can be noted from this figure, except for  $T_{gs}^i$ , all other temperature outputs are strongly sensitive to the rain temperature such that with  $\langle \gamma \rangle$  values for  $T_{gs}^r$ ,  $T_w$ , and  $T_{gs}^{ar}$  are 11.0, 11.1, and 4.4 °C respectively. This emphasizes the importance of determining the rain temperature accurately. The reason that  $T_{gs}^{ar}$  is less sensitive in comparison to the temperature outputs during the rainfall is that this temperature output is modified indirectly by the rain temperature because the final ground surface temperature during rainfall is the initial condition of the simulation after rainfall ends where  $T_{gs}^{ar}$  is solved for (similar justification can be made for the rain intensity as the input).

The second input that the model outputs are most sensitive to is the pavement albedo.  $T_{gs}^i$  is the most sensitive temperature output to the pavement albedo in comparison to others because in the data we used in the model, the downwelling shortwave radiation is higher before the rainfall than during and after due to the cloudiness during and after rainfall. In addition, as we expected, the  $\langle \gamma \rangle$  values corresponded to the pavement albedo are negative, meaning that if we increase of pavement albedo the temperature outputs decrease because of less available energy in the energy budget of the ground surface (which consequently leads to a cooler runoff temperature).

The  $\langle \gamma \rangle$  value corresponding to the pavement heat conductivity has a negative sign for  $T_{gs}^i$ , but it is positive for other temperature output. This can be attributed to the fact that, before rainfall, while the pavement is absorbing energy, the higher the conductivity of the pavement the more heat will be transfer from the pavement surface to the deeper parts of the subsurface. Therefore, the ground surface temperature remains cooler for the pavements with higher heat conductivity. However, during and after rainfall, while the heat is still being advected away by the runoff (or evaporation for after rainfall) at the surface, the pavements with higher conductivity have more stored heat and can transfer it more rapidly to the surface. Therefore, the higher conductive pavements have higher surface temperature than the lower conductive ones during and after rainfall.

**Figure 1.** (a) Results of sensitivity analysis for temperature outputs, (b) for flux outputs

Figure 1b shows the sensitivity analysis for the evaporation and heat flux outputs. Similar to the temperature outputs, the flux outputs are very sensitive to the rain temperature specially the evaporation and heat fluxes during rainfall (with  $\langle \gamma \rangle$  of  $-115 \text{ W m}^{-2}$  and  $37 \text{ W m}^{-2}$  respectively). Although evaporation flux after rainfall is modified indirectly by the rain temperature, the  $\langle \gamma \rangle$  for this flux is still comparable to the  $\langle \gamma \rangle$  value for the heat flux during rainfall. Again, similar to the temperature outputs, pavement albedo rank as the second input to which the model outputs are most sensitive. The evaporation after rainfall ( $LE^{ar}$ ) is the most sensitive output to the pavement albedo, then  $LE^r$  and  $H^{ar}$ , and finally  $H^r$  is the least sensitive to the pavement albedo. The sensitivity of the evaporation and sensible heat fluxes during rainfall to the rain intensity are higher than the corresponding sensitivity after the rainfall. This is expected since rain intensity directly modify the variables during rainfall, but indirectly modulates the ones after rainfall. Finally, the flux outputs are least sensitive to the thermal conductivity of the pavement among; this might be because the evaporation and heat fluxes are calculated at the interface between the runoff and air while the thermal heat conductivity of the pavement affects directly the subsurface and ground surface heat processes.

We are also interested in the effects of different surface energy budgets (here we just consider shortwave, longwave, evaporation and sensible heat fluxes) on the model outputs during rainfall. To investigate this, we choose  $T_{gs}^r$  as the target output, and evaluated how  $T_{gs}^r$  changes from its base value,  $T_{gs}^{b,r}$  (the ground surface temperature during rainfall when all the energy budget terms are considered in the model), when we turn off (set to zero) a specific energy budget term in the model. Figure 2 shows the result of this analysis. It indicates that without considering the evaporation flux, the model predicts  $T_{gs}^r$  about  $0.6 \text{ }^\circ\text{C}$  higher. The longwave flux is the second most important term for predicting  $T_{gs}^r$  with  $T_{gs}^r - T_{gs}^{r,b} = 0.4 \text{ }^\circ\text{C}$ . Without considering the shortwave flux, the model predicts  $T_{gs}^r$   $0.6 \text{ }^\circ\text{C}$  cooler than its base value. Usually the shortwave radiation has bigger impacts on the surface temperatures; however, in our application since the shortwave radiation is small during the rainfall (because of cloudiness), it has a lower effect on the energy processes of the problem. Finally, the sensible heat flux has the least impact on  $T_{gs}^r$  with  $T_{gs}^r - T_{gs}^{r,b} = 0.2 \text{ }^\circ\text{C}$ .

**Figure 2.** The effect of individual energy budget terms on the ground surface temperature

## DISCUSSIONS AND CONCLUDING REMARKS

In this paper, we conducted a set of sensitivity analyses for a runoff-pavement heat transfer model in order to determine how carefully one should determine different pavement and ambient properties that are needed inputs of the model. The analysis showed that the model is very sensitive to rain temperature. It is an important result because usually the models that predicts heat processes on the pavement during rainfall assume rain temperature is equal to air temperature (or previous models that assumed a dew point temperature as the rain temperature

[Herb *et al.*, 2009]). Therefore, considering the difficulties in measuring the rain temperature, more consideration is needed when choosing the value of rain temperature as the input of the model. Another important take away from the sensitivity results is the role of the pavement albedo in modifying the surface temperature and fluxes before, during and after rainfall. The results showed that albedo of the pavement mainly affects the temperature of the pavement before the rain starts. This leads the pavement to be hotter when the rain starts, which can then lead to a hotter effluent entering the storm drainage network that ultimately joins the streams and can then have advects effect on their health [Nelson and Palmer, 2007]. Finally, we showed that among the discussed energy budgets terms in this paper, evaporation and longwave radiation play an important role in cooling the hot ground surface during the rainfall, while the shortwave radiation has an opposite role although the magnitude of the net shortwave is typically smaller during the rainfall due to clouds. Using the results of the sensitivity analysis and important energy budget terms, one can develop a reduced runoff-pavement heat transfer model that predicts the important temperature and flux outputs accurately with reduced computational demands. Such a reduced model is more suitable for implementation in coarser geophysical models.

### ABSTRACT

Recent trends in urbanization processes are causing serious threats at both local and global environmental scale. Greenhouse gas emissions, heat waves, and the heat island effect are constantly growing in intensity and produce increasing discomfort and health impacts in urban populations. In this context, the building sector is currently developing advanced and adaptive materials for building envelope and paving surface applications characterized by high energy performance and low embodied energy. Most of these innovative materials are firstly analysed at the component scale by means of laboratory investigations, while their effect on the built environment is generally assessed at a later stage, by means of advanced computer simulations in buildings and urban microclimate monitoring or modelling. In this context, this work focuses on the evaluation of the UHI modulation potential of materials with advanced dynamic optical properties, i.e. variable surface albedo, for surface urban canyon applications. Specifically, the Princeton Urban Canopy Model (PUCM) is applied with the aim of investigating the potential of advanced urban roofing material to modulate the urban heat island. The aim is to minimize the heat island in the summer but to let it develop in the winter, using roofing applications characterized by a dynamic temperature-dependent optical behavior. In particular, the effect of thermochromic materials on local energy transport phenomena is assessed and benchmarked against more common cool roof solutions. Results show that the modified UCM can effectively be implemented to represent temperature-dependent albedo variations. Additionally, this study demonstrates that using thermochromic materials produces a smart optical response to local environmental stimuli and allows enhanced short wave solar reflection in summer conditions, reduced reflected solar fraction in winter, and adaptive properties during transition periods.

### INTRODUCTION

An urban heat island (UHI) is a metropolitan area that is much warmer than its rural surroundings, where the maximum temperatures occur within its densest parts (Kolokotroni and Giridharan, 2008; Giannopoulou et al., 2011). Recent research contributions suggest that even relatively small cities, i.e. of just over 200,000 people, could be affected by this detrimental phenomenon, which consequently could be more common than expected (Borbora and Das, 2014; O'Malley et al. 2015). All this considered, a deeper understanding of the main causes and effects of the UHI is nowadays of paramount importance, together with the development of ever more effective mitigation strategies and solutions. The existing literature acknowledges several mitigation strategies such as air ventilation, shading of buildings,

expansion of green surfaces, use of water and use of high albedo materials on buildings' surfaces (O'Malley et al. 2015). In particular, using cool roofing materials has been found to be highly effective in reducing both surface and air temperature peaks in the urban environment in summer (Takebayashi and Moriyama, 2012). However, they were also found to negatively affect the same parameters in winter conditions, where a roof with a low albedo value allows to increase the solar gains through the building walls, and consequently, reduce the building energy use (Hosseini and Akbari 2014; Pisello et al., 2016). All this considered, some researchers have investigated the possibility of using thermochromic pigments, i.e. parcels that respond to the surrounding environment by reversibly changing their colour from darker to lighter tones as the temperature rises (Ma et al., 2001), to produce innovative building coatings (Karlessi et al., 2008).

In this work, the Princeton Urban Canopy Model (PUCM) (Li et al. 2014; Yang and Wang 2015) is used to investigate the potential of such dynamic albedo materials as UHI mitigation strategies in the summer, while also investigating their possible countereffect in winter.

## METHODS

The Princeton UCM adopts the single-layer "big-canyon" representation for urban areas, and uses an advanced surface exchange scheme, coupling the transport of energy and water inside urban canopies. It considers the one-dimensional energy balance for an infinitesimally-thin surface layer of each considered  $i$ -th surface ( $i$  = ground, wall and roof), at the surface-air interface, which can be expressed as:

$$R_n = H + LE + G \quad (1)$$

where  $R_n$  is the net radiation,  $H$  is the sensible heat flux,  $LE$  is the latent heat flux (from soil evapotranspiration and/or plant transpiration) and  $G$  is the heat storage term (flux into the surface). The net radiation  $R_n$  is defined as the sum of the net shortwave and longwave radiation from each considered surface  $i$  ( $i$  = ground, wall and roof),  $S_i^{net}$  and  $L_i^{net}$ , respectively. The shortwave component is defined based on the multiple reflection scheme (up to 2 reflections) according to equation 2:

$$S_i^{net} = (1 - \alpha_i) S_i^{total} + \sum_j \alpha_j S_j^{total} \frac{A_j}{A_i} \psi_{j \rightarrow i} (1 - \alpha_i) + \sum_j \alpha_j S_j^{total} \sum_k \frac{A_j}{A_k} \psi_{j \rightarrow k} \alpha_k \frac{A_k}{A_i} \psi_{k \rightarrow i} \quad (2)$$

where  $\alpha_i$  is the albedo,  $\psi_{j \rightarrow i}$  is the view factor from surface  $j$  to surface  $i$ ,  $S_i^{total}$  is the total shortwave radiation per unit area incident on surface  $i$ , and  $A_i$  is the area of surface  $i$  relative to the canyon width or sky area in two dimensions (W).

While the longwave component is defined as:

$$L_i^{net} = \sum_j \varepsilon_j L_j \frac{A_j}{A_i} \psi_{j \rightarrow i} + \sum_j L_j \sum_k \frac{A_j}{A_k} \psi_{j \rightarrow k} (1 - \varepsilon_k) \frac{A_k}{A_i} \psi_{k \rightarrow i} - \varepsilon_i \sigma T_i^4 \quad (3)$$

where  $\varepsilon$  is the emissivity,  $\sigma$  is the Stephan-Boltzmann constant,  $T_i$  is the surface temperature of the  $i$ th surface, and  $L$  is the flux of longwave radiation emitted from each surface or the downward longwave radiation from the sky. Here, the  $j$  index denotes ground, walls, trees, or sky, and the  $k$  index denotes ground, walls, or trees only.

The Princeton UCM implements an explicit resolution for sub-facet heterogeneity in building walls, rooftops and ground facet, each of which is independently modeled by using unique

physical and thermal attributes. Consequently, the thermo-optical properties of every single surface introduced in the model may be separately controlled. In this work, the albedo of the roof is dynamically defined as a function of the roof temperature at the outermost layer that responds in a finite time (not instantly) to temperature changes according to:

$$\alpha(T) = \alpha_{dark} + \frac{\alpha_{cool} - \alpha_{dark}}{2} (1 + \operatorname{erf}(t_{norm}(T))) \quad (4)$$

where  $\alpha(T)$  is the albedo at temperature  $T$ ,  $\alpha_{dark}$  is the albedo for temperatures below the thermochromic transition temperature ( $T_{tc} = 30^\circ\text{C}$ ),  $\alpha_{cool}$  is the albedo for temperatures above the thermochromic transition temperature,  $\operatorname{erf}(t_{norm})$  is the error function, and  $t_{norm}$  is the normalized time, defined as a function of the thermochromic transition interval  $t_{TC}$  and, consequently, of the roof surface temperature. The thermochromic transition interval was selected to be 20 minutes based of previous researches (Karlessi et al., 2008).

Three different roof configurations were considered and compared in this work: dark roof ( $\alpha=0.15$ ), thermochromic roof ( $\alpha=0.15 \rightarrow 0.75$ ), and cool roof ( $\alpha=0.75$ ). Each configuration was simulated for 4 different months: May, July, October 2011, and January 2012, and finally average day profiles were defined for each of them.

The simulations were carried out considering an urban canyon located in Princeton (NJ), characterized by an aspect ratio (building height over street width) of 0.80 and a built-up area fraction equal to 0.84. Local environmental boundary conditions obtained from a dedicated weather station, with a sampling rate of 30 minutes also placed in Princeton were used as forcing constraints in each of the three-considered scenario. More in detail, the model was driven by air temperature, specific humidity, atmospheric pressure, wind speed, shortwave radiation, longwave radiation and precipitation values, which were interpolated from the original weather data to fit the simulation time interval (10 seconds), throughout the simulation.

## RESULTS AND DISCUSSIONS

Results for the four months simulations are shown in Figure 1; depicted are the roof surface temperature ( $TR$ ), sensible heat flux ( $HR$ ) and latent heat flux ( $LER$ ) of the three considered roof configurations. As can be seen, the dark roof always presents the highest values for all the considered months, while the cool roof is always associated with the lowest surface temperature and heat fluxes. This behavior is good in terms of UHI mitigation potential during the hottest months, but inevitably reduces the heat gains during winter, causing a more intense energy consumption for heating purposes in this period of the year and negating some of the winter-time benefits of the UHI at the city scale. The thermochromic roof, on the other hand, shows the interesting ability to dampen the heat gains during summer, producing a more stable temperature profile during the average day of the month in May and July, while preserving the beneficial behavior of the dark roof in October and January, when the thermochromic transition temperature is almost never reached, and consequently the roof keeps a lower albedo and is able to absorb heat from the incident incoming radiation.

Table 1 summarizes the maximum and minimum temperature and heat flux values observed in the three considered configurations for the four simulated months. As expected, the thermochromic roof is characterized by an intermediate behavior that allows it to closely approach the cool roof profile during the hottest months (34.0 vs 33.5°C of maximum temperature for the thermochromic and the cool configuration, respectively), and reproduce the dark roof behavior in the cooler months ( $TR_{min} = -1.8^\circ\text{C}$  in both cases).

Figure 1. Roof surface temperature, sensible and latent heat flux, and inward heat flux for the three considered roof configurations, i.e. dark, thermochromic and cool roof.

Large differences can also be observed when the roof sensible ( $HR$ ) and the latent ( $LER$ ) heat fluxes are considered. More in detail, the thermochromic roof reduces the maximum sensible heat flux released in the atmosphere from 430.4 to 288.1  $\text{Wm}^{-2}$  when compared to the dark roof configuration, which is a significant reduction in terms of UHI mitigation potential, although lower than the one obtained in the cool roof configuration, i.e. 86.7  $\text{Wm}^{-2}$ . As for the latent heat flux, of course the minimum value is not different from one configuration to the other, but the maximum one was found to be equal to 38.3, 20.7 and 11.8  $\text{Wm}^{-2}$  for the dark, the thermochromic and the cool roof configuration, respectively.

Finally, the heat flux at the interface between the indoor air domain and the internal roof surface is reduced from 47.2  $\text{Wm}^{-2}$  in the dark roof configuration to 22.5  $\text{Wm}^{-2}$  in the thermochromic roof, and to 19.6  $\text{Wm}^{-2}$  in the cool roof one. In winter conditions, on the other hand, the introduction of the dynamic albedo reduces the outward heat losses obtained using the cool roof configuration only from  $-83.8$  to  $-83.1$   $\text{Wm}^{-2}$  (in this case the minus sign denotes that the heat flux is transferred from the inside towards the outer environment). This ability to absorb heat in the winter is a beneficial advantage of the thermochromic roof.

The atypical temperature and heat fluxes profiles obtained for the thermochromic roof is a consequence of its dynamic nature that allows it to adjust its ability to reflect the incoming radiation as a function of the local surface temperature. Figure 2 shows the albedo variation profile obtained for the thermochromic roof during a representative week in May. As can be seen, each time the roof temperature overcomes the thermochromic transition temperature  $T_{TC}$ , the albedo starts to increase, and finally reaches the cool roof limit value of 0.75.

Table 1. Considered scenarios with the respective albedo values and the obtained maximum and minimum roof temperature (TR), sensible heat flux (HR), latent heat flux (LER) at the outer surface, and the heat flux at the inner surface (Qin) values.

	Dark roof (DR)	Thermochromic roof (TCR)	Cool roof (CR)
Albedo (-)	0.15	0.15→0.75	0.75
TRmax (°C)	44.2	34.0	33.5
TRmin (°C)	-1.8	-1.8	-1.8
HRmax (Wm <sup>-2</sup> )	430.4	288.1	86.7
HRmin (Wm <sup>-2</sup> )	-0.03	-0.46	-1.06
LERmax (Wm <sup>-2</sup> )	38.3	20.7	11.8
LERmin (Wm <sup>-2</sup> )	0	0	0
QinRmax (Wm <sup>-2</sup> )	-83.1	-83.1	-83.8
QinRmin (Wm <sup>-2</sup> )	47.2	22.5	19.6

Figure 2. Albedo profile and roof surface temperature during a typical week in May for the thermochromic roof.

## CONCLUSIONS

In this work, the UHI mitigation potential of an innovative thermochromic roof, capable of dynamically changing its albedo between 0.15 and 0.75 was investigated and compared to more common solutions such as a classic dark roof ( $\alpha=0.15$ ) and a high performance cool roof ( $\alpha=0.75$ ). The three roof configurations were investigated considering four different month-long simulations in order to evaluate the performance of the roofs in summer and winter conditions (July 2011 and January 2012), as well as during transition periods (May and October 2011). Results confirm that the thermochromic roof's ability to dynamically change its albedo to reflect the incoming solar radiation in response to the surface roof temperature has beneficial impacts. More in detail, when the roof surface is characterized by temperatures below the transition threshold, the thermochromic configuration behaves as a classic dark roof, allowing the overall urban surface to absorb heat in the form of solar heat gains. This reduces the winter penalty of the high performance cool roof and reproduces the temperature and heat flux profiles of the more convenient dark roof configuration during cooler periods. Every time the roof surface overcomes the transition threshold temperature, on the other hand, the thermochromic roof starts to change its albedo, and within a maximum time of 20 minutes (coloring or decoloring time interval) behaves as a high albedo roof with high solar reflectance capability. Consequently, the thermochromic coating allows to reduce the heat gains during warmer months and reduces both the roof surface temperature and heat fluxes, which will positively affect the UHI effect in its surroundings.

In conclusion, the use of thermochromic coatings in building roofs can indeed be considered as an interesting solution to mitigate the increase of air temperatures in the urban environment during summer, while maintaining the positive absorption of solar radiation in winter. Future research should, however, be conducted in order to investigate the effect of thermochromic materials with different transition temperatures and albedo variation profiles. Additionally, it

would be interesting to quantify the benefits associated with this innovative roof configuration in terms of resulting building energy loads and consumption, and also to quantify its consequences on the overall urban microclimate.

### **ABSTRACT**

In the past several decades, psychological aspects have become important to holistic building occupant comfort and satisfaction evaluations. Psychological dimensions of comfort include occupants' opportunities to interact with their indoor environment and perceived control over the indoor environment. Current post-occupancy evaluations tend to focus on collecting quantitative data, despite overwhelming evidence that contextual factors can profoundly impact occupant comfort. This paper proposes and tests a novel method for data collection to study adaptive comfort opportunities. A smartphone-based survey was developed to concurrently collect office occupants' subjective evaluations of usability and comfort of spaces, in addition to photographs of all key building interfaces. The photos were coded to obtain quantitative characteristics of offices, such as whether the interface is obstructed. With a sample of 39 office workers, this paper reveals the effectiveness of this novel photograph-based survey method, while also providing some initial quantitative and qualitative results.

### **KEYWORDS**

Adaptive comfort, building usability, post-occupancy evaluation, photographs

### **INTRODUCTION**

Building designers and operators should strive to provide comfortable spaces for two reasons: (1) occupant comfort is a desirable property and because it is closely linked to occupant productivity (Leaman & Bordass, 2000), and (2) comfortable occupants are less inclined to take energy-intensive actions (e.g., opening windows when mechanical heating is on and closing blinds and turning on lights during and after periods of daylight glare). The study of occupants' thermal perception is rooted in studies addressing the relationship between physical indoor thermal conditions, physiological responses, and the perception of these conditions by humans (Fanger, 1970). ASHRAE Standard 55 (ASHRAE, 2017) defines thermal comfort as "that condition of mind which expresses satisfaction with the thermal environment and is assessed by subjective evaluation." Psychological and behavioral influences on perception have been recognized as being critical aspects of thermal comfort for over four decades (Humphreys, 1976). Indeed, non-physiological metrics can have a significant impact on occupants' reported satisfaction with indoor environmental quality (IEQ) (Kim & de Dear, 2012).

One of the non-physiological factors is perceived control. Through their extensive post-occupancy evaluation experience, Leaman and Bordass (2000) stated that "In study after study, people say that lack of environmental control is their single most important concern...". Laboratory studies have also shown a positive relationship between perception of thermal conditions and perceived control (Schweiker & Wagner, 2016). While adaptive thermal

comfort models used in standards (e.g., Standard 55 (ASHRAE, 2017)) implicitly recognize that providing adaptive opportunities to occupants (namely operable windows) improves occupant tolerance for a wider range of indoor temperatures, Standard 55 does not explicitly quantify the effect of differences in perceived control. Approaches towards such quantification are scarce and still lack generalizability (Schweiker and Wagner, 2015). Moreover, research on building usability is still in its infancy (Day and Heschong, 2016). More critically, there continues to be a trend towards greater automation under the false premise that taking control away from occupants improves comfort (Leaman and Bordass, 2000).

The theme of perceived control links human comfort with occupant behavior. Research on occupant comfort and occupant behavior—be it related to thermal, visual, or acoustic aspects—is typically performed in either a controlled laboratory environment or *in situ* (Parsons, 2014). Common quantitative research methods use one or both of: 1) surveys that ask occupants about their perceived level of comfort and control and the available and exercised controls, and 2) sensor measurements to collect data about environmental and/or physiological conditions. However, contextual factors such as workplace cleanliness, flexibility to move furniture, presence of other occupants, and ease of use of building systems, all play a critical role in occupants' likelihood to exercise adaptive opportunities (Kim and de Dear, 2012; O'Brien and Gunay, 2014). Traditional surveys are typically not capable of capturing these complex and subtle predictors of perceived opportunities for adaptive control. Moreover, surveys rely on self-reporting, which can yield significant error. Pritoni, Meier, Aragon, Perry, and Pepper (2015) performed a survey on thermostat-related behavior, including a request for participants to upload a photograph of their thermostat. They found that only 50% of occupants who claimed that they use programmable features of their thermostat were actually using them, according to the photographs. In general, participants may not possess the insight required to identify phenomena of interest and significance.

To understand contextual factors, researcher walk-throughs are frequently used, whereby the researcher takes notes and photographs. Such qualitative data can help explain anomalies in quantitative data and can serve as exploratory research to guide future research directions (Day, Theodorson, et al. 2012). However, walk-throughs are time-consuming, may jeopardize the safety of the researcher, and are subject to the Hawthorne effect (O'Brien, Gilani, et al. 2018).

This paper proposes a new survey-based research method to yield new insights about the relationships between perceived comfort and availability of adaptive opportunities and usability of building systems and interior design elements. The aim is also to continue collecting convincing anecdotal evidence to support the philosophies and design implications of providing adaptive opportunities to building occupants. To achieve this, the researchers sought to develop a method that could yield many of the benefits of field studies and obtain large datasets about comfort and building usability without a requirement for researchers to visit properties. This paper presents the survey and then briefly provides initial analysis and discussion.

## METHODOLOGY

A number of research questions were posed for this research; this paper only briefly explores these questions using the current survey campaign and resulting sample of 41 participants. The questions are fundamental (e.g., what is the correlation between presence of adaptive opportunities and perceived control?); application (e.g., what lessons can be learned for future building design?); and, methodological (e.g., are the photographs as effective as researcher

walk-throughs?). The short length of this paper limits the amount of analysis to illustrative purposes.

Stemming from the primary research objectives of this study, a survey was developed and piloted. For brevity, the survey is not included in this paper. Survey sections include questions on: (1) confirmation that the participants are currently in their primary office space (and in Canada for the current study); (2) perceived level of comfort; (3) occupants' ability to improve indoor environmental quality; (4) availability of, distance to, ease of use of, concern about disturbing fellow occupants if using, and frequency of using: *window shading devices, operable windows, desk fans, thermostats, space heaters, overhead lighting, and task lighting*; (5) nature of furniture; (6) opportunities to reorient or relocate in the event of discomfort; and, (7) general features or characteristics of offices that they like or do not like. Fundamental to the survey, participants were asked to take and upload a photo of the adaptive opportunities listed in item 4 (if applicable) and item 7; up to nine photos were uploaded per participant. Depending on whether the above seven main adaptive opportunities were available, the participants were required to respond to between 41 to 83 questions, though many were repetitive (e.g., asking about many aspects of comfort). LimeSurvey (Figure 1) was selected because of its suitability for smartphone applications and ability of participants to upload their photographs.

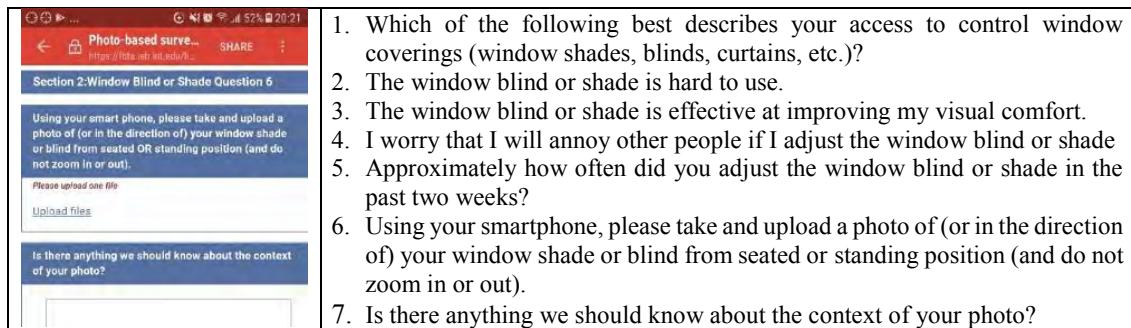

Figure 1. Sample screenshot of survey and sample questions for window shading devices.

Ethics clearance was obtained from the university research ethics board; the ethics documentation had particular focus on ensuring that occupants, buildings, and organizations could not be identified in photographs and that the photographs would be securely stored. To encourage participation, a \$10 Amazon gift card was offered to all participants who completed the survey with valid responses. Participants were recruited via three separate postings over two months on the lead author's Facebook wall. A posting on a local Reddit group yielded many incomplete and invalid responses. Survey responses were manually validated for completion and to confirm that conditions for participation were complied with, where possible. For instance, several participants responded from inside a vehicle and one participant uploaded a photo of their desk behind which a tropical plant could be seen outside (an unlikely circumstance in the Canadian winter). Approximately 50% of prospective participants who answered at least one question did not complete the survey, while approximately 20% of surveys that were completed were considered invalid (see Discussion). For valid responses, the mean and standard deviation for the completion times were 16.4 and 9.0 minutes. Despite considerable effort in recruitment and a relatively generous incentive, 41 valid responses were obtained out of the targeted 100. The responses occurred between December and February; thus, results were studied within the context of winter conditions (e.g., responses about operable windows have limited meaning). The results include between five and 33 photos uploaded for each of the seven categories of adaptive opportunities.

## ANALYSIS AND RESULTS

This section describes the analysis approach and results for selected questions that were posed in the Methodology. Figure 2 shows the overall availability and proximity of adaptive opportunities.

Figure 2. Availability of adaptive opportunities

Next, the influence of office type on participants' reported ability to improve comfort through adaptive actions on a five-point scale from very poor (1) to excellent (5) was explored. Given that the data are generally not normally distributed, a non-parametric test (the Kruskal Wallis test) was used to assess differences in responses between office types, as annotated in Figure 3.

Figure 3. Relationship between office type and adaptive opportunities and comfort. The \* and \*\* denote significance of <0.05 and <0.01, respectively. Note: mean values on the y-axis assume the Likert scale responses are equally-spaced.

To illustrate the power of photographic data to help explain outliers, the relationship between participants' rated availability of blinds/shades and ability to reduce daylight was explored (Figure 4). A best-fit line, under the assumption that the data can be converted to into equally-spaced categories, is shown on the plot. In general, the presence and proximity of a shading device is a moderately good predictor of occupants' ability to reduce daylight levels. Six outliers were examined to reveal new insights about how the participants interpreted the questions and responded. The two photos for points below the best-fit line show that although the shading devices were nearby, they were obstructed (as explicitly written by the participant).

Notably, the occupants who took the top four photographs appear to be seated quite far away from the windows, in general, and may not be subject to chronic daylight glare. These results, which cover only a small part of the collected data, demonstrate that important contextual factors are necessary to understand the quantitative responses. Moreover, they provide anecdotal evidence to support previous research that indicated the importance of minimizing obstruction of blind interfaces (Day et al., 2012). Meanwhile, Figure 3 suggests that occupants have a greater sense of control, more adaptive opportunities, and greater comfort in private spaces.

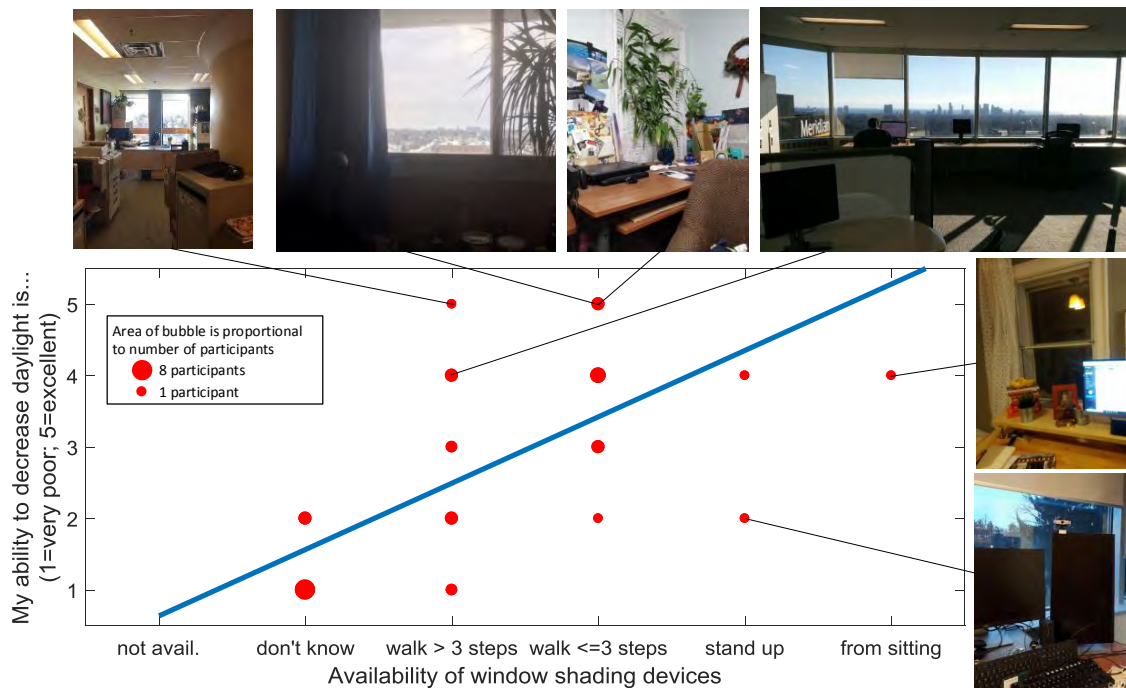

Figure 4. Example of using photographs to explain outliers in a simple correlation.

## DISCUSSION

Briefly, this section provides some lessons learned and comments about the effectiveness of the photograph-based survey. The photographs were effective at providing contextual information about why a participant responded a certain way. However, this was limited to visual evidence unless the participant also provided comments to describe the photo (as was done for 109 out of 131 photos). In many cases, cases where the participant responded unexpectedly (e.g., outliers of Figure 4), interpretation of the photograph provided otherwise-missing explanation. However, in some cases photographs did not explain unexpected quantitative results. A study with walk-throughs and in-person interviews could largely resolve this limitation because the researcher could inquire about anomalies. However, on the balance, the current approach yielded significant explanatory power along with the aforementioned benefits. Recruitment of participants was significantly more difficult than expected. The researchers' acquaintances seemed to feel more responsible for supporting this project than unknown participants. However, the researchers' professional networks were avoided because of their tendency to have subject expertise (e.g., knowledge of comfort theory). One participant exited the survey early, noting that government workers cannot take photos of their workplace. In retrospect, the survey should have been slightly more specific about what to capture in photographs. There was minor confusion for overhead lights about whether to capture the luminaires or the interface. The survey specified that all photos should be taken from the

primary location of work, regardless of whether the interface was visible from this location in order to assess whether there was a clear view.

## CONCLUSIONS

This paper introduced a novel post-occupancy evaluation survey that required participants to capture and upload photographs of building interfaces, adaptive opportunities, and other comfort-related items. The paper provides analysis of an initial sample of 41 participants who are office workers in Canada. Whereas previous POE surveys did not have the ability to capture contextual information about office spaces (e.g. obstruction of interfaces or presence of other occupants), the qualitative data provided by the photographs can help explain outliers and other anomalies. Future work is needed to further analyze the data, refine the survey, and expand deployment.

## **Benchmarking the energy efficiency of office buildings in Belo Horizonte, Brazil**

Ana Carolina de Oliveira Veloso<sup>1,\*</sup>, Roberta Vieira Gonçalves de Souza<sup>1</sup>

<sup>1</sup>Federal University of Minas Gerais, Brazil

*\*Corresponding email: acoveloso@gmail.com*

### **ABSTRACT**

In countries in which energy efficiency regulations are already consolidated or in the process of being consolidated, an important parameter to be verified is the relative consumption of electric energy of existing buildings in accordance with established ranges of consumption for different types of buildings. In the present paper ISO 52003-1 methodology was applied to create a benchmarking for office buildings for the city of Belo Horizonte, Brazil and the work discusses the implications of using the standard's methodology for the Brazilian scenario. To fulfill this objective, it was necessary to gather electric energy consumption data for this type of buildings as well to survey for building constructive data. For the classification of buildings according to their consumption, a methodology was developed to isolate the annual consumption per area of the towers from EUI data for the whole building. Besides, information such as garages existence, lighting power density of the garages and the number of lifts was collected in loco as in many cases there was not access to the building projects. The results showed that due to the large variation in consumption data, the use of the average EUI instead of the median EUI value results in a better distribution for the towers energy consumption classification. This precaution can prevent excessive resistance in the market if a public benchmarking policy is established. Therefore, it's concluded that the understanding of the consumption of electrical energy of the buildings plays a fundamental role in the establishment of goals for the new buildings.

### **KEYWORDS**

Energy use benchmark; energy consumption; office buildings; sensitivity analysis.

### **INTRODUCTION**

Energy is a major factor in global efforts to achieve sustainable development (Vera and Langlois, 2007) and buildings can be the key to achieving this goal (Rey et al., 2007), because they account for about 40% of the world's energy consumption (IEA, 2008). Thus, it is estimated that there is great potential to mitigate consumption in this sector. In Brazil, the energy matrix of buildings is closely linked to the use of electric energy, and buildings in the residential, commercial and public sectors account for 42.5% of this consumption (BRASIL, 2017).

Due to economic growth, developing countries have experienced a large increase in their energy consumption (Iwaro and Mwasha, 2010). According to the National Energy Plan 2030 (MME, 2007), the energy consumption of buildings in Brazil is projected to grow 3.7% per year by 2030. Lamberts et al. (2014) point out that every decision made during the design process can influence the buildings' thermal and luminous performance. Therefore, the understanding of the influential factors in the consumption of electrical energy of the buildings will have a fundamental role in the establishment of goals for the new buildings to be constructed.

According to Lamberts et al. (2014), a building is more energy efficient than another when it provides the same environmental conditions of comfort to its user, with lower power

consumption. In countries which energy efficiency regulations are already consolidated or under consolidation, an important parameter to consider is the relative consumption of electricity according to the building typologies. This type of survey is called benchmarking, which is a method used to compare the energy and/or efficiency of a building with a reference value (Perez-Lombard et al., 2009; Signor, 1999; U.S.D.E.C.B.I, 2009). From a collected database, it is possible to propose new criteria for the construction, as well as to evaluate existing criteria and improve the management of buildings of different performances (Chung et al., 2006). The information on the building performance and the indicators implemented in the regulations should be clear and detailed so that the user knows the level reached by the building (Nikolaou et al., 2015).

In July 2009, the Technical Regulation of Quality for Energy Efficiency Levels of Commercial, Services and Public Buildings (INMETRO Directive No. 163) was launched in Brazil. The purpose of this regulation is to "create conditions for the labeling of the energy efficiency level of commercial, service and public buildings" (BRASIL, 2010). In this regulation the classification of buildings varies according to five levels, with "A" being the most efficient and "E" being the least efficient. The first benchmarking initiative in Brazil was made for bank branches in a study developed by the Brazilian Council for Sustainable Construction (CBCS). The benchmarking methodology for this typology was developed through linear regression analysis using data on electricity consumption, energy audits, and climate corrections (Borgstein and Lamberts, 2014).

ISO 52003-1- Indicators, requirements, ratings and certificates - Part 1: General aspects and application to the overall energy performance (ISO 52003-1:2017), launched in 2017, defines the ways of calculating the energy performance of buildings and procedures for setting reference values. Several European Union countries such as France, Germany, Italy, Portugal, United Kingdom are required to implement this standard.

Veloso et al (2017) article served as a basis for the present benchmarking study. The authors analyzed seven design features that influence the electricity consumption in office buildings for Belo Horizonte. According to the study, the air conditioning mode showed to be the most important feature with up to 58% impact in the electricity consumption prediction (the studied building modes were: unconditioned, mixed mode air conditioning and central air conditioning). For each air conditioning mode WWR, façade solar absorptance and SHGC also showed to be relevant design features in the consumption prediction of office buildings. The presence of glazed façade, the presence of solar shading devices and building age were also tested but with no significant results.

In view of the above, the objective of this article the application of ISO 52003-1 in the Brazilian scenario and the implications of proposed changes in the standard methodology in the establishment of a benchmarking for office buildings. It is important to emphasize that in Brazil the access to the data of electric energy consumption and characteristics of the buildings is restricted and for the most part stealthy and for that reason, it was necessary to develop a methodology for the buildings characterization.

## **METHODS**

### **Experimental Design**

For the present study a sample of buildings in the city of Belo Horizonte – Brazil was used. According to the climatic classification of Köppen, Belo Horizonte is classified as a Cwa climate, a hot and temperate climate with mild winter, 18 °C average temperatures in winter

and 22 °C in summer. The mild climate explains a high occurrence of mixed air conditioning in office buildings, that is, natural ventilation is used most of the time and only on hot days the air conditioning system is turned on. The number of office buildings in the city was accessed from a database provided by the City Hall. This database contains information from the IPTU (Urban Land and Territorial Tax) of all the existing buildings in the city approved until 2011. It was identified that until 2011, there were 568 buildings for commercial use and/or services from three to twenty-five floors and a gross floor area of more than 1,000 m<sup>2</sup>.

### **Consumption data**

For the analysis of the electric energy consumption, the consumption data of the 568 buildings were requested and the consumption data of 101 buildings were made available by the electric energy company of the city. Electricity consumption data available is from 2012 to 2014, divided monthly, and with no identification of this measuring unit in the building due to privacy State policies. In the received database, it was not possible then to discriminate the electricity consumption of the floor or room or the common use areas of the building, which led to the need for an on-site survey. Once EUI is quite different in office areas and garages of office buildings the aim of this survey was to separate the electricity consumption of the tower from the building garages. The decision to divide the building in these two parts (garage area and tower) was done because in the city the garage area varies greatly, from office buildings presenting no garage from buildings which present garages that represent up to 1/3 of the total constructed area.

It's important to emphasize that it was not possible to access the internal loads of the studied buildings as access usually is granted only to the common areas of the buildings.

### **Survey of building areas**

From the 101 buildings in which electricity consumption data was obtained, only 50 complete projects were made available by City Hall of Belo Horizonte. For the building sample to be larger, the other 51 buildings were visited to verify the existence or not of a garage. It was then possible to identify that 13.7% of the buildings visited did not have garages. For those buildings the building area provided by the IPTU or the by the architectural plans was considered as being the tower area. For the other buildings the tower areas were obtained by the architectural plans or by on-site visits.

### **On-site survey of the garages electricity consumption**

To obtain the electricity consumption of the towers it was necessary to estimate the electricity consumption of the garages. This was done through a survey of the installed lighting system (number of lamps, lamp and ballast power and use hours) and the number of elevators of the sample buildings. The installed power multiplied by the number of hours of use was used to define the electricity consumption of lighting and elevators, considered to be the electricity consumption of the garages. To estimate the electricity consumption of the towers, the average electricity consumption data provided by the energy company was used and the electricity consumption of the garages was withdrawn.

### **Building Classification**

For the building EUI estimation, only the electricity consumption of the building towers was used, divided by the corresponding area. The methodology of ISO 52003-1:2017 to determine the benchmark scales then was applied to the defined EUI. This standard presents a methodology for establishing a certificate of energy efficiency for buildings, including energy performance indicators. It allows the indication of the energy class of a certain building in comparison to the benchmark. ISO 52003-1:2017 establishes seven levels of efficiency - from

A to G. In Brazil, for commercial, service, public and residential buildings, this index varies from A to E. For the classification to be on the same scale used in buildings in Brazil, the highest limits established in ISO 52003-1:2017 were not used to determine the classification of buildings in the present work.

## RESULTS

Figure 1 (a) shows the Energy Use Intensity - EUI ( $\text{kWh/m}^2/\text{year}$ ) of the sample buildings. The graph (a) in the figure allows the verification of the significant differences between the EUI when the whole building is considered and when towers' and garages' EUI are considered separately. The upper and lower absolute variations are represented by the points, and the lower and upper part of the box represents the percentiles of 25 and 75% of EUI variations. The center line displays the data median and the upper asterisks the outlier values. The symbol inside the box shows the average value of the sample. It is observed in the Figure 1 (b) that in the tower there is a significant variation in the tower EUIs and that 75% of the buildings consume up to 100  $\text{kWh/m}^2/\text{year}$ . It's also important to stress that if only centrally air-conditioned building towers were considered the mean EUI would be of 173  $\text{kWh/m}^2/\text{year}$ .

Figure 1. (a) Boxplot with the variation of total, tower and garage EUI; (b) Histogram of the towers EUI.

It is noticed that since the mean and median are not equal, the distribution is not normal, the mean value being greater than the median value. The standard deviations show that there is a great data variability. The average tower EUI is 30% higher than the whole building EUI and the highest electricity consumption found in the tower is an unusual value in the sample.

The EUI limit values using the EUIs with the median EUI value according to the ISO 52003-1: 2017 methodology, can be seen in Table 1. It can be observed that 50% of the towers were rated D and E. Based on these results, the mean value in place of the median was also tested and what can be verified is that there was a better distribution of the buildings among the classifications. The increase in the consumption limit for each classification was of 38.5%.

Table 1. Table of EUI electricity consumption limits of buildings and percentage per item.

		A	B	C	D	E
Median	EUI [ $\text{kWh/m}^2/\text{year}$ ]	27.48	39.02	54.95	77.48	
Value	Percentage of buildings	27%	6%	18%	13%	36%
Average	EUI [ $\text{kWh/m}^2/\text{year}$ ]	38.05	54.03	76.10	107.30	
Value	Percentage of buildings	32%	17%	14%	14%	23%

## DISCUSSIONS

After the implementation of energy efficiency regulations in buildings it is necessary to understand how efficient buildings are in relation to their energy consumption. Therefore, the role of benchmarking is to create reference values. The discussion of the benchmarking of electricity consumption of buildings is recent in Brazil, and there are just a few studies on this subject in the country. A major obstacle is the lack of accessible data in Brazil, which led to the need of creating a methodology to extract data from both the building projects when accessible and from on-site visits when not.

It's important to stress that the present study considered both mixed mode and centrally conditioned mode and divided the electricity consumption of garages and building towers. This decision along with the peculiarities of a continental tropical mild climate makes it difficult to compare EUI values with other studies in the literature.

It was found that there is a great variation in the electricity consumption among the sample buildings. The electricity consumption of the towers showed to be 418% higher than the garages consumption, which justified the separation of this electricity consumption. Still there was great variation of electricity consumption among the building towers due to the fact that there is diversity in the air conditioning mode. The building towers that use central air conditioning in their entirety being the largest consumers, should be studied separately for a better understanding of the specificities of their energy consumption, but once the sample available for the present study could be considered small, this was not done.

A higher number of samples might generate a better distribution using the median EUI value as proposed in ISO 52003-1: 2017 but what is perceived in Figure 1 and confirmed in Table 1 is that the mean EUI is always greater than the median EUI in the samples, showing that the EUI does not follow a normal distribution. Thus, due to the large variation in the EUI, as shown in Figure 1 (b), the use of the average in the value of the EUIs presented a better distribution in the classification of the towers. So as a suggestion for a possible public policy it is believed that the use of the average EUI would generate less resistance in the market given the available sample.

## CONCLUSIONS

The construction, operation and use of buildings represent an important part of the country's energy consumption and therefore also present a great potential for energy conservation. The understanding of the buildings' consumption plays a fundamental role in the establishment of goals for the new buildings to be constructed and for retrofit policies for the existing buildings. The methodology of ISO 52003-1:2017 was important to create the ratings in this work and being slightly modified, presented a good distribution of the buildings in each level.

It is important to emphasize that this work is one of the first steps in the development of energy benchmarking for Brazil. As government, stakeholders, building owners and energy companies realize the importance of understanding the energy consumption of buildings for the country's economy, data might become more accessible and thus, it is expected that the analysis conducted in this work can be done for other types of buildings and even repeated for the same typology with a greater sample size.

The results presented in this work are a first picture of the situation of the energy consumption of office building towers with an area above 1,000 m<sup>2</sup> in the city of Belo Horizonte. It's believed that this data can serve as a basis for future work in which major design features and occupancy

patterns can be analyzed to get a better understanding of the major influencing factors in electricity consumption of this typology.

## Exploring occupants' impact at different spatial scales

Sara Gilani<sup>1,\*</sup>, William O'Brien<sup>1</sup>, H. Burak Gunay<sup>1</sup>

### ABSTRACT

Buildings' users have widely been accepted as a source of uncertainty in building energy performance predictions. However, it is not evident that the diversity of occupants' presence and behavior at the building level is as important as at the room level. The questions are: How should occupants be modeled at different spatial scales? At the various scales of interest, how much difference does it make if: (1) industry standard assumptions or a dynamic occupant modeling approach is used in a simulation-based analysis, and (2) probabilistic or deterministic models are used for the dynamic modeling of occupants? This paper explores the reliability of building energy predictions and the ability to quantify uncertainty associated with occupant modeling at different scales. To this end, the impacts of occupancy and occupants' use of lighting and window shades on the predicted building lighting energy performance at the room and building level are studied. The simulation results showed that the inter-occupant variation at larger scales is not as important as at the room level. At larger scales (about 100 offices), the rule-based model, custom schedule model, and stochastic lighting use model compared closely for predicting mean annual lighting energy use.

### KEYWORDS

Occupant modeling approaches; Spatial resolution; Custom schedules; Rule-based models; Building performance simulation.

### INTRODUCTION

Occupants have widely been considered as a source of the gap between the predicted and measured energy performance of buildings (Menezes et al., 2012; de Wilde, 2014). Likewise, previous studies indicated that occupants' impact on the energy performance of buildings varies between occupants (Haldi and Robinson, 2011; Saldanha and Beausoleil-Morrison, 2012; Clevenger et al., 2014). This variation in occupants' presence and behavior may begin to cancel out their impacts on the energy use for larger buildings. Therefore, the stochastic nature of occupants' presence and behavior at the building level may not be as important as at smaller scales. A few studies challenged the notion of simulating the whole building's energy performance using the probabilistic modeling approach (Parys et al., 2011; Evins et al., 2016). This modeling approach has been widely used in studying occupants in a simulation-based analysis. However, it is not evident whether using this modeling approach at larger scales yields the wide range of occupants' impacts on the energy performance of a building as that at the room level. To address the gaps in the literature, the main objective of this paper is to systematically assess the impact of occupants on the energy performance of buildings at different spatial scales. The focus of this paper is on the domain of lighting use, though the general conclusions are expected to apply to other occupant-related domains. The methodology of this paper is to implement four occupant model forms for the lighting use in a simulation-based analysis, while occupancy and window shade use domains are simulated using the probabilistic modeling approach. Simulation-based analysis of the impact of

occupant modeling approaches for occupancy and window shade use domains at different spatial scales has been previously presented (Gilani et al., 2018).

## OCCUPANT MODELING

For the analysis of the impact of occupants at different spatial scales, a simulation-based analysis methodology was implemented. As there is little consensus on which occupant modeling approach best represents occupants' impacts on the energy performance of buildings in a simulation-based analysis (Mahdavi and Tahmasebi, 2015), four modeling approaches have been used in the current study for the domain of lighting use. Occupant modeling approaches can be categorized as: (1) static versus dynamic, and (2) deterministic versus probabilistic. Dynamic models represent the two-way impact that occupants and building can have on each other, whereas static models neglect this impact. Parameters of probabilistic models and generated numbers in Monte Carlo simulation method (Gilks et al., 1996) are chosen randomly for each simulated occupant and/or at each timestep. Therefore, outputs of probabilistic models may alter at each simulation run while results of deterministic models do not change every time they are simulated. The resulting four model types are shown in Figure 1. In this paper, both static/dynamic and deterministic/probabilistic approaches were implemented in simulation for the lighting use domain, however occupancy was modeled with the static-probabilistic modeling approach and window shade use was modeled using the dynamic-probabilistic modeling approach. For the static modeling of lighting use, standard and custom schedules were incorporated; whereas for the dynamic modeling of lighting use, stochastic and rule-based models were used. A brief description of the model forms which were implemented in simulation in this paper is provided in the following sections.

Figure 1. General categories of occupant modeling approaches.

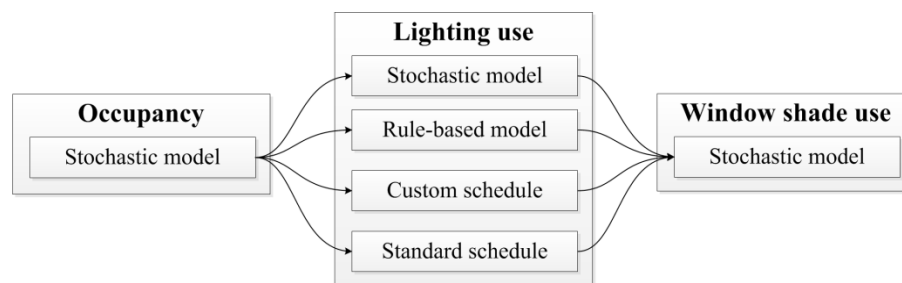

Figure 2. Four combinations of occupant model forms for occupancy and lighting and window shade use domains.

### Standard schedule

For the static-deterministic modeling of lighting use, the standard schedule from National Energy Code of Canada for Buildings (NECB) (National Research Council Canada, 2015), was used (Figure 3). NECB's (2015) lighting schedule is almost identical to the lighting schedule in ANSI/ASHRAE/USGBC/IES Standard 189.1 (2014).

### Custom schedule

Custom schedule was the other model form that was used for the static-deterministic modeling of lighting use. To develop custom lighting use schedules, 100 annual run periods of the stochastic models (as described later) were simulated using the Monte Carlo simulation method (Gilks et al., 1996). The hourly ratio profiles of lights-on during occupied or unoccupied periods on weekdays were generated based on the outputs of the 100 simulation run periods. To this end, the hourly lights-on ratios during occupied or unoccupied periods were calculated for each of the 100 annual run periods. The mean hourly lights-on ratios during occupied or unoccupied periods were computed using the weighting method based on the total occupied or unoccupied hours of each simulated office (Figure 3).

Figure 3. Hourly custom schedules for lights-on ratio during occupied and unoccupied hours and standard schedule.

### Rule-based model

A rule-based model, which consists of thresholds to trigger occupants' manual light switch-on actions, was developed for the dynamic-deterministic modeling of light switch-on actions. Lights were set to be turned off automatically with a 30-minute time delay. The workplane illuminance ( $E_{in}$ ) was considered as the predictor for the light switch-on actions (Hunt, 1979; Reinhart and Voss, 2003; Haldi and Robinson, 2010; Gunay et al., 2017). The thresholds for light switch-on actions were calculated based on the outputs of the 100 annual run periods of the stochastic models (as described next). To this end, a wide range of plausible values were systematically set for thresholds until the annual lighting energy use of 100 annual simulations were almost identical to the results of 100 simulations using the stochastic models.  $E_{in}$  was obtained 500 and 950 lx for light switch-on actions upon arrival and during intermediate periods, respectively.

### Stochastic model

For the probabilistic modeling of the considered domains in this paper, three existing stochastic models were implemented: (1) Page et al.'s (2008) occupancy algorithm, (2) Gunay et al.'s (2017) light switch-on model, and (3) Haldi et al.'s (2016) window shade use model. For the occupancy domain, daily presence profiles and mobility parameters, which are required inputs for Page et al.'s (2008) occupancy algorithm, were generated using 17 months' worth of data collected in 24 offices in an academic building. Similar to O'Brien et al.'s (2016) study, a three-mode Gaussian mixture model (GMM) was fit to the profiles of daily occupied ratio for each monitored office. The probabilities of turning on lights and opening or closing window shades were estimated using the generalized linear model (GLM). Lights were assumed to be turned off automatically with a 30-minute time delay.

### SIMULATION

For each of the four combinations of the model forms (see Figure 2), 150 annual run periods were simulated. This number was determined as the results of a sensitivity analysis of 1000 annual simulation runs showed that the coefficient of variation of the lighting electricity use

on the sample sizes of larger than 150 offices was less than 10%. The parameters of the occupancy and light switch-on models were generated randomly from the normal distribution of the required variables with the mean value and the covariance of the variables. The diversity approach proposed by O'Brien et al. (2016), which is based on keeping the joint variability between each pair of parameters, was used to address the variations in occupants' presence and lighting use. To consider the diversity in window shade use, Haldi et al.'s (2016) approach on using generalized linear mixed model (GLMM), was implemented.

A typical office space located in Ottawa, Canada, was simulated in RADIANCE-based daylighting tool DAYSIM (Reinhart, 2001) to calculate the workplane and ceiling illuminance in the simulated office for a typical year. To simulate indoor illuminance at partial shade movements using Haldi et al.'s (2016) window shade use model, five shade positions were simulated: fully open, quarter closed, half open, quarter open, and fully closed. Occupant models were implemented in MATLAB, where the DAYSIM daylighting simulation outputs were used as inputs. The timestep for the simulation in DAYSIM and MATLAB was set as 5 minutes. The office space had the dimensions of  $W \times L \times H = 4.0 \times 4.0 \times 3.0$  m. The exterior south-facing window of the office had the width of 2.4 m and the height of 2.0 m with the sill height of 0.8 m. The reflectance of the floor, walls, and ceiling were set as 0.2, 0.5, and 0.8, respectively. The window glazing was assumed to have the visible transmittance of 0.44 and the visible transmittance of the window shade was assumed to be 0.2.

## RESULTS AND DISCUSSION

Figure 4 shows the mean of the annual lighting electricity use for when the stochastic models were implemented for occupancy and window shade use, whereas four light switch-on models were implemented for lighting use (see Figure 2). Figure 4 also shows the coefficient of variation ( $CV$ ) of the annual lighting electricity use, which is the ratio of the standard deviation to the mean annual lighting electricity use. For each of the considered number of offices, samples of offices were chosen randomly with replacement and with the size equal to the corresponding number of offices from the 150 offices. Figure 4 indicates that the annual lighting energy use averaged across the 150 simulated offices was predicted to be about 2.3 kWh/m<sup>2</sup> when the stochastic and rule-based models and custom schedule were used for light switch-on events. With the standard lighting schedule, which does not give credit for daylight, the lighting use was predicted to be about three times as much as the stochastic light switch-on model. Figure 4 shows that the average annual lighting energy use in random sampling of different numbers of offices gives similar values after a given number of offices. The standard deviation of the annual lighting energy use did not change significantly after a given number of offices as well. These observations follow the *Central Limit Theorem*. Note that since the stochastic occupancy model was used, the lighting energy use varied when the static-deterministic lighting use models were used.

To find the number of offices at which the mean annual lighting energy use approached a consistent value, the  $CV$  was calculated. The obtained  $CV$  indicated that the occupant modeling approach highly influences the office building size at which the standard deviation fell below 10% of the mean lighting energy use. The rule-based model and custom schedule for lighting use provided a similar prediction of the annual lighting energy use to the stochastic model. However, they require a smaller number of offices to provide a good approximation of the lighting use of a larger office building (Table 1).

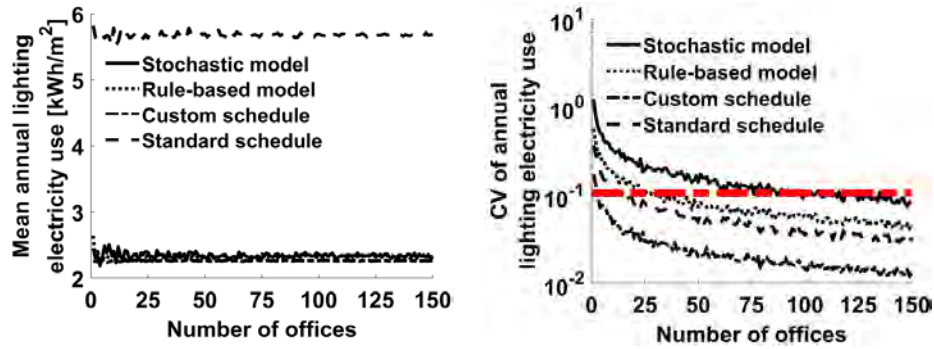

Figure 4. Annual lighting electricity use of samples with different sizes based on the simulation results of 150 annual run periods. Red dashed line represents  $CV$  of 10%.

Table 1. Number of offices at which lighting electricity use approached a consistent value with different modeling approaches for occupants' lighting use.

Lighting use model	Number of offices	Mean lighting electricity use of 150 offices (kWh/m <sup>2</sup> )
Stochastic model	87	2.3
Rule-based model	30	2.3
Custom schedule	3	2.3
Standard schedule	17	5.7

## CONCLUSION AND FUTURE WORK

This paper evaluated how the variations in occupants' presence and behavior can affect the predicted lighting electricity use at different spatial scales under different occupant modeling approaches for lighting use.

The results indicated that while occupants have been considered as an uncertainty source in the prediction of building energy performance, the inter-occupant variations at larger scales is not as important as at the room level. Therefore, building engineers may not need to be concerned about inter-occupant diversity in large office buildings if their objective of simulating buildings is to reliably predict the average annual lighting energy use of buildings. However, stochastic models still play an important role in a simulation-based design, such as evaluation of the robustness of a particular design. The results of this paper indicated that rule-based lighting use model and custom lighting use schedules can reasonably represent occupants' impact on the energy performance of buildings at larger scales. For an office building which is comprised of more than 100 private offices, rule-based lighting use model and custom lighting use schedules can be used instead of stochastic models to provide a good approximation of the lighting electricity use of the office building.

This research assumed that the lighting use of each office was controlled independently. However, one control system may be used for a group of offices. Future research on the impact of the number of offices which are controlled together is necessary. Impact of variation in occupants' characteristics, such as occupants' age, gender, and profession, at different spatial scales should also be studied.

### ABSTRACT

It is important to create comfortable indoor environments for building occupants. This study developed neural network (NN) models for predicting thermal comfort in indoor environments by using thermal sensations and occupants' behavior. The models were trained by data on air temperature, relative humidity, clothing insulation, metabolic rate, thermal sensations, and occupants' behavior collected in ten offices. The models were able to predict similar acceptable air temperature ranges in offices, from 20.6°C to 25°C in winter and from 20.6°C to 25.6°C in summer. The comfort zone obtained by the NN model using thermal sensations in the ten offices was narrower than the comfort zone in ASHRAE Standard 55, but that obtained by the NN model using behaviors was wider than the ASHRAE comfort zone. This investigation demonstrates alternative approaches to the prediction of thermal comfort.

### KEYWORDS

Indoor environment, Model training, Data collection, Air temperature, Relative humidity

### INTRODUCTION

Currently, people in North America spend roughly 90% of their time indoors. Therefore, it is important to create comfortable, healthy, and productive indoor environments for the occupants. To improve an indoor environment for building occupants, one would need a good method for evaluating the environment. Current evaluation methods for thermal comfort can be divided into two categories: using questionnaires under controlled indoor environments (Fanger, 1970; Chow et al, 1994; Cheong et al, 2006) and without varying controlled parameters (De Dear, 1998; Mishra et al, 2013). However, the two types of thermal comfort model do not consider the influence of occupants' behavior on thermal comfort. Therefore, the two categories of evaluation methods may not be ideal for evaluating the thermal comfort in actual environments.

Evaluation of thermal comfort should be based on thermal sensations in actual environments rather than in controlled environments. In an actual environment such as an office, occupants go about their daily activities in surroundings with which they are familiar. However, numerous studies (Langevin et al, 2015; Luo et al, 2014) have found that occupants' behavior changes their thermal sensations, because the behavior impacts their expectations of thermal comfort. Therefore, it is necessary to develop an evaluation method for indoor thermal comfort that considers occupants' thermal sensations and behavior in actual environments. The purpose of this study is to develop methods for evaluating thermal comfort in actual environments by using thermal sensations and occupants' behavior.

## METHODS

### Data collection

This investigation collected data on air temperatures, relative humidity, clothing levels, thermal sensations, thermostat set points, and room occupancy in ten offices in the Ray W. Herrick Laboratories at Purdue University, Indiana, USA. Among the ten offices, half of them were multi-occupant student offices, and the rest were single-occupant faculty offices. Five faculty members and more than fifteen students participated in the data collection. This study collected thermostat set point data from the building automation system (BAS) every five minutes. Each office had a thermostat that enabled the BAS to control the air temperature set point within the range of 18.3°C to 26.7°C. We used data loggers (Sper Scientific 800049) in each office to collect air temperature and relative humidity every five minutes. We used a questionnaire to collect the thermal sensation (-3 for cold, -2 for cool, -1 for slightly cool, 0 for neutral, +1 for slightly warm, +2 for warm, and +3 for hot) and clothing level from the occupants when they were inside the offices as well as their behaviors in adjusting the thermostat set point or their clothing level, arriving at the office, and leaving the office. This study assumed that occupants actively adjusted the thermostat set point for their comfort, because the cost of maintaining a comfortable environment is typically not on their minds. Note that all data collection in this study was approved by Purdue University Institutional Review Board Protocol # 1704019079.

### Neural network models

With the collected data, this study used neural network models to correlate the indoor environmental data with occupants' thermal sensation and behavior. As this investigation sought to correlate occupants' thermal sensation and behavior with indoor environmental parameters, it was necessary to identify two separate NN models. As shown in Figure 1, an NN model has a layered structure usually comprised of three layers: an input layer, a hidden layer and an output layer.

Figure 1. Structure of the NN models, with four input parameters in the input layer, ten neurons in the hidden layer, and one output parameter in the output layer. The “w” and “b” in the hidden layer and output layer represent weight matrix and bias, respectively. The transfer function in the hidden layer was a logistic function

This investigation used an NN model to predict thermal comfort. According to the PMV thermal comfort model (Fanger, 1970), six parameters have an impact on thermal comfort: air temperature, relative humidity, clothing insulation, air velocity, metabolic rate, and mean radiant temperature. Our study assumed that the mean radiant temperature was the same as the room air temperature. Our measurements showed that the air velocity in the offices was less than 0.2 m/s, and thus the impact of air velocity on thermal comfort can be neglected. To predict thermal comfort, the NN model requires only four input parameters. According to the ASHRAE Handbook – Fundamentals (ASHRAE, 2017), the occupants could sit or walk inside their offices, and the corresponding metabolic rates were 60 W/m<sup>2</sup> and 115 W/m<sup>2</sup>, respectively. The insulation values for different clothing ensembles worn by participants in this study was also based on ASHRAE Handbook - Fundamentals.

This investigation used another NN model to predict occupants' behavior. We assumed that the input parameters of this NN model were again air temperature, relative humidity, metabolic rate, and clothing insulation. The output of the behavioral NN model is the occupants' behavior.

We used “-1” for raising the thermostat set point or adding clothes when occupants feel cool, “0” for no behavior when the occupants feel that the environment is acceptable, and “1” for lowering the thermostat set point or reducing the clothing level when they feel warm.

This study used Matlab Neural Network Toolbox to build and train the two NN models. The training process entailed finding the weight matrix and bias in the NN models that would minimize the error between the model outputs and targets. The targets were the actual thermal sensation and behavior occurrences that had been collected. We used the Levenberg-Marquardt algorithm to train the two NN models.

## RESULTS

### Data collection

Data were collected in all four seasons of 2017. In each season, we collected the data for more than one month in every office. Table 1 shows the percentage of occupants' behavior occurrences at different thermal sensations in the offices. When the occupants felt hot (+3) or cold (-3), they always adjusted the thermostat set point or their clothing level. However, if the occupants felt warm (+2) or cool (-2), the percentages of behavior occurrences were only 72.2% and 53.3%, respectively. When they felt slightly warm (+1) or slightly cool (-1), the percentages of behavior occurrences dropped further to 17.6% and 26.4%, respectively. According to the collected data, there were several cases in which occupants felt uncomfortable, but no behavior occurred. For example, when feeling uncomfortable immediately after entering the office, some occupants preferred to adjust the thermostat set point after some time had passed. In other cases, the HVAC system may not have responded quickly to the latest adjustment, yet the occupant waited for a while even though he/she may have felt uncomfortable. There are several possible reasons. First, sometimes the control of the HVAC system had some time delay. Second, if the occupant raised or lowered the set point a lot, it would take more time to respond. Third, the room air temperature was hard to respond the low set point if the office was occupied with many occupants and their computers were on, or because of the sunlight in exterior zone. In these cases, the occupants' behavior did not reflect their true desires in regard to controlling the indoor environment. For multi-occupant offices, meanwhile, an acceptable indoor environment may have been a compromise among several occupants. Some occupants may have felt uncomfortable, but they did not adjust the thermostat set point because the other occupants were not complaining about the comfort level, or they were unsure whether others would feel the same way. Table 1 correlates occupants' behavior occurrences with their thermal sensations.

Table 1. Percentages of behavior occurrences under different thermal sensations in the offices

<i>Thermal sensation</i>	<i>Behavior occurrences</i>		
	-1	0	1
-3	0%	0%	100%
-2	0%	46.7%	53.3%
-1	0%	73.6%	26.4%
0	0%	100%	0%
1	17.6%	82.4%	0%
2	72.2%	27.8%	0%
3	100%	0%	0%

### Comfort zones predicted by the two NN models

Figure 2 illustrates the comfort zones for the office environment in winter and summer obtained by the NN model using thermal sensations. The default clothing level was 1.0 Clo and 0.5 Clo in winter and summer in ASHRAE Standard 55 (ASHRAE, 2013), respectively. We assumed that the office occupants were sitting, and thus their metabolic rate was 1.0 MET. For the

comfort zone outlined in green in the figure from slightly cool to slightly warm, the air temperature ranged from about 20.6°C to 25°C in winter and from about 20.6°C to 25.6°C in summer. The lower and upper bounds of the absolute humidity in the comfort zones were the minimum and maximum of the absolute humidity found in the data, which may not be equivalent to the comfort boundaries. Within the range of the data, humidity does not seem to have been a key thermal comfort parameter in the offices.

Figure 2. Comfort zones for office environments in winter (left) and summer (right) obtained by the NN model with the use of thermal sensations.

Figure 3 illustrates the acceptable zones for an office environment in the winter and summer seasons obtained by the NN model using behavior. An acceptable environment is one in which occupants can work without adjusting their behavior, although they may feel slightly uncomfortable. An unacceptable environment is one in which occupants have to adjust the thermostat set point or their clothing level. This study used the information in Table 1 to define the acceptable zones for various percentages of the occupants. The blue, green and orange zones in Figure 3 represent the humidity and temperature ranges within which 88%, 76% and 15% of the occupants did not adjust the thermostat set point or their clothing level. Under the assumption that “no behavior” signifies an acceptable environment, the acceptable indoor air temperature for 76% of the occupants ranged from 21.1°C to 25.6°C in winter and 20.6°C to 25°C in summer. The results of the behavior NN model also indicate that the humidity had little impact on behavior in the offices in different seasons. This was because our data were collected within a narrow humidity range. Furthermore, office occupants could not signify their humidity preferences by any of the adjustment actions that were recorded.

Figure 3. Acceptable zones for office environments in winter (left) and summer (right) obtained by the NN model using behavior.

The acceptable zones obtained by the NN model with the use of behavior, shown in Figure 3, are similar to the comfort zones obtained by the NN model using thermal sensations, displayed in Figure 2. The good correlation between the two sets of results implies that one may evaluate the indoor environment in offices by using either of the NN models.

### Comparison of the comfort zones with the ASHRAE comfort zones

Figure 4 compares the comfort zones obtained by the two NN models with the ASHRAE comfort zones. The blue outlines indicate the ASHRAE zones, which uses a PMV range from -0.5 to 0.5 and an acceptability of 80% for the occupants. The comfort zones obtained by the NN model using thermal sensations are narrower than the ASHRAE comfort zone. This implies that the office occupants were pickier than the occupants participated in the study of obtaining ASHRAE comfort zone. However, the comfort zone obtained by the NN model using behaviors was wider than the ASHRAE comfort zone, especially in summer. This is because we assumed that the absence of behavior signified an acceptable environment. However, in some situations as stated before, the occupants may have felt that the environment was unacceptable, yet they exhibited no behavior. Thus, these situations led to a higher acceptability of the indoor environment in the offices.

In addition, the comfortable room air temperature predicted by the two NN models in summer was about 2.2°C lower than the temperature of the ASHRAE comfort zone. One possible reason is that the office occupants were not responsible for the electricity bill and often set the temperature lower than would be desirable in the comfort zone in order to cool the room more quickly. Actually, setting a lower temperature does not cause faster cooling but over cooling.

Figure 4. Comparison of the comfort zones obtained by the two NN models and the ASHRAE comfort zones in winter and summer.

### DISCUSSIONS

The NN models have been developed to determine the relationship between the adjustment of thermostat set point and clothing level or thermal sensations, and air temperature and relative humidity. High-quality data were necessary for training the models. However, we used a questionnaire to collect clothing level data. The choices on the questionnaire were limited, but an overly long list might have confused the participants. In addition, we used metabolic rates for sitting and walking without accounting for differences in gender or age. Furthermore, the actual activities of the occupants were not limited to sitting and walking. Any discrepancies may have significantly impacted the robustness of the training process and thus the prediction accuracy of the NN models. In addition, since humidity was not controlled in the offices, the models may not be appropriate when the humidity level exceeds the range of the study.

## CONCLUSIONS

In this study, we collected data in ten offices in Indiana, USA and built two NN models to determine the relationship between air temperature and relative humidity, and occupants' thermal sensations and behavior. This investigation led to the following conclusions:

(1) Under the assumption that a slightly cool to slightly warm environment is comfortable for occupants, the air temperature should be between 20.6°C and 25°C in winter and between 20.6°C and 25.6°C in summer. For a 76% acceptance rate, the corresponding indoor air temperature should be between 21.1°C and 25.6°C in winter and between 20.6°C and 25°C in summer. The two NN models provided similar results. Hence, we can use the behavior of occupants to evaluate the acceptability of an indoor environment in the same way that we use thermal sensations.

(2) The comfort zone obtained by the NN model using thermal sensations in the ten offices was narrower than the comfort zone in ASHRAE Standard 55, but the comfort zone obtained by the NN model using behavior was wider than the ASHRAE zone.

## ACKNOWLEDGEMENT

The authors would like to thank Dr. Orkan Kurtulus of CHPB at Purdue University for his kind assistance in setting the BAS in the Herrick Laboratories building. We would also like to thank all the occupants of the offices for their participation and assistance in obtaining the data reported in this study. The research presented in this paper was partially supported by the national key R&D project of the Ministry of Science and Technology, China, on "Green Buildings and Building Industrialization" through Grant No. 2016YFC0700500, in addition to the main support from CHPB at Purdue University.

## **Quantification of building energy performance uncertainty associated with building occupants and operators**

Sara Gilani<sup>1,\*</sup>, William O'Brien<sup>1</sup>

<sup>1</sup>Carleton University, Ottawa, Canada

*\*Corresponding email: SaraGilani@email.carleton.ca*

### **ABSTRACT**

Occupants play an important role in building energy performance, while building operators are the other side of the coin. This research quantifies the relative impact of probabilistic versus standard occupant models on building energy use. Energy performance of a high-performance reference small office building in Ottawa, Canada, is investigated using a simulation-based analysis. The impact of building users is studied by systematically altering occupant and operator-related domains, including occupants' presence and use of lights, window shades, operable windows, plug-in appliances, and thermostats. The results showed that the predicted natural gas energy use increased by a factor of about two compared to the reference occupant models. The predicted electricity energy use decreased about 49% compared to the reference occupant models. This deviation for the gas use resulted from modeling all six domains and for the electricity use resulted from simulating all six domains except for the window shade and operable window use using probabilistic models and operators' adjusted thermostat setpoints with the air handling unit scheduling to be on all day. The maximum deviation of the predicted electricity energy use with occupants' adjusted thermostat setpoints caused by the simultaneous probabilistic modeling of the four domains of occupants' presence and use of lighting, plug-in appliances, and thermostat. The lighting use domain showed the highest main effect on the energy use. The findings of the examination of occupant and operator-related modeling assumptions emphasizes the necessity to consider both operators' and occupants' impact on the predicted energy performance of the small building-scale model.

### **KEYWORDS**

Building occupants and operators; Uncertainty; Building energy performance; Simulation-based analysis; Probabilistic models.

### **INTRODUCTION**

Building engineers are required to design buildings that comply with building standards in the design phase of new constructions. However, constructed buildings which were designed to be energy-efficient may not meet building engineers' expectations due to the uncertainties associated with the predicted energy performance in a simulation-aided design process (Macdonald and Clarke, 2007). One of the widely-recognized sources of uncertainty in the predicted energy performance of buildings is how buildings are used in reality (Menezes et al., 2012; de Wilde, 2014). Occupants are perceived as the main users of buildings; however, operators are the hidden users who may divert real energy performance of buildings from what were expected. Consequently, the degree of uncertainty associated with buildings' operators may rival the uncertainty caused by buildings' occupants. The great degree of uncertainty from buildings' users on building energy performance and the corresponding importance of improving modeling practice have been repeatedly emphasized by the occupant behavior research community. For instance, Clevenger and Haymaker (2006) quantified

occupants' impact on the energy use of two typical buildings in the USA by changing different ranges for the occupant-related schedules, loads, and densities, individually and in a combination of all the considered occupant behaviours. Similarly, Hopfe and Hensen (2011) performed an uncertainty analysis of various occupant-related loads and densities. In contrast to Clevenger and Haymaker's (2006) approach of implementing discrete ranges, Hopfe and Hensen (2011) used the Monte Carlo analysis within a continuous distribution of the considered parameters (Macdonald, 2002). Furthermore, Hong and Lin (2013) incorporated a similar approach to Clevenger and Haymaker's (2006) study and compared the energy use of a typical office room for the two extreme ranges of using energy to a standard energy usage. While the aforementioned studies evaluated the impact of different building users' behaviours on the energy use of a room or building-scale model, there is still the gap in the literature with respect to the relative impact of occupants and operators on the energy use of buildings.

To address this gap, the current research performed an assessment of uncertainty associated with occupants and operators on the annual energy use of a building-scale model. The main objective of this paper is to quantify the relative impact of buildings' occupants and operators on the energy performance of buildings. Occupant and operator-related domains which were studied in this paper include: occupants' presence and use of lights, window shades, operable windows, plug-in appliances, and thermostats. Probabilistic models for each of these domains were applied systematically one at a time as well as with different numbers of domain combinations to quantify the impact of each domain and differently sized groups of domains with two sets of air handling unit (AHU) schedules and two thermostat adjustment models. The main research questions of the current study are: (1) What is the relative effect of different occupant and operator-related domains on the energy performance of buildings? (2) Among the considered domains in the current research, which domain causes the highest main effect on the energy use? (3) Relevant to the previous question, the interaction of which domains causes the highest effect on the energy use?

## METHODOLOGY

This section describes the building model, occupant and operator models which were implemented in simulation, and the simulation process.

### Building model description

The office building was modeled in SketchUp and OpenStudio on the basis of ANSI/ASHRAE/USGBC/IES Standard 189.1 (2014) for a high-performance small office building in climate zone 6A (Figure 1). Thermal energy demand of each office was delivered by independently controlled variable air volume boxes with reheat coil. Independently controlled hot water baseboard heaters delivered supplementary heating to each office. Each perimeter office had an operable window with the opening area of  $0.1 \text{ m}^2$ . The heating demand of the simulated model, which was located in a heating-dominated climate, was delivered by a gas boiler.

Figure 1. Geometry and envelope specifications of the office building model.

### Occupant and operator models

A one-storey office building model was simulated in this study. The building consisted of one core open-plan office and 16 perimeter private offices. Standard schedule-based and probabilistic occupant models were incorporated in simulation (Table 1). Probabilistic models were implemented in the EMS application of EnergyPlus. The case study building was assumed vacant on weekends. Lights were assumed to be turned off automatically with 30-minute time delay after occupants left their offices. A daylight sensor to serve as an input to the occupant's manual light and shade adjustments was located at a height of 0.8 m in the center of each perimeter office. For the corner offices, it was assumed that once occupants took action to use operable windows and/or shades, they adjusted both operable windows and/or shades.

To perform a relative comparison between occupants and operators' impact, based on an informal study of numerous Canadian commercial buildings energy audits, two AHU modes were implemented to represent one major aspect of operator behavior: (1) always on, and (2) from 6am to 6pm on. To investigate the operators and occupants' impact, two thermostat adjustment models were implemented: (1) occupant agent, and (2) operator agent. Heating and cooling setpoints were set 21 and 24°C from 6am to midnight and were set back to 15.6 and 26.7°C the rest of the day. This setpoint adjustment was set when Gunay et al.'s (2018) model of occupant-agent thermostat adjustment was implemented. Heating and cooling setpoints were set to 21 and 24°C at the beginning of each annual run time for when Gunay et al.'s (2018) model of operator-agent thermostat adjustment was implemented. This thermostat setpoint setting follows Gunay et al.'s (2018) study, as once an operator changed thermostat setpoints, changes were kept fixed unless occupants requested another adjustment. The upper cooling setpoint was confined to 30°C. It was assumed that operators only adjusted thermostats between 7am and 4pm.

Table 1. Occupant and operator models.

Domain	Models		
	Probabilistic models		Standard-based schedule
	Private offices	Open-plan office	
Occupancy	Page et al.'s (2008) occupancy algorithm	O'Brien et al.'s (2018) model	ANSI/ASHRAE/USGBC/IES Standard 189.1 (2014)
Lighting use	Reinhart's (2004) light switch-on model		
Window shade use	Haldi et al.'s (2016) model	-	Always open
Operable window use	Haldi and Robinson's (2009) model	-	Always closed
Electric equipment use	Gunay et al.'s (2016) model	O'Brien et al.'s model (2018)	ANSI/ASHRAE/USGBC/IES Standard 189.1 (2014)
Thermostat adjustment	Gunay et al.'s (2018) model of occupant or operator thermostat adjustment	Gunay et al.'s (2018) model of operator thermostat adjustment	

### Simulation

The timestep was set as five minutes. To quantify the impact of the occupant and operator-related domains, probabilistic models for each domain were used: (1) one at a time, and (2) different numbers of domain combinations. The domain(s) that was (were) not chosen to be simulated using the probabilistic model, was (were) simulated using the standard-based schedules. The results of a study involving 100 annual simulations showed that 20 annual

simulation runs was adequate that the difference between the minimum and maximum standard deviation to the average gas and electricity energy use fell below 10%. Since incorporating probabilistic occupant models for all the domains resulted in the highest uncertainty compared to when all the domains are not simulated using the probabilistic models, the required simulations for each domain combination was determined as 20.

## RESULTS AND DISCUSSION

The reference small office building using the default occupant and operator-related values (i.e. base case) was simulated for one annual run period. The energy performance of the simulated building model was compared to the reference occupant models based on two performance measures: (1) total natural gas use for heating demands, and (2) total electricity use for cooling demands, lights, electric equipment, the fan, and pumps. To present results in this section, occupants' presence and use of lights, blinds, operable windows, plug-in appliances, and thermostats are hereafter referred to as: "O", "L", "B", "W", "P", and "T".

Figure 2 shows the results of implementing probabilistic models for the considered domain(s) on the energy use. Note that occupants' thermostat adjustment model was implemented in these cases. This figure shows that, generally, the interaction between a larger numbers of domains which were simulated using probabilistic models caused the predicted energy use to deviate from the base case more than those using probabilistic models for only a portion of the considered domains. The maximum effect on the electricity use was when the probabilistic models for the domains of occupants' presence and use of lights and plug-in appliances were incorporated in simulation. Figure 2 indicates that generally, AHU mode 1 caused higher deviation of the predicted natural gas energy use from the base case (with AHU mode 1) compared to AHU mode 2, while AHU mode 2 caused higher deviation of the predicted electricity energy use from the base case (with AHU mode 1). For example, the gas energy use increased by 70% with AHU mode 1, while it increased by 41% with AHU mode 2 when all considered domains were simulated using probabilistic models. On the other hand, the electricity energy use decreased by 40% with AHU mode 1, while it decreased by 52% with AHU mode 2 when all considered domains were simulated using probabilistic models.

Figure 2. Comparing impact of various domain combinations with two AHU schedules.

Figure 3 compares the energy use when operators or occupants adjusted thermostat setpoints. This figure shows that adjustment of temperature setpoint by operators resulted in higher deviations in the predicted energy use from the base case compared to when occupants adjusted thermostat setpoints. Figure 3 indicates that generally the maximum deviation of the predicted electricity energy use from the base case was when occupants' presence and use of

model in a heating-dominated climate zone. The relationship between the current results and different climates is necessary future work.

## **Towards a New Way of Capturing Occupant Well-being**

Mark Allen<sup>1,\*</sup> and Mauro Overend<sup>1</sup>

<sup>1</sup>University of Cambridge, United Kingdom

### **ABSTRACT**

Occupant well-being is undergoing a surge of interest in both the research community and industry, as the potential benefits of increased levels of well-being become better quantified and understood. Well-being science itself is also constantly evolving, moving from the traditional negative view of depression and mental disorders as markers of well-being, towards the more positive notion of flourishing, which is feeling good and functioning well. This paper first sets out the key elements of well-being, as found in psychology literature. Surveys and interviews are the main methods used to capture the well-being of individuals and populations, yet completion rates can be low, occupants distracted or irritated by requests to complete surveys and the data infrequent or irregular. Instead, cameras emerge as a potential economic way to gain information about occupants. Their comfort, health and well-being can be monitored with a high frequency, low intrusion and low cost through the use of facial emotions and movements. To this end, a small pilot study is carried out to examine the effectiveness and practicality of data capture by cameras. Data from a new naturally ventilated office building in Cambridge, United Kingdom, is inspected alongside more traditional well-being assessment techniques. It finds that occupants quickly forget that they are being monitored by the cameras and are very engaged with the research, keen to see if it can help improve their workspace. The results and experience from this pilot study form the basis of a more extensive programme of investigations that are described at the end of this paper. The aspiration is to develop this method so that it can be deployed as part of a wider toolkit to holistically capture high quality information about the comfort, health, and well-being levels of building occupants.

### **KEYWORDS**

well-being, occupant satisfaction, smart buildings, comfort, smart sensing

### **INTRODUCTION**

Levels of depression, stress, and anxiety have risen drastically since 2012, with 50% more incidents being reported in workplaces worldwide (Weiner, 2015). Further, the number of people living and working in urban areas is increasing significantly, a further 2.5 billion from today's figure by 2050 (United Nations, Department of Economic and Social Affairs, 2014). With urban areas becoming more dense and green spaces disappearing (CPRE, 2017), the health and well-being of people living in these areas could suffer (Maller *et al.*, 2006). However, people are beginning to take a greater interest in their own health and well-being, with the global wellness market now being three times larger than the pharmaceutical industry (Yeung and Johnston, 2014). This is mirrored in the current explosion of interest in health and well-being in the built environment, with companies such as WELL and Fitwell creating standards to promote good design and improved building control strategies. Further, through creativity and productivity improvements, research is starting to understand and put a value on the effect of increased levels of comfort, health, and well-being on businesses. While historically the construction sector has focused a lot on reducing the energy use of buildings, around 90% of a typical businesses expenditure can be attributed to people, as opposed to only 1% to end-use

energy costs (WGBC, 2014). This reinforces the need to focus on people when designing, controlling or refurbishing buildings, particularly as energy gets cheaper and cleaner, as renewables take over from fossil fuels (Renewable Energy Agency, 2017).

Health and well-being have many definitions (Dodge *et al.*, 2012) but perhaps the most commonly used is that enshrined in the constitution of the World Health Organisation (WHO) which states: '[health is] a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity' (WHO, 1948). This positive focus is also mirrored in new well-being research, where flourishing, (a high level of well-being) is defined by Huppert & So (2013) as '(...) the experience of life going well. It is a combination of feeling good and functioning effectively'. The extent of the built environments contribution (or lack thereof) to an occupant's level of well-being, and how this interrelates with the nature of work and interactions at work is complex.

This paper sets out the background and initial work done on the development of a new type of sensor, which may be able to provide high quality data on the comfort, health, and well-being of building occupants. This sensor could stand alone or form part of a wider toolkit to holistically monitor occupants, helping us better our understanding in this area. The name 'well-being sensor' is purposely optimistic, particularly considering that experts in psychology cannot agree as to exactly how well-being should be measured or defined (Huppert, 2014). The initial idea is therefore to ascertain what information can be gathered about occupants' interaction with the environment from their facial expressions and movements. This moves away from the more traditional Fanger (1973) type approach, which measures environmental characteristics with average levels of activity and clothing levels and infers occupant comfort from those metrics (Figure 1). There exist several sensors for measuring the individual environmental characteristics (temperature, CO<sub>2</sub>, etc.), however, the underlying research question in this study is: could a sensor be developed to measure 'well-being' from people directly?

### AFFECTIVE COMPUTING

Affective computing is 'computing that relates to, arises from, or influences emotions' (Picard, 1995). This study takes advantage of recent improvements in this area of research, specifically emotion and action unit recognition software, such as OpenFace (Baltrusaitis *et al.*, 2016), to establish whether and how they could be used to gauge

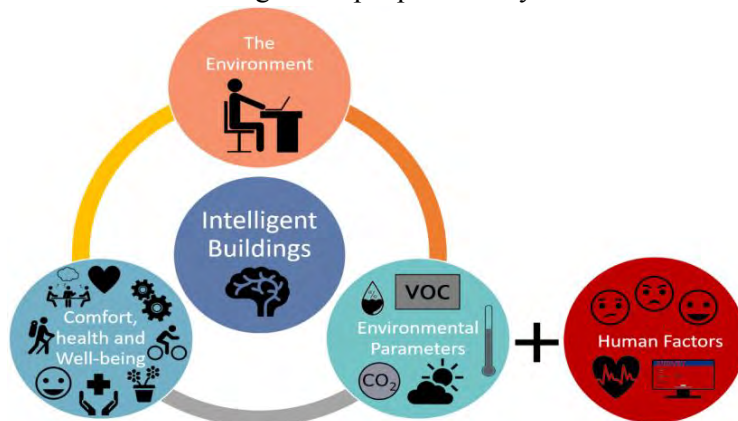

Figure 1 – Intelligent buildings need to include human factors

in order to maximise occupant comfort, health and well-being.

elements of the comfort, health, and well-being of building occupants. These softwares are quite prevalent now and, with the incorporation of artificial intelligence and machine learning, some can even recognise emotions better than humans (Bartlett *et al.*, 2014). Further, OpenFace, which uses non-verbal facial behaviours, has been shown to identify differences between suicidal and non-suicidal groups (Laksana *et al.*, 2017). Using these programs to gauge occupant comfort, health, and well-being could enable the Building Management System (BMS) to proactively change environmental conditions within a building (such as temperature or air quality) with the objective of maximising occupant comfort, health and well-being.

## WELL-BEING

There exists an ongoing, lively debate as to what elements make up overall levels of well-being and on the relative contribution of each individual element. For this study, the Warwick-Edinburgh Mental Well-being Scale (WEMWBS) was chosen as the survey to measure mental well-being as it is one of the most popular and proven scale available. It is generally used to track levels of well-being in populations, but it is suitable for tracking well-being on an individual level, thus making it appropriate for studies and interventions at a local scale (Stewart-Brown *et al.*, 2011). THE WEMWBS survey used for this study consists of fourteen statements, asking the participant to describe on a scale of 1 to 5 how often they have experienced those thoughts or feelings over the last 2 weeks. The questions are as follows: • I've been feeling optimistic about the future • I've been feeling useful • I've been feeling relaxed • I've been feeling interested in other people • I've had energy to spare • I've been dealing with problems well • I've been thinking clearly • I've been feeling good about myself • I've been feeling close to other people • I've been feeling confident • I've been able to make up my own mind about things • I've been feeling loved • I've been interested in new things • I've been feeling cheerful. Similar to populations, there exists a distribution of levels of well-being in buildings as set out in Figure 2. If these levels can be measured more frequently, we can fine tune the design and control of buildings to shift this entire distribution to the right. Improving well-being levels, which may bring productivity and creativity benefits as by-products.

## OBJECTIVES

The key objectives of this research are:

- Review and understand well-being from a 'Psychology' perspective and how this relates to buildings.
- Review existing well-being capture methods and the current state of the art.
- Develop a method to continuously capture elements of occupant well-being from video data.
- Deploy this in several offices to test using a mixed-methods approach.
- Consider future applications.

Figure 2 – The well-being distribution in a population and target to shift this further right.

## METHOD

The methodology used for this study is similar to that used by the Cambridge Computer Lab in their studies using OpenFace (Baltrusaitis *et al.*, 2016). Their method is as follows:

- First, they discuss with a psychologist how they might go about diagnosing a particular condition, e.g. psychosis.
- They then use their software on two groups of people, one with and one without psychosis.
- When analysing their data, they see if there are any statistically significant differences between the two groups, enabling a 'diagnosis' from their software.

This research will take a similar approach. By combining the established method of occupant surveys with cameras and Microsoft's Emotion software, it will be possible to analyse the data and find correlations which infer the same result from survey and camera data sets. Further, from the literature it is clear that there is not a vast body of knowledge about this topic in engineering journals. Rather, most publications tend to be found in computer science, medical and psychology journals. This is a challenge, as the methodologies used by different disciplines can differ substantially. This research will attempt to move towards a methodology more suited

to the study of wellbeing (Giddings, 2012). Known as a ‘mixed-methods’ approach, it is an ‘intellectual and practical synthesis based on qualitative and quantitative research’ (Johnson *et al.*, 2007). This approach was also used by Anderson *et al.*, (2016) with surveys and observations complimenting each other in a natural experiment on well-being in a public space.

Two distinct types of experiment will be undertaken. The first set, referred to as ‘natural experiments’, include monitoring people in their offices as they go about their daily routine. This will then go on to observe how their ‘well-being’ changes as the environment changes significantly, such as when an office is refurbished or hydroponic plants are introduced. The second type of experiment will look at shorter term changes and will take place in an ‘environmental room’. In this room, people will work in isolation whilst various parameters (such as the facade type) are changed and monitored. Throughout the course of both types of experiments, regular, detailed surveys are given whilst occupants are also monitored by a camera. A small-scale proof of concept pilot study was conducted, and is discussed herein. This allowed for many lessons to be learned, ranging from the practicalities of the process of monitoring itself to the analysis of the data.

### PILOT STUDY AND CONCEPT

The James Dyson Building is a mechanically assisted naturally ventilated office building located in Cambridge, United Kingdom. It consists of 4 almost identical floors, each with large open plan offices for PhD students and several cellular offices along the west side for administrators and academics. Six participants took part in the pilot study. They were each filmed every day for 2 months in the summer of 2017 from 9am until 5pm via a webcam connected to a laptop. This created over 500GB of data, which was then processed to assess the emotions of the occupants using Microsoft Emotion Recognition API in 100MB chunks. This process will be automated in future studies to save time. It also highlighted the fact that a lot of data was captured when people weren’t in the office, with the Microsoft API indicating that it could find no faces. The six participants were also given surveys to measure well-being (WEMWBS) and satisfaction with the office environment (Center for the Built Environment (CBE), Berkley).

### RESULTS

The results are limited due to both the small sample size and the limits of Microsoft’s API on data size. Further, Microsoft stopped supporting the emotion from video API halfway through the study. Figure 3 shows the

Figure 3 - WEMWS survey, average occupant response to each question

Figure 4 – Average occupant response to the CBE survey on satisfaction with the office environment.

average occupant response to the WEMWBS questionnaire. Figure 4 shows the average response to the CBE survey, showing that the office performed well when compared to buildings in the CBE database and similar to mixed-mode buildings, although the lighting could be improved. Figure 5 plots these two survey results against each other. While there are too few points to find a definitive connection, there does appear to be a link between occupant satisfaction and mental well-being. Figure 6 incorporates results from the Microsoft Emotion API, again there are too few points to find clear correlation between variables.

## DISCUSSIONS

Interpreting this data is difficult due to the small number of participants and the labour and computer intensive data analysis method chosen for this pilot study. It is however quite clear that occupants lie on a spectrum of well-being, even in this small study. There is insufficient data to support a correlation or indeed a relationship between occupant satisfaction and well-being. The pilot study did however provide important lessons for future experiments. Online surveys proved to be simple to create and complete, providing data in an easy to use format. Further, the method of monitoring via web-cams atop occupant's computer monitor was also successful.

Figure 5 - CBE occupant satisfaction (left) plotted against WEMWBS (bottom).

Figure 6 – Average group emotions and average office temperature on the same graph over 8 days.

## CONCLUSIONS AND FUTURE WORK

A lot was learned in the course of this pilot study, particularly in how to better acquire data. The data is really too large to be post-processed and so, in future experiments, it will have to be processed in real time. The lessons from this pilot study form the basis of a newly-developed data capture method which uses a Raspberry Pi and camera in a user-friendly case which enables data to be captured and processed onboard, or on the cloud. Further, they can be placed either on top of monitors or simply as desk decoration. They are currently being deployed in a much larger experiment which will cover the entire four floors of the James Dyson Building, as well as MATElab (a living laboratory based in Cambridge) and several other offices. We hope that this new, larger dataset will allow us to find any statistically significant correlations between the facial action units or emotions and the level of comfort, health and well-being of the occupants. This could then be used to control building elements, such as adaptive facades (Loonen *et al.*, 2017), in a more intelligent, occupant centred manner, providing a very useful input into future building management systems.

## ACKNOWLEDGEMENTS

I would like to thank the EPSRC, Trimble, BRE and Microsoft for enabling this research. Further to my supervisor and colleagues in the gFT and FIBE research groups for their support.

## **Conserving Energy, Conserving Buildings: Airtightness Testing in Historic New England Homes**

David Fannon<sup>1,2,\*</sup>, Jamaica Reese-Julian<sup>1</sup>

<sup>1</sup>School of Architecture, Northeastern University. Boston, MA.

<sup>2</sup>Department of Civil & Environmental Engineering, Northeastern University. Boston, MA.

\*Corresponding email: david.fannon@northeastern.edu

### **ABSTRACT**

As a location of early European settlement, New England enjoys a wealth of historic buildings, which represent a rich cultural heritage and insight into New England life. Their longevity also offers the opportunity to identify the characteristics of long-lasting buildings, and to guide design for the historic buildings of the future. Old buildings are inherently *sustainable*; both because of abstract ideas like “embodied energy” but also by sustaining history and culture over time. This study combines field methods from *vernacular architecture* (a branch of material culture studies) and *building science* (which exists between architecture and engineering) to conduct detailed investigations buildings representing four centuries of New England residential construction. Methods include detailed physical measurements of each building, interior and exterior photography, as well as air leakage measurement with a blower door. Buildings are contextualized from the historical literature, and scientific measurements are compared to the literature of both contemporary and other past buildings. Applying these methods to everyday buildings reconnects the study of building performance to its material, technical and cultural context, as well as the behavior of the occupants whose shelter and comfort it is meant to provide. At the same time, the information about the environment created by the building adds depth and nuance to the understanding of the cultural attitudes and activities of generations of occupants and supports the continued stewardship of these shared cultural resources. This research enriches the narrative of historic human and building interaction: infusing scientific questions of *how* buildings work with the cultural context and human intentions that dictate *why*. Understanding and preserving old buildings includes environmental as well as cultural conservation, prompts us to think of reversible interventions, and militates against the hubris of present thinking that assumes current knowledge and approaches are optimal, and therefore eternal.

### **KEYWORDS**

Blower Door; Vernacular; Historic Buildings; New England; Building Conservation

### **INTRODUCTION**

Pressurization testing using blower doors is a direct, and relatively inexpensive method for quantifying the airtightness of buildings (ASHRAE, 2013). Sherman concisely recounts the history, principles, and applications of blower door pressurization in buildings (1995). For detached homes—which tend to rely on uncontrolled infiltration through the envelope for ventilation—airtightness has important influence on energy conservation, indoor air quality, and identifying deficiencies for repair (Chan, Joh, & Sherman, 2013). These concerns are perhaps even more critical in historic structures, particularly those being maintained by non-profit stewardship organizations as house museums, given the tangle of preservation, maintenance, repair, alteration, cultural and economic considerations. In this context, airtightness testing may be a valuable tool. Beyond the benefit to individual buildings,

“understanding the magnitude of leakage in the building stock is important for prioritizing both research efforts and conservation measures” (M. Sherman, 2007). It is clear from the context that he means *energy* conservation, however, the same statement could equally apply to the practice of *building* conservation, particularly of vernacular buildings, both as a pragmatic measure, and as a tool for historical analysis. It may be surprising then how little data are available regarding the airtightness of historic—or even particularly old—buildings.

Sherman and Dickerhoff compiled the results of 1,492 residential airtightness tests from across the United States, to characterize the existing building stock. The data was used to investigate five building criteria that could impact leakage, including year of construction. While acknowledging the potential selection bias (much of the data came from weatherization programs) the authors found a positive relationship between leakiness and age for buildings prior to 1980 (M. H. Sherman & Dickerhoff, 1998). To address the overrepresentation of older buildings in previous data—the feature of greatest value for the present study—a subsequent database compiled blower door results from some 73,000 buildings, many shortly after construction, to yield a set only slightly older than the American Housing Survey dataset (M. H. Sherman & Matson, 2002). Using that data, an exhaustive 2003 study found that older homes are generally leakier than newer homes and described a roughly lognormal distribution. However, the authors went on to identify complex interactions among year built, floor area, and occupant income, with older, smaller and lower-income homes showing higher leakage rates (Chan, Price, Sohn, & Gadgil, 2003). It is difficult to apply these findings directly to the historic homes considered here, but these results do illustrate a similar situation in which building science is complicated by—while simultaneously offering insight about—social, cultural and economic issues. Finally, a 2013 study expanded that database to include results from blower door testing some 134,000 detached homes, and conducted regression analysis to explain the substantial variation among buildings. Limitations in the available data required the authors to categorize year of construction, with the oldest grouping including all buildings built before 1960. However age was identified as one of the most influential parameters, increasing Normalized Leakage by a factor of 2.2 (Chan et al., 2013).

## METHODS

This study conducted air pressurization tests with a blower door in historic New England homes following ASTM-E1827-11 (2017) and ASTM-E779-10 (2010). Ten properties were tested in June and July 2015. Multi-point tests, typically at intervals of 10 Pa, were used in all buildings. Additional points (smaller pressure intervals) were used when building size, leakiness, or equipment limitations made it impossible to achieve a 50 Pa pressure difference. Except where curatorial concerns (e.g. intrusion of chimney soot) dictated otherwise, the results of pressurization or depressurization tests were combined to calculate results. Mechanical and plumbing systems were sealed prior to testing to ensure air leakage across the exterior envelope.

### Equipment

Tests were conducted using a Retrotec Model 1000 calibrated fan, with accuracy of  $\pm 3\%$  of flow. For larger and leakier properties requiring a two-fan setup, a model 3 fan from The Energy Conservancy (TEC) with accuracy of  $\pm 3\%$  of flow when used with the corresponding gauge. Measurements were taken using a Retrotec Model DM32 5A WiFi gauge, running then-current firmware version 2.3.62, accurate to  $\pm 1\%$  of pressure reading or  $\pm 0.50$  Pa (whichever is greater). When needed, the second fan was paired with a TEC model DG-700 gauge, with a stated accuracy of 1% of the reading, or  $\pm 0.15$  Pa, whichever is greater.

External pressure taps were split with a tee and located a minimum of 5m from the testing door, near the midpoints of two walls to balance local pressure differentials. Internal readings were taken at the gauge. All tubes were checked for leaks with the manometer, and manufacturer-recommended field calibrations conducted at the start of each test. Baseline pressure corrections were taken for a minimum of 60 seconds, and retaken whenever testing was interrupted. After stabilization, pressure and flow measurements were recorded with time-averaging of at least 5 seconds, and up to 60 seconds on windy days. A Kestrel 3500 pocket weather station, with a 0.1°C resolution, and  $\pm 0.5^\circ\text{C}$  accuracy, was used to record indoor and outdoor temperatures.

Figure 1: Test Locations

### Sample Buildings

The historic buildings presented in this report are managed by Historic New England, generally as house museums, and represent a broad range of sizes, ages, locations, construction types, and levels of restoration (Historic New England, 2017). Table 1 summarizes key attributes about the sample buildings, including the year of construction (although many were later modified) and primary structural material drawn from HNE records.

Table 1: Attributes of the Sample Buildings

Name	Construction Type	Year	Floors	Envl. Area (m <sup>2</sup> )	Vol. (m <sup>3</sup> )
Pierce House	Timber Frame	1683	3	438	585
SPL Stone House	Stone & Brick	c.1690	2	1463	2,745
Arnold House	Stone, Heavy timber	1693	2.5	404	503
Cogswell's Grant	Wood Frame	1728	2	850	1,597
Casey Farm	Timber Frame	c.1750	2	720	1,183
Langdon House	Wood Frame	1784	3	910	1,614
Lyman Carriage House	Heavy Timber	c.1793	2	823	1,309
Phillips House	Wood Frame	1820	3	1126	2,355
SPL Carriage Barn	Heavy Timber	c.1850	2	453	526
Gropius House	Wood Frame	1938	2	533	632

Buildings are located throughout New England, as shown in Figure 1. In addition to the blower door testing, each building was documented through field measurement and photography to confirm existing drawings and/or develop drawings for the area, volume and surface-area.

### RESULTS

Summary results for each historic property are presented in Table 2 using several metrics. Air Changes Per Hour at 50 Pa pressure difference (ACH50), is a popular, single parameter based on the airflow measurements and building volume. Alternatively, dividing the volumetric flow by the surface area of the enclosure yields envelope flow; which is useful for envelope studies, particularly on geometrically-complex buildings like some in the sample. Effective Leakage Area (ELA) is sometimes characterized for lay readers as the size of the hole if all the leaks were combined and offers a seemingly direct metric that belies the complexity of measurement.

Table 2: Summary results from air-tightness testing sample buildings

Name	ACH50	Envelope Flow (L/s·m <sup>2</sup> )	ELA (m <sup>2</sup> )	NL
Pierce House	17.9	6.60	0.278	2.42
SPL Stone House	11.6	6.05	0.576	1.92
Arnold House	30.4	10.52	0.348	1.99
Cogswell's Grant	10.4	5.45	0.321	1.10
Casey Farm	14.4	6.55	0.415	1.58
Langdon House	10.9	5.38	0.453	0.82
Lyman Carriage House	13.5	5.96	0.376	1.14
Phillips House	10.8	6.29	0.479	0.95
SPL Carriage Barn	33.9	2.84	0.136	1.18
Gropius House	9.1	2.99	0.122	0.85

For context, the testing results are also presented in terms of Normalized Leakage (NL)—a metric commonly used by ASHRAE—and plotted in Figure 2 along with airtightness data for a sample of U.S. homes drawn from the literature (M. H. Sherman & Dickerhoff, 1998).

Figure 2. Plot of normalized air leakage as a function of age<sup>1</sup>. Historic buildings from this study are noted with color-filled shapes based on primary structural material: diamonds (wood) circles (masonry) and triangles (timber). Hollow squares indicate reference averages and standard deviations for irregular age-based bins drawn from Sherman & Dickerhoff (1998).

## DISCUSSION

As shown in Figure 2, older buildings are generally less air-tight than newer buildings, but even the oldest properties tested exhibit leakage rates broadly aligned with those in the pre-1980 historic record. While only a small sample, extending the historical record by approximately

<sup>1</sup> The testing for this study took place over 2 months; however not all houses in the reference set were tested at the same time, so as in the reference, “Age” is calculated with a base year of 1994. It is important to note that “age” cannot distinguish the effect of improvements in construction from the effect of deterioration over time.

two centuries suggests that the positive relationship identified in the literature (M. H. Sherman & Dickerhoff, 1998; Chan et al., 2003) continues, but the nature of the relationship may be complex. Naturally, the scarcity of U.S. buildings from this time, and each building's unique circumstances and history of change, necessarily complicate any generalization. While the collective results offer some general insight, these data also afford only a limited view of each unique home. Understanding the interaction of airtightness with complexities of changes over time are a bridge to a deeper and richer understanding of each building's performance, from the thermal comfort of the occupants to the labour and economic costs of fuel. These curatorial and historical interpretations require a case-study approach and are not presented here; however, they do point to a didactic function of performance testing old buildings. It is tempting to seek lessons in resilience from the sample buildings as among the most durable buildings of their era (the others having not survived), for example based on the suggestive link between leakage and construction material. Yet even putting aside the countless other factors that affect building durability, the sample buildings' status as house-museums complicates any suggestion that these structures offer direct strategies for long-term durability and performance in the New England climate. Belonging to an organization focused on the stewardship of historic buildings and landscapes, these homes are more carefully maintained and more thoughtfully modified than other buildings. Likely their longevity is both a product of care and the impetus for it, so better understanding how to care for them, and how they work demands humility and nuance.

The homes in the sample tend toward vernacular rather than monumental architecture; built for living and having endured long histories of occupation and adaptation prior to becoming museums. Now that they are owned by Historic New England, and preserved as significant examples of historic building, each has undergone various degrees of restoration, both to ensure the physical persistence of the structure into the future, as well as to represent—or interpret—cultural history as an artifact of a time and place. The homes in the sample exhibit a range of curatorial approaches. At one extreme, repairing leaks and openings in the enclosure with period-appropriate materials and techniques restores the performance of the envelope as well as the appearance, with all the associated advantages and liabilities. On the other extreme, modern interventions—albeit usually invisible—may be desirable or essential, particularly to control moisture in liquid and vapor form. For example, one of the projects in this sample required substantial envelope renovations to correct deficiencies in the roof-edge detail and to install flashing under the windows. These details intentionally altered the performance of the original design, although the appearance is all but indistinguishable (Bronski & Gabby, 2013). In another example, bronze weather stripping at windows is an essentially invisible modern intervention when the windows are closed yet provides a seal against air and moisture necessary for the economical operation of modern environmental controls quite unlike the original construction. This reality also reflects a significant challenge for house museums: the buildings in the sample must persist and ensure suitable interior environments for the artifacts inside, such as furniture and decorative arts, without continuous occupancy or the original environmental technologies. The homes in the sample are no longer heated primarily by wood burning fireplaces, and so a common intervention consists of removeable, plastic-wrapped foam plugs to seal the unused chimney flues, thereby dramatically reducing what would have been a major path for air movement out of these buildings. Since none of these buildings are “original” it is fair to wonder whether modern testing reveals anything about the historical reality, however, regardless of changes, to the extent these old buildings are “really” old, the results describe “real” old buildings. As with all history, the measurements of airtightness presented here incorporate both historical facts, and our modern reinterpretation of them.

## CONCLUSIONS

As expected from the literature, blower-door testing a sample of historic, primarily vernacular New England homes built between 1683 and 1938 revealed increased leakage with increased age. Although a numerically small sample, the buildings in this group extend the record of airtightness data in U.S. homes by nearly two centuries, to a period from which there are relatively few existent structures to test. The variation in the data demonstrate that buildings particularly very old buildings, exhibit a range of performance, and militate for specific and nuanced investigations to the history of change over time. Such investigations—while perhaps prompted by and valuable for preservation and curatorial activities—also illuminate the homes performance as shelter: adding a directly human dimension to the study of vernacular history. The persistence and resilience of these vernacular buildings offer buildings scientists examples to study and from which to learn the behavior of structures which have endured—or more precisely, have been *made* to endure—in a specific climate for a long time.

### **ABSTRACT**

Given the massive scientific progress on passive and active solutions to reach near-zero-energy targets, the necessity to consider occupants' behavior as a key variable affecting field energy performance of buildings has become a crucial issue to face. In this panorama, a variety of deterministic and stochastic models, also supported by experimental investigations have been developed in the last decade. This paper builds upon previous contributions to analyze the real occupancy of an office building populated by peers' offices monitored for 2 years by means of microclimate and energy-need field stations. After demonstrating that the peers do not behave the same and do not control in equivalent ways indoors microclimate parameters (e.g. air temperature, desk illuminance, etc.), internationally acknowledged models and field-collected data are compared through dynamic simulation. The estimation of final energy need of different considered scenarios is calculated and the relative difference is highlighted as a possible indicator about the role of building occupancy profiles in affecting energy need prediction. Additionally, EEG experimental test are used to assess the correlation of workers' subjective emotions with external thermal stimuli. Results of final energy need estimation showed to vary by about 20% by only selecting the occupancy simulation scheme, and non-consistent prediction trends are found out while investigating lighting and electric appliances needs. Accordingly, as concerns the human psychological response to the variation of thermal conditions, negligible emotional reactions are found among the different tested workers when suddenly altering comfort conditions indoors.

### **KEYWORDS**

Occupant behavior; Dynamic thermal-energy simulation; Continuous monitoring; Behavior modeling; Scientific Contextual EEG.

### **INTRODUCTION**

Given the acknowledged primary influence of building occupants' behavior on indoor microclimate and energy needs, the understanding of energy related occupant behavior in buildings is a key issue for performance evaluation and optimization at the design stage (Brown and Cole, 2009). In this view, researchers have been working on the understanding and modeling of occupants' behavior in buildings to enable more reliable predictions of building performance (Hong et al. 2016). With the aim of comparing pre- and post-performance of building, Gupta and Gregg (2016) evaluated the actual performance of two low-energy retrofitted buildings in UK. In both buildings, measured annual gas consumption were lower than expected, while electricity consumption was higher as compared to predictions made by energy models, due to occupancy pattern and occupant behavior. In order to face standardized occupancy modeling approach, different stochastic models have been proposed. Such models aim at realistically describing general (Diao et al. 2017) and single energy-related occupancy behaviors, such as people's presence (Mahdavi and Tahmasebi,

2015), windows opening (Fabi et al. 2015), natural ventilation control, and appliances power loads (Zhao et al. 2014). Furthermore, adaptive thermal comfort behaviors have to be understood and taken into account. O'Brien et al. (2016) suggested that the necessary sample size to simulate and exploit occupant diversity between building occupants and uncertainty is dependent on the uniformity of the monitored population. Accordingly, occupants' behavior prediction may become particularly hard in those buildings occupied by a wide variety of users. On the other hand, peer occupants are usually assumed to have identical response to similar environmental conditions and in determining building thermal-energy performance. However, different peer occupants' personal attitudes and habits were found to differently affect the indoor environmental behavior of buildings (Pisello et al. 2016). Therefore, peers' actions homogeneity assumption can involve significant discrepancies in the thermal-energy performance of different areas situated even in the same building position (Kim et al. 2016). In fact, occupants' actions in buildings are related not only to physical stimuli, but also to multi-physics and non-measurable stimuli, in terms of thermal, acoustics, lighting, air quality issues. In this view, further research efforts, in terms of methodologies and simulation tools, are required to elaborate reliable predictive models integrating people energy needy actions into building energy modeling programs (Yan et al. 2015).

In this panorama, the purpose of the present study is to assess the capability of different existing deterministic and stochastic occupancy models for office buildings, usually considered in building dynamic simulation, to comprehensively depict occupants' behavior. To this aim, simulations are compared against real occupancy data continuously monitored in a research office building. Moreover, the discrepancy in terms of final building energy requirements is verified when considering two static standard models, a recent stochastic model, and case-specific models developed based on real monitored data. Additionally, the correlation between occupant's subjective emotions and comfort conditions variation is assessed through neural response tests. Considering the existing literature, the innovative contribution of this research is to compare the performance of different occupancy models in simulating the influence of real offices occupants on total building energy consumption by taking into account the mutual dependence of various occupants' actions. Therefore, different energy-related parameters affected by personal attitudes in office buildings are taken into account. This work builds upon a previous study by the same authors (Pisello et al. 2016) where energy-related peer occupants' behaviors were investigated through field monitoring and peers were found to behave differently based on personal habits and cultural background. Therefore, the capability of a tool based on EEG (Electroencephalography) to assess human perception of discomfort conditions and associated emotional states is evaluated.

## METHODS

The research procedure implemented in this study consists of the following steps:

- Experimental continuous monitoring campaign of equivalent office rooms of a building occupied by peer occupants. Analysis of occupancy-related parameters such as energy need, indoor air temperature, illuminance over the working plane, appliances electricity consumption, and windows and door operation;
- Development of the building model and dynamic simulation when considering various occupancy schedules, i.e. static standard, stochastic, real monitored data-based;
- Data analysis and comparison of thermal-energy dynamic simulation results for the different occupancy scenarios in terms of daily trends of occupant related parameters and building total energy consumption;
- Evaluation of models representing the occupants' behavior in the five monitored office rooms against additional monitored data;

- EEG experimental test of selected occupants under different comfort conditions to assess the correlation of workers' emotional response and external thermal stimuli.

### **Experimental campaign**

The experimental monitoring campaign has been carried out in the case study office building, located in Perugia (central Italy) from late spring 2015. The behavior of a group of peer employees working in 5 office rooms has been continuously monitored through dedicated monitoring stations constituting a Wireless Sensors Network (WSN) system. The selected office rooms presents the same characteristics in terms of geometry, energy systems, and each one is equipped with two/three computers according to the number of workers. The monitoring campaign investigates the main parameters related to (i) indoor microclimate and (ii) occupants' activity inside each office room. A more detailed description of the monitoring campaign, setup, and sensors is reported in (Pisello et al. 2016).

### **Dynamic simulation and occupancy scenarios**

Building modeling and thermal-energy dynamic simulation is carried out through EnergyPlus v8.1 simulation engine (Crawley et al. 2000). Different occupancy models are considered for dynamic simulations: two static models, conventionally implemented in building dynamic simulation, i.e. the UK NCM (National Calculation Method for Non Domestic Buildings) standard (UK DCLG, 2004) ("standard" scenario) and the ASHRAE model based on Standard 62.1-2007 and Standard 90.1-2016 ("ASHRAE" scenario); and the stochastic model obtained from the "Occupancy Simulator" tool (LBNL 2011; Luo et al. 2017) ("occ\_sim" scenario). Moreover, continuously monitored data in the five offices from June 2015 to January 2016 are considered to develop seasonal, i.e. warm and cold season, occupancy schedules to model five scenarios representative of the different offices occupants ("office\_1", "office\_2", "office\_3", "office\_4", and "office\_5" scenarios). In particular, heating and cooling set-points, lighting use, and appliances energy use are taken into account. Simulation results with the three reference occupancy scenarios are compared with real monitored occupants' behaviors in terms of daily trend of occupancy-related physical parameters affecting building energy consumption in summer (July) and winter (January). Additionally, the simulation of the five experimental data-based occupancy scenarios is carried out to evaluate the discrepancy with the reference scenarios in terms of total annual building energy requirement (including HVAC, lighting, and appliances). Moreover, occupants' behavior data monitored in the office rooms during summer 2016 and winter 2016/2017, are used for the evaluation of the developed occupancy schedules. Therefore, the developed models are evaluated when compared against the additional experimental data.

### **EEG experimental tests**

To assess the neural response of workers to external thermal stimuli, the EMOTIV EPOC+ neuroheadset (Figure 1) and software are used. In fact, this tool is capable, among other things, to report the real time changes in the subjective emotions experienced by the user, thanks to the *Affectiv* detection tab of the Xavier ControlPanel software. More in detail, the neuroheadset allows to acquire the user's EEG, which is then post-processed through the supplied software. Therefore, the tool is tested to assess the correlation between human emotions and the variation of external physical stimuli. To this aim, tests are performed to the same peer occupants working in similar office rooms ("user\_1" to "user\_5") when exposed to different thermal conditions, while working at the computer. More in detail, the effect of short-term alteration of the thermal comfort, i.e. by increasing the internal heat gains and, therefore, the air temperature, on the different occupants' emotions is evaluated. Therefore, each occupant is subjected to three test sessions when varying the discomfort time:

- “base”: 30 minutes in a thermally comfortable environment;
- “1/2”: 15 minutes in a thermally comfortable and 15 in a discomfortable environment;
- “1”: 30 minutes in a thermally discomfortable environment.

Figure 1. EEG experimental test. Left) Test example, Right) Neuroheadset.

## RESULTS

### Comparison of occupancy models

Firstly, the trend of occupancy-related simulated parameters in the “standard” and “ASHRAE” scenarios with respect to the monitored data during a summer and a winter day, show that the standardized implemented procedures are neither representative of occupants’ individual attitudes nor of their average behavior and tends to overestimate (“standard”) and underestimate (“ASHRAE”) occupants’ energy needs. As concerns the “occ\_sim”, since only the occupancy presence schedule is changed in this scenario, with respect to the “standard”, negligible differences are found in a single-day-term. Switching to the total annual energy consumption for the eight occupancy scenarios, i.e. the three reference and the five experimental data-based, simulation results confirm the high variability of building energy consumption depending on the considered occupancy scenario. In fact, the monitoring-based occupancy scenarios present lower HVAC annual energy consumption with respect to the reference “standard” scenario, up to 19.7% for “office\_2”. Concerning annual lighting use, all monitoring-based scenarios present lower energy consumption with respect to the three reference scenarios, up to about 13.2 kWh/m<sup>2</sup> per year (“office\_4”). Additionally, although considered as peers, the occupants of the five office rooms show notably different electricity energy use and indoor thermal preference, especially in summer. Finally, the simplified occupancy models developed according to the data monitored during year 2015/2016 were evaluated when compared against the experimental data collected during the following year. Figure 2 depicts the trend of simulated parameters with respect to measured data for an average day in summer. The comparison of measured and simulated parameters stresses the higher, yet still not adequate representativeness of experimental data-based occupancy models, compared to standard and stochastic models. However, relevant discrepancies are still noticed, since occupants’ behavior is inconstant and influenced by multi-physical and multi-dimensional parameters to be more deeply investigated. Similar results are obtained in winter.

### EEG tests results

EEG tests are performed to verify the possibility to correlate the variation of external physical stimuli with worker’s subjective emotions. Results (Table 1) show that the analyzed feelings are generally not affected by alteration of thermal conditions. However, some exceptions are noticed: one of the tested occupants experiences focus and excitement reduction in thermally discomfortable conditions, while another one shows excitement increase when increasing the time of exposure to discomfortable conditions. Nevertheless, this singular results cannot be considered representative. Instead, results generally show that non-physical factors, i.e. focus and involvement in the performed tasks, are more significant drivers of personal emotions and behaviors than physical factors, i.e. thermal conditions. In this view, it has to be considered the short test period and the moderate thermal alteration, which may have affected such result.

Figure 2. Average trend of data monitored in the five office room with respect to simulated data in a summer day. Up left) Indoor air temperature, Up right) Illuminance over the work plane vs. lighting energy use, Bottom) Appliances electricity use.

## CONCLUSIONS

The purpose of the present study is to verify the capability of different standard static and stochastic occupancy models to predict the behavior of real occupants of an office building. To this aim, occupancy behavior-related environmental and energy parameters were monitored in five rooms of a office building to develop experimental data-based occupancy models. Moreover, an EEG based tool is tested as complementary tool to improve occupant behavior understanding and prediction. Results show that the standard occupancy models are neither representative of specific occupants' preferences and peak energy demand nor of their averaged behavior, both in the short-term and in the long-term. In fact, the standardized existing procedures do not take into account the adaptability of human comfort and energy-saving or -wasting habits of office occupants. Conversely, the occupancy scenarios developed based on the experimental data showed to better represent the real daily occupants' attitudes, yet discrepancies are still noticed, due to inconstant human behavior affected by multi-

physical and non-physical stimuli. In this view, neural response tests are demonstrated to be a reliable tool to improve this multidisciplinary analysis. However, this method requires further investigations, by performing several tests, to provide outstanding results that strengthen the first findings obtained in terms of correlation between subjective emotions and environmental conditions.

## ACKNOWLEDGEMENT

This work is part of the case-study research activity of the IEA-EBC program Annex 66: Definition and Simulation of Occupant Behavior in Buildings. Part of this research is carried out within the framework of COLO ARTE by Fondazione Cassa di Risparmio di Perugia, (Grant Cod. 2016.0276.02). The authors' acknowledgements are due to the European Union's Horizon 2020 program under grant agreement No 678407 (ZERO-PLUS).

### **ABSTRACT**

The indoor thermal environment is conventionally considered homogeneous as anchored on a universal thermal comfort paradigm, although occupants' experience is often diversified and influenced by several physio-cognitive factors. Personal comfort devices aim to enhance thermal comfort acceptance through localized heating and cooling while reducing overall energy consumption as temperature set-points of centralized HVAC systems can be relaxed. To further incentivize the adoption of distributed HVAC systems, it is critical to examine the energy benefits and the spatial characteristics of heterogeneous thermal environments.

Here we developed a parametric framework based on building energy modeling coupled with a spatial visualization of micro-climatic thermal fields, which respond to a variable space occupation. HVAC system loads and indoor environmental conditions, extracted from the energy model, are integrated with an analysis of the human thermal balance. As a case study, a thermoelectric-based system for personalized thermal comfort was considered in an office space, based on a specific layout of workstations and meeting rooms. The contribution of distributed heating and cooling systems to the overall HVAC energy consumption was analyzed for the office, and the micro-climatic variability was visualized based on transient occupation patterns.

Understanding the impact of variable occupation for the building energy balance is significant for developing performative metrics for next-generation distributed HVAC systems. At the same time, it can inform novel design strategies based on micro-climatic controls to maximize personalized thermal comfort and enhance the quality of indoor environments.

### **KEYWORDS**

indoor micro-climates, energy modeling, responsive environments, personalized thermal comfort, thermal field visualization.

### **INTRODUCTION**

Expanding the temperature set-points of Heating, Ventilation and Air Conditioning (HVAC) systems may unravel new strategies to reduce building energy consumption and incentivize the adoption of distributed systems for enhanced thermal comfort. Energy savings up to 73% were projected when extending the temperature setpoints of conventional Variable Air Volume (VAV) system to near 30°C for cooling and 17°C for heating (Hoyt, Arens, & Zhang, 2015). Under these conditions, Personalized Comfort Systems (PCS) may provide maximum thermal comfort to occupants and hypothetically utilize less energy than centralized HVAC systems (Amai, Tanabe, Akimoto, & Genma, 2007; Bauman et al., 2015; Kong, Dang, Zhang, & Khalifa, 2017). However, the relationship between PCS and ambient conditions is still largely unexplored, particularly throughout an entire year. The objective of this study is to examine the potential benefits of localized heating and cooling systems for energy savings and

occupants' comfort, and provide means of spatial visualization of micro-climatic conditions indoors. As post-occupancy evaluation shows, thermal comfort acceptance in office spaces is a critical aspect to be considered because it has an impact on building operational energy and indoor environmental quality (Huizenga, Abbaszadeh, Zagreus, & Arens, 2006). Providing means of modeling and visualization of indoor micro-climates has the potential to facilitate the adoption of distributed HVAC systems beyond the strive for system efficiency for a more human-centric design approach.

## METHODS

An energy model was developed to examine HVAC system loads, indoor environmental conditions, and determine human heat balance within an occupied space. An 800m<sup>2</sup> multi-zoned office space with 75% window-to-wall ratio was modeled in *OpenStudio*, a validated energy modeling software. The New York City typical meteorological year was utilized for calculations under ASHRAE 90.1 2013 construction assemblies, schedules, and internal loads. A Variable Air Volume (VAV) HVAC system type was considered for the simulation for typical baseline and expanded temperature set-point ranges. Ladybug plugin allowed for a direct integration of energy modeling from *OpenStudio* into the *Rhinoceros-Grasshopper* environment (Roudsari, Pak, & Smith, 2013). In this study, indoor air temperature, relative humidity, air flow rates, surface temperatures, and HVAC energy loads were examined in *Rhinoceros-Grasshopper* to determine the human energy balance and energy consumption parameters. Finally, the efficacy of the supplemental heating and cooling was assumed at 0.5, implying that for example, 50W of power would provide 25W of active localized heating or cooling to each occupant (Kong et al., 2017). A Coefficient Of Performance (COP) of 2.5 was also assumed for the supplemental HVAC system, which refers to current targets aimed by the authors on a solid-state HVAC system under research. The *Modular Indoor Micro-Climate* (MIMiC) system is based on a modular thermoelectric heat pump coupled with a temperature-optimized thermal storage for reversible, localized heating and cooling which may also be deployed in office environments. The detailed workflow, including the variables and procedural steps described in this study, is illustrated in Figure 1.

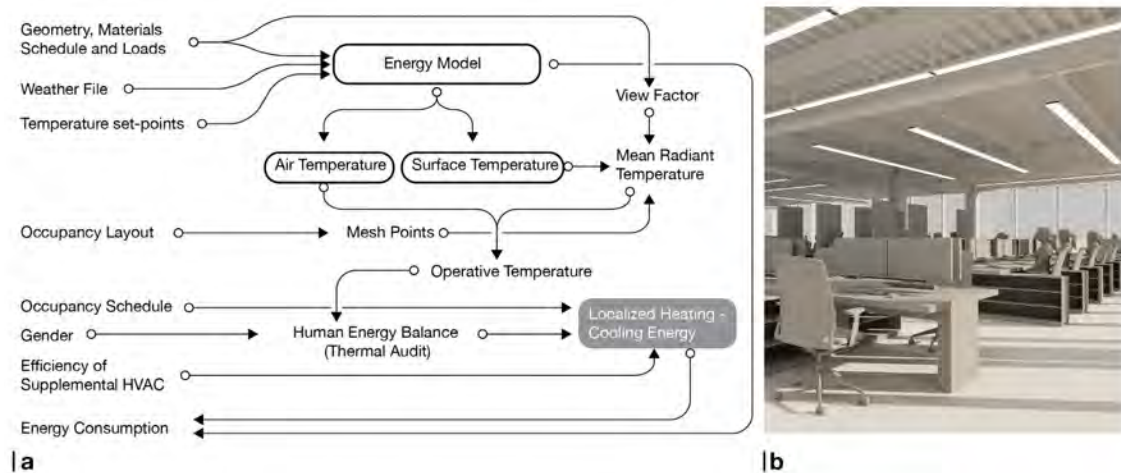

Figure 1. Diagram of the energy model workflow (left) and partial rendering of the office space considered for energy modeling (right).

### Human Heat Balance

In current standards, thermal comfort is primarily assessed using the Predicted Mean Vote or the Adaptive Comfort ranges, for which there is no explicit gender differentiation (ASHRAE, 2004; Kingma & van Marken Lichtenbelt, 2015). Thereby, the thermal audit process was utilized to determine the human heat balance with the environment (Parsons, 2014). Assuming a relaxed temperature set-point, it is possible to characterize the resulting heat to be supplied or removed ( $S$ ) using the following equation:

$$S = (M - W) - ((C + R + E_{sk}) + (C_{res} + E_{res})) \quad (1)$$

Where  $M$  represents the rate of heat generated by the body or metabolic activity,  $W$  is the rate of any mechanical work,  $R$  is radiation,  $C$  is convection,  $E_{sk}$  is the rate of total evaporative heat losses from the skin,  $C_{res}$  is the rate of convective heat losses from respiration, and  $E_{res}$  is the rate of evaporative heat losses from respiration. In this study, beside the radiant portion of the thermal balance, the environmental conditions are assumed to be homogeneous within the thermal zones but varying over time. The mechanical work ( $W$ ) component was considered null and thermal conduction neglected. The metabolic activity ( $M$ ), a critical factor in the determination of the energy balance, was gender-specific (Kingma & van Marken Lichtenbelt, 2015). In particular, the female metabolic rate was considered as  $48 \text{ Wm}^{-2}$  when performing light work. Male metabolic activity was derived from ASHRAE (2004), being at  $60 \text{ Wm}^{-2}$  under light work in office environments.

### Mean Radiant Temperature

As radiant thermal exchanges constitute a large component of the human thermal balance (Parsons, 2014), this studied focused on calculating the Mean Radiant Temperature (MRT) for a specific occupation layout within an office space. The equation for the MRT is assumed as (La Gennusa, Nucara, Rizzo, & Scaccianoce, 2005):

$$T_r = \sqrt[4]{\sum_{i=1}^N F_{S \rightarrow i} T_i^4} \quad (2)$$

Where  $F_{S \rightarrow i}$  represents the view factor between the receiving geometry, here a person, and a building internal enclosure ( $i$ ), for which the surface temperature ( $T_i$ ) is derived from the energy model. Although the calculation of the view factor is computationally expensive, this study utilized the following, validated approximation (Walton, 2002):

$$F_{S \rightarrow i} \approx \frac{-1}{\pi A_S} \sum_S \sum_i \frac{(\vec{r} \cdot \vec{n}_S)(\vec{r} \cdot \vec{n}_i)}{(\vec{r} \cdot \vec{r})} \Delta A_S \Delta A_i \quad (3)$$

Where  $\vec{r}$  is the vector connecting the centers of the finite areas  $\Delta A_S$  and  $\Delta A_i$ ;  $\vec{n}_S$  and  $\vec{n}_i$  are their normal vectors at the center point, and the dot product indicated scalar multiplication between vectors. A recursive calculation was coded in Python within the Grasshopper platform, to better interface with the results coming from the energy model as depicted in Figure 2.

Figure 2. Approach for calculation of MRT and micro-climatic visualization: (a) office layout determining occupants position in space; (b) multi-zone energy model provides surface temperatures on hourly basis; (c) point cloud definition for view factor; (d) visualization of the operative temperature.

## RESULTS

The overall HVAC energy saving are projected in 14% relative to baseline conditions when the temperature set-points are extended from 22°C to 26°C for cooling and from 21°C to 19°C for heating (Table 1). The HVAC energy savings account for the supplemental heating and cooling for each occupant based on the satisfaction of their specific human thermal balance. The energy expenditure for the MIMiC supplemental system accounts for about 1/5 of the overall energy consumption under expanded temperature set-points. However, different behaviors were observed when considering heat loads on an hourly basis. For a typical summer day such as June 21<sup>st</sup> (Figure 3, a), the energy expenditure associated with expanded temperature set-points and the supplemental system were consistently lower than baseline condition. Conversely, for a typical winter day, such as December 21<sup>st</sup> (Figure 3, b), no substantial energy savings during heating demands were observed. Also, the energy expenditures for regaining comfort almost nullified the benefits given by expanded heating temperature set-point. Mainly, from mid-morning to early afternoon, the expansion of temperature set-point did not produce any energy savings particularly in the later afternoon. The extreme peaks in heating demand around 5AM (Figure 3,b) were observed only for some days and not consistent in terms of intensity, although a more detailed investigation is required.

Table 1. Summary of the HVAC energy consumption for baseline and experimental conditions.

	a. Baseline	b. Relaxed Temp. Set-Pt	c. MIMiC	Total (b+c)	Energy Savings (%)
HVAC Energy Consumption (kWh/yr)	64,069	46,547	8,288	54,835	-14%
HVAC Energy Density (kWh/m <sup>2</sup> - yr)	80.2	58.3	10.4	68.7	

Figure 3. HVAC energy consumption for a typical cooling (a) and typical heating (b) day.

The micro-climatic maps of the operative temperature are represented for a typical summer and winter day at 1PM (Figure 4). The maps, resulting from the integrated computation of the mean radiant temperature and heat balance, suggest that the operative temperature is generally higher than relative air-temperature set-points. Such discrepancy is more pronounced during the summer day (Figure 4,a) where occupants closer to the envelope and the core may experience higher operative temperature than near the core. Instead, on winter time (Figure 4,b), the benefit of the solar exposure can be inferred from the micro-climatic map, for which south-west portion of the floor plate has 2°C higher operative temperature than central and north-east exposed spaces. Finally, gender differences in operative temperatures can be observed from the micro-climatic maps, where blue-colored areas are indicative of males with typical preferences for colder air temperature set-points (Kingma & van Marken Lichtenbelt, 2015).

Figure 4. Synthetic visualization of localized cooling (a) and heating (b), and associated energy consumptions for a typical summer day

## DISCUSSIONS

The energy savings observed herein align with previous studies on the expansions of temperature set-points, although this study project less generous savings (Hoyt et al., 2015). While the energy consumption of the supplemental system for heating and cooling is minimal, it cannot be ignored from the overall building energy balance. The integrated energy model also allows to evaluate the economic feasibility of the supplemental systems for specific cases. In fact, for this study, the simple payback of the MIMiC systems is 8.3 years for a commercial application under NYS energy rate and assuming \$80 per system installed in each occupied space. Different paybacks may be obtained when considering the benefits of productivity, however further studies are required. The operative temperature has larger swings than air temperature set-point offset, which may be associated with large glazed areas and their effects on mean radiant temperature. The impact of glazing and partitions on the operative temperature is more pronounced in areas closer to vertical envelopes as shown by the micro-climatic maps. The ability to model and visualize the operative temperature through the refined calculation of the MRT to determine the view factor, represents a key contribution of this study. Two limitations are given by not considering the furniture from the MRT calculation and the uniform distribution of air temperature in the different thermal zones. Future studies can incorporate the methodology presented herein and introduce means to model air temperature and occupation patterns with finer resolution. At the early stage of the design process, which this study targeted, practitioners and architectural scientists may utilize this methodology to evaluate both energy savings, thermal comfort implications, and economic feasibility for different primary and supplemental HVAC options.

## CONCLUSIONS

The ability to provide personalized thermal comfort may unleash novel strategies for reducing building energy consumption and address raising concerns on indoor environmental quality, such as gender-specific thermal comfort preferences. This study reported on an integrated modeling and visualization framework for predicting energy savings from expanded temperature set-points and supplemental heating and cooling systems to equalize thermal balance based on different metabolic rates. The application of the modeling approach on a largely-glazed office space showed annual energy savings of 14% relative to a baseline condition. Also, different micro-climatic conditions were observed when calculating the operative temperature using a fine point could as representation of the floorplate occupancy. Integrating energy modeling and spatial visualization may provide useful insights for early-stage decision-making process on HVAC systems and sub-systems, and occupant comfort.

## ACKNOWLEDGEMENT

The work was primarily conducted at the Rensselaer Polytechnic Institute. The authors would like to thank Dr. Theodorian Borca-Tasciuc for his support on heat transfer and energy balance equations. The work was supported by NYSTAR.

### **ABSTRACT**

In Europe, some historical cities have more than 50% of buildings dated from before 1920. Nowadays, these buildings faces challenges when adapted to the current necessities of livability, environmental and economical sustainability. Literature demonstrates that occupants' comfort perception and consequent behavior affect buildings' energy efficiency and are influenced also by the building configuration. Despite a large number of studies in literature investigating occupants' behavior and comfort in different situations, there is a lack of such studies for historical buildings. Therefore, the objective of this paper was to characterize occupants' thermal and comfort perception in two historical buildings during summer season. In these terms, results of objective measures were compared to occupants' evaluations of the indoor environment. Results showed that, for both case studies, despite the good thermal performances of the building fabrics and the fact that almost all of the occupants like to work in a historical building (they would also choose it instead of a modern one), most of them didn't rate the building as comfortable from a thermal point of view.

### **KEYWORDS**

Thermal comfort, Historical buildings, Heritage preservation, Energy retrofit.

### **INTRODUCTION**

These days, a great amount historical heritage buildings are reconverted for activities that differ from the originals, involving a complex processes of building adaptation and energy retrofit (Martínez-Molina, Tort-Ausina, Cho, & Vivancos, 2016). In this field, many studies recognized the positive role played by traditional materials and historic building configurations in mitigating outdoor conditions (Belpoliti *et al.*, 2017). However, two aspects should be considered carefully in the energy retrofit process. First, the implementation of new HVAC systems, because being designed for different technological contexts their installation entail an unavoidable duress on the historic fabric (Filippi, 2015). The second aspect is the so-called "human factor". According to Fouseki and Cassar (2014), the tension between heritage preservation and the need for occupants' thermal comfort is a bigger challenge then finding aesthetic-suitable solutions for historical buildings' energy retrofit. The same authors reported a lack of knowledge regarding occupants' perception of historical buildings and the necessity to do researches on how people feel and behave towards these buildings. Also Agbota (2014) highlights the importance of studying the unintended consequences of energy retrofit interventions for historical buildings' occupants. In this field, Anderson and Robinson's study (2011) showed that despite people appreciation of their home's historical evidence, their main concern was to enhance their thermal comfort in winter. In these terms, Crockford (2014) highlighted the central role of educating occupants in being aware of how the historic building functions and could be exploited in order to host a "twenty-first-century lifestyle".

The objective of this research is to investigate the relationship between occupants' thermal and comfort perception and indoor environmental conditions in two case studies of the same historic period and geographical area. The study was conducted in summer season. .

## METHODS

This study is embedded in a larger research investigating different aspects of energy efficiency, indoor environmental quality and occupants' comfort and behavior in historic buildings. This research combined objective field measurements of temperature and subjective data obtained through a questionnaire survey. For this paper data from two case studies were chosen considering the availability of indoor environmental monitoring, historic period of the buildings, occupants' activity and geographical area.

### Case studies

The two case studies are both located in the suburban territory of Turin (Italy). The first is the Rivoli castle, which is the product of a reconstruction of XVIII Century and a restoration of XX Century, finished with the opening of the current Contemporary Art Museum in 1984. Today the museum is registering more than 100,000 visitors per year and is listed in the UNESCO World Heritage List. The building, in which the last restoration maintained the original configuration and distribution, has a floor area of about 10,000 m<sup>2</sup>. The surface hosts expositive areas and offices. From a constructive point of view, the Castle is a massive masonry building. During the summer season the building is passively cooled. Two types of occupants performing comparable metabolic activities were taken into account in this building: office workers and security staff of the expositive area. For the analyses, an existing network of eight Data Loggers (DLs) (model testo 175 H1), homogeneously distributed in the first and second floor of the building, was exploited. The second case study, the Centro di Conservazione e Restauro La Venaria Reale (CCR), founded in 2005, is a research, restoration and education center in which conservators, art historians and scientists work within laboratories, offices and classrooms. The CCR is based in the XVIII Century "La Venaria Reale" complex, a royal residence listed in the UNESCO World Heritage list. From a constructive point of view, the building is quite similar to Rivoli Castle; the only big difference is that the internal structure of the building was refurbished to host classrooms, offices and laboratories. For this research only offices were considered. During summer, offices are conditioned with a cooling system with a general set point of 24°C during working hours. However, in each room users are able to regulate indoor temperature with a range of +3°C/-3°C or even turn off fan coils. Regarding windows, only a part of occupants have the possibility to operate them. In both case studies, a monitoring campaign was carried out from June to September 2017. At CCR the monitoring data, consisting on the air temperature of six offices, were extracted from the temperature probes (Sauter EYB250F201) located on offices' walls, near the fan coils.

### Analyses

The data were analyzed with the following procedure. First, for both cases analyses were made in order to assess DLs' measurements differences and calculate the daily fluctuation of temperature as an average of those in the same range. Second, mean daily temperatures were calculated for the whole summer season and compared with mean daily outdoor temperature of the nearest meteorological station, for both cases located in Turin. Third, the thermal indoor environmental quality was evaluated according to ASHRAE 55 (2004) and EN 15251 (2008) standards. For ASHRAE 55, analyses were done according to the prescriptions for "Naturally conditioned spaces". While for Rivoli Castle this would have been the only choice, being a passively conditioned building, for CCR the choice was partly due to the necessity of comparing it with the other building and partly due to the absence of data regarding humidity ratio, mean radiant temperature and air speed. For these analyses, indoor operative temperature was assimilated to average air temperature because all the conditions of

ASHRAE 55 Appendix A-Case 1 were met. Regarding EN 15251 standard, evaluations of indoor environmental conditions were made following Annex A “Recommended criteria for the thermal environment” indications. While for Rivoli Castle the evaluations were made only according to the second section, dedicated to buildings without mechanical cooling systems, CCR was evaluated according to both first section (dedicated to mechanical heated and cooled buildings) and second section. Fourth, subjective perception of indoor environment was evaluated basing on data from a questionnaire. In particular, authors took into account one part of the third section (Comfort conditions and preferences) and the second section (Cultural background, habits and changing attitude). The two aspects taken into account from the third section were:

- Thermal sensation vote (TSV), according to ASHRAE 55’s seven point scale (-3=cold, -2=cool, -1=slightly cool, 0=neutral, 1=slightly warm, 2=warm, 3=hot);
- Comfort evaluation according to a 5 point scale (-2=very uncomfortable, -1=moderately uncomfortable, 0=neutral, 1=moderately comfortable and 2=comfortable).

The questionnaire took place only once at the end of the season, so the evaluations were referred to the whole just-ended summer. The two considered questions of the second section were:

- If occupants like working in a historical building (yes, no, I don’t care);
- If occupants would choose to work in a modern or in a historical building.

For both case studies, the response rate was sufficient to consider occupants’ sample as representative of the building according to ASHRAE 55 “Survey of Occupant responses to Environment” section (22 respondents out of 35 for Rivoli Castle and 16 out of 19 for CCR).

## RESULTS

Figure 1 shows mean indoor daily temperature and maximum indoor daily temperature of both case studies compared with the outdoor mean daily temperature data of the nearest meteorological station. Indoor mean daily temperatures of the case studies were not very different despite the presence of a cooling system in CCR (which actually had, in general, higher indoor temperature). The only noticeable difference is in the shape of profiles, which is more jagged for CCR, probably due to a fluctuating use of the cooling system. The maximum and average indoor temperature profiles show that there is not much fluctuation between day and night, because of the high thermal mass of both buildings. For both cases, indoor temperature profiles follow outdoor conditions, confirming a typical high-massive behaviour of the building envelope.

Regarding the indoor environment evaluation, Figure 2 and Figure 3 present the results of the application of ASHRAE 55 and EN 15251 standards for not mechanically cooled buildings. The graphs show the monitored average daily operative temperature compared to the prevailing mean outdoor temperature. Based on the results shown in Figure 1, at CCR there could be a high amount of users turning off their fan coils or regulating it with the highest temperature available ( $27^{\circ}\text{C}$ ). As a general comment, both buildings seem to behave quite well from a thermal point of view. In fact, considering ASHRAE 55 standard, in both cases almost all daily average temperature fall in the 80% acceptability interval. Regarding the 90% acceptability interval, which is not a normative requirement, 92% of values registered at Rivoli castle fall in this interval, while the equivalent percentage of CCR is 71%. Regarding the EN15251 standard, Figure 3 shows that both cases would be classified in Category I. Of course it should be noticed that for CCR these results would be relevant to the standard only assuming that the cooling system is not used.

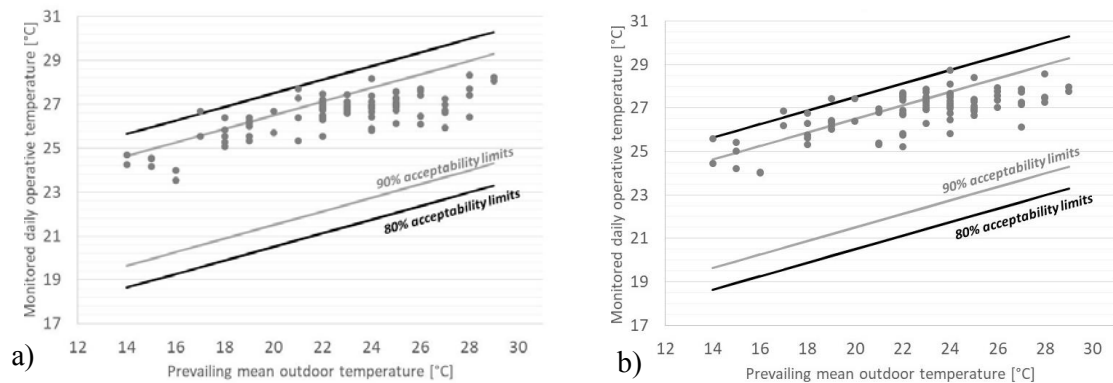

Figure 2. Indoor environment analysis - ASHRAE 55 standard. a) Rivoli Castle b) CCR.

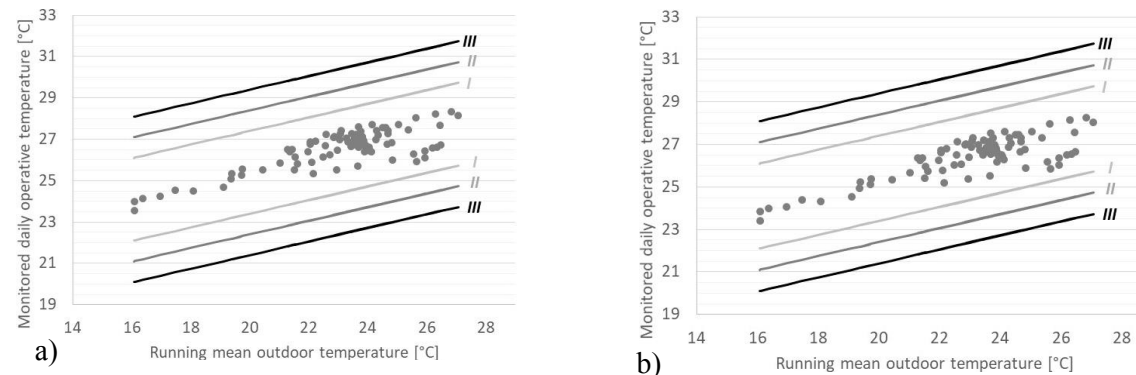

Figure 3. Indoor environment analysis - EN 15251. a) Rivoli Castle b) CCR.

Figure 4. Indoor environment analysis (buildings with mechanical cooling) – EN 15251. CCR

Figure 4 presents CCR's indoor temperature profile evaluation with respect to the guidelines for mechanically cooled buildings according to EN 15251 standard. The figure shows that until the beginning of September the building does not comply even with Category III.

Figure 5 shows occupants' TSV and comfort evaluation. For Rivoli Castle the graph shows the combination of the two types of occupants considered. Referring to Figure 5.a, less than 70% of Rivoli Castle occupants voted between -1 (slightly cool) and +1 (slightly hot), with a quite homogeneous distribution of votes in the "warm" sensation part of the scale. About CCR occupants' TSV, percentages show a quite homogeneous distribution across all the scale, but only 57% of occupants voted between -1 and +1. Referring to Figure 5.b, two approaches could be used to describe results. The first is that only 19% of Rivoli castle and 14% of CCR occupants are comfortable (voted 1 or 2), the second is that 62% of Rivoli castle and 28% of CCR occupants are not uncomfortable (voted between 0 and 2). In the following, Table 1 describes Rivoli Castle's votes dividing office and exhibition part workers.

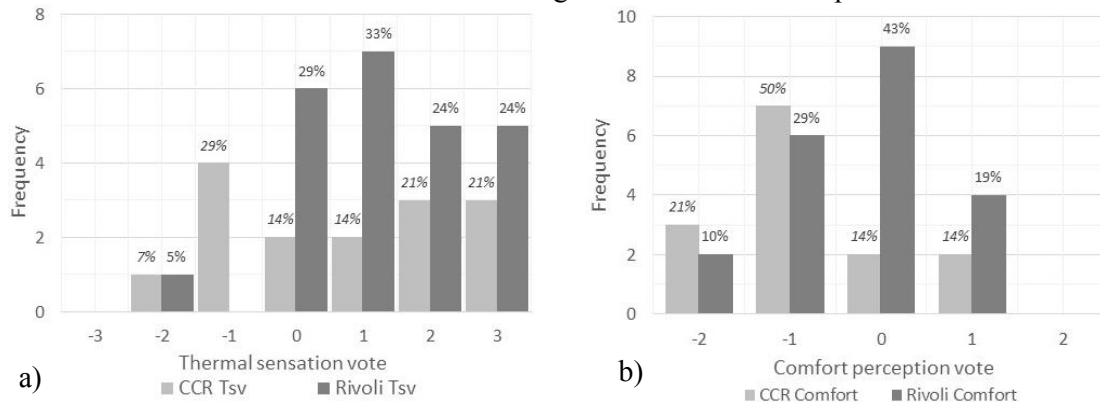

Figure 5. a) Thermal sensation vote and b) Comfort perception vote in the two case studies.

Table 1. Rivoli TSV and comfort votes (Comf) among office (Off.) and exhibition staff at Rivoli Castle.

Off.	Exb.	Off.	Exb.	Off.	Exb.
-1<TSV<+1	-1<TSV<+1	Comf>=0	Comf>=0	Comf>=1	Comf>=1
88%	46%	75%	54%	13%	23%

The answers related to the general attitudes towards historical buildings mentioned in method section showed that 95% of Rivoli Castle's and 93% of CCR's occupants like to work in a historical building. Moreover, 95% of Rivoli Castle's and 86% of CCR's occupants would choose to work in a historical building instead of a modern one.

## DISCUSSIONS

The case studies investigated for this research offered the opportunity to have an idea of occupants' thermal comfort perception within the historical building in which they work. In general, occupants' evaluations were different from what it was expected looking at the indoor environment analyses performed according to the standards. Considering the CCR for example, referring to the analysis represented in Figure 4, it was expected that a large majority of people would have expressed a TSV between 1 and 3, but instead the percentage is about 56%, with also 30% of people feeling slightly cool. In this frame it is also curious that with a temperature set-point of 24°C the temperature profiles is quite stable around 27°C. A possibility could be that people felt too cold so they decided either to increase the set-point to 27°C or turn off the fan coils. Having this large opportunity of configuring their environment, a good comfort rate would be expected. Instead, only 28% of CCR occupants feel not uncomfortable (which is surprising in comparison to 62% of Rivoli Castle, which is passively

cooled). Two reasons could be identified: either people turn off fan coils because of punctual discomfort (e.g. disturbing position of the cool air flow) or they don't know how to properly use their control opportunities. It should be also noticed that a certain amount of occupants at CCR don't have access to windows. Further analyses should be done to see if this group of occupants have a specific pattern. Regarding Rivoli Castle, the two analyses represented in Figure 2 and 3 did not predicted very well occupants' evaluation of thermal perception and comfort. For these analyses two groups of occupants were considered. Among the groups, it should be noticed that in general workers of the exposition part were less satisfied with their environment. A possible explanation is that they are not allowed to personally open windows (they have to ask to a person in charge) so their control opportunities are lower.

## CONCLUSIONS
